Herbert H. Uhlig

March 3, 1907–July 3, 1993

This Handbook is dedicated to the memory of Herbert H. Uhlig.

Herbert Uhlig began his career at MIT in 1936 where, with the exception of the interruption caused by World War II, he remained until his retirement nearly 40 years later, bringing the MIT Corrosion Laboratory to a level of international prominence that it retains to this day as a major center of excellence. He helped to establish the Corrosion Division of The Electrochemical Society in 1942 and served as President of the Society in 1955–1956. His characteristics as an uncompromising innovator and meticulous scientist who insisted on reliable data and on achieving results led to the success of his many endeavors as educator and mentor, including the Corrosion Handbook, published in 1948, that he conceived, organized, and edited.

E. D. Verink, Jr.

8 **Pourbaix Diagrams for Multielement Systems** 103
W. T. Thompson, M. H. Kaye, C. W. Bale, and A. D. Pelton

9 **Computation of Pourbaix Diagrams at Elevated Temperature** 111
M. H. Kaye and W. T. Thompson

10 **Galvanic Corrosion** 123
X. G. Zhang

11 **Dealloying** 145
R. Heidersbach

12 **Passivity** 151
J. Kruger

13 **Localized Corrosion of Passive Metals** 157
H. Böhni

14 **Stress Corrosion Cracking** 171
R. N. Parkins

15 **Hydrogen-Induced Cracking and Sulfide Stress Cracking** 183
M. Elboujdaini

16 **Corrosion Fatigue** 195
Y.-Z. Wang

17 **Flow Effects on Corrosion** 203
K. D. Efird

18 **Erosion–Corrosion in Single- and Multiphase Flow** 215
J. Postlethwaite and S. Nešić

19 **Carbon Dioxide Corrosion of Mild Steel** 229
S. Nešić

20 **High-Temperature Oxidation** 247
C. A. C. Sequeira

21 **Thermochemical Evaluation of Corrosion Product Stabilities for Alloys in Gases at High Temperature** 281
W. T. Thompson, R. C. John, and A. L. Young

22 **A Procedure to Compute Equilibrium Gas-Phase Speciation for Use with Predominance Diagrams** 287
M. H. Piro, B. J. Lewis, and W. T. Thompson

23 **Atmospheric Corrosion** 299
P. R. Roberge

24 **Atmospheric Corrosion in Cold Regions** 327
G. A. King

25 **Corrosion by Soils** 333
T. R. Jack and M. J. Wilmott

26 **Microbial Degradation of Materials: General Processes** 351
J.-D. Gu, T. E. Ford, and R. Mitchell

27 **Corrosion Probability and Statistical Evaluation of Corrosion Data** 365
T. Shibata

PART II NONMETALS

28 **Corrosion of Refractories and Ceramics** 387
M. Rigaud

29 **Corrosion of Glass** 399
B. Grambow

30 **Microbiological Degradation of Polymeric Materials** 421
J.-D. Gu, T. E. Ford, D. B. Mitton, and R. Mitchell

31 **Durability of Concrete** 439
V. M. Malhotra

32 **Microbiological Corrosion of Concrete** 451
J.-D. Gu, T. E. Ford, and R. Mitchell

33 **Microbial Degradation of Wood** 461
P. I. Morris

34 **Use of Chemicals to Prevent Degradation of Wood** 469
J. N. R. Ruddick

PART III METALS

35 **Metal–Matrix Composites** 481
L. H. Hihara

36 **Environmental Degradation of Engineered Barrier Materials in Nuclear Waste Repositories** 503
R. B. Rebak

37 **Corrosion Behavior of Electrodeposited Nanocrystals** 517
U. Erb

38 **Corrosion of Shape Memory and Superelastic Alloys** 529
L. E. Eiselstein

FOREWORD

In the roughly 10 years since the appearance of the second edition of the *Corrosion Handbook,* new technologies and new engineering systems have found their way into the global marketplace at an increasing rate. It is no wonder now that a third edition would be timely and appropriate. It is also no surprise that the third edition would expand the scope of the previous editions to include chapters on composites such as are used in airframes, shape memory alloys which find application in medical devices, and electrodeposited nanocrystals as well as application-specific chapters which address the materials of construction of the engineered barriers for nuclear waste containment, ethanol-induced stress corrosion cracking of carbon steels, and other such topics. An entirely new section on corrosion monitoring also appears in the third edition.

Corrosion is ubiquitous: All engineering systems are subject to environmental degradation in service environments, whether these systems are used to meet the energy needs of the inhabitants of this planet; to provide clean air; to treat and transport water, food, and other products typical of our commercial world; to both save and improve the quality of our lives; and to ensure the readiness of those engineering systems that are of importance in terms of national defense and homeland security as well as many others. From heart stents to nuclear electric generating stations, corrosion is part of our world.

The *Corrosion Handbook* continues today, as it has since its first appearance over 60 years ago, to serve as a trusted resource to generations of corrosion engineers. There are many reasons to believe that its presence in the libraries of engineering practitioners of all kinds is greater now than ever before. First, it appears that much of the expertise in this area of technology, which resided for decades in the staff and laboratories of metal producers, has retired and is not being replaced as many of the metal producers have responded to the global economy of the past decade and more. Second, the interest of young people in engineering education, including corrosion engineering, is also in decline. Third, as the global economy recovers from the meltdown of the recent past, nations with a strong manufacturing base that creates products of value to the market will respond most quickly. But this will require an educated and informed engineering workforce. It is a concern to me that industrialized nations all over the world are on the brink of losing this technological infrastructure through retirement, the decline of traditional manufacturing industries, and declining student interest. Without a means of capturing this expertise in a useful form the next generation of engineers are going to find a gap in their knowledge base. I am confident that this volume will be of value in that context. Every industrialized nation must have the capacity and intellectual strength necessary to design, manufacture, and maintain either contemporary engineering systems or emerging engineering systems that may find their way into the marketplace of the future. The *Corrosion Handbook* remains an invaluable resource in that regard, and once again Winston Revie has assembled a world-class group of authors in producing a comprehensive volume covering the entire field of contemporary corrosion engineering.

R. M. LATANISION

Director (Emeritus)
The H. H. Uhlig Corrosion Laboratory, MIT, and
Corporate Vice President
Exponent–Failure Analysis Associates, Inc.
Natick, Massachusetts

FOREWORD TO THE SECOND EDITION

The first and, prior to the current volume, only edition of the *Corrosion Handbook* was published in 1948. It represented a heroic effort by Professor Herbert Uhlig and the leadership of the relatively newly established Corrosion Division of the Electrochemical Society. It was intended, as Professor Uhlig recorded in the Preface to the 1948 edition, to serve as ". . . a convenient reference volume covering the entire field of corrosion, to bring together, in effect, much of the information scattered broadly throughout the scientific and engineering literature." Its success was equally heroic: the *Corrosion Handbook* has served generation after generation of corrosion engineer and today, more than a one-half of a century since its first appearance, the volume remains a trusted resource in the personal libraries of many of those who populate the world's engineering community.

Over the years that I knew Professor Uhlig personally, he often mentioned to me his concern for the need to produce a revised edition of the Handbook. I am confident that he would have been very pleased that one of his doctoral students at MIT, Winston Revie, had taken up this challenge. Winston, just as his mentor, is a meticulous and innovative corrosion scientist. This truly monumental revision of the *Corrosion Handbook* is certain to serve the engineering community well as we enter the new millennium. Much has happened in corrosion science and engineering since 1948, and the contributors to this volume, an assembly of the international leaders in the field, have captured these changes wonderfully well. The breadth of corrosion and corrosion control is made clear by the inclusion of ceramics, polymers, glass, concrete and other materials as well as of metals, the focus of the first edition. The introduction of standards into corrosion science and engineering is emphasized as is life prediction, and economic and risk analyses associated with environmental degradation of materials.

While the introduction of new technologies has dramatically changed virtually every aspect of life on the Earth in the fifty years since the appearance of the *Corrosion Handbook*, what remains a persistent reality in the engineering enterprise is that engineering systems are built of materials. Whether an airframe, integrated circuit, bridge, prosthetic device or, perhaps as we shall see in the not too distant future, implantable drug delivery systems—the chemical stability of the materials of construction of such systems continues to be a key element in determining their useful life. This new edition of the *Corrosion Handbook* will serve, among others, designers, inspectors, owners and operators of engineering systems of all kinds, many of which are unknown today, for generations to come. Dr. Revie has succeeded, just as did his mentor in 1948, in producing a convenient reference volume covering the entire field of corrosion.

Cambridge, Massachusetts

PREFACE

The objective in preparing this third edition of *Uhlig's Corrosion Handbook* has been to provide an updated book—one affordable volume—in which the current state of knowledge on corrosion is summarized. The fundamental scientific aspects and engineering applications of new and traditional materials and corrosion control methods are discussed, along with indications of future trends. The book is intended to meet the needs of scientists, engineers, technologists, students, and all those who require an up-to-date source of corrosion knowledge. This new edition contains a total of 88 chapters divided among six parts:

I. Basics of Corrosion Science and Engineering
II. Nonmetals
III. Metals
IV. Corrosion Protection
V. Testing for Corrosion Resistance
VI. Corrosion Monitoring

Topics discussed in chapters that are new in this edition include failure analysis (Chapter 1), principles of accelerated corrosion testing (Chapter 73), metal–matrix composites (Chapter 35), nanocrystals (Chapter 37), ethanol stress corrosion cracking (Chapter 50), computation of Pourbaix diagrams at elevated temperature (Chapter 9), high-temperature oxidation (Chapters 20 and 74), dealloying (Chapter 11), and diagnosing, measuring, and monitoring microbiologically influenced corrosion (MIC) (Chapter 88). Dr. Tomomi Murata has provided some very insightful introductory notes on the effects of climate change, life-cycle design, and corrosion of steel under changing atmospheric conditions.

Throughout the book, extensive reference lists are included to help readers identify sources of information beyond what could be included in this one-volume handbook.

It is a pleasure to acknowledge the authors who wrote the chapters of this edition as well as the reviewers, who, in anonymity, carried out their work in the spirit of continuous improvement. I would also like to acknowledge the members of the Editorial Advisory Committee, who made many constructive suggestions to help define, focus, and clarify the discussions in this new edition. I would like to acknowledge Mary Yess and her staff at The Electrochemical Society Headquarters in Pennington, New Jersey, for their support during the preparation of this book. I greatly appreciate the encouragement and support of Bob Esposito and his staff at John Wiley & Sons, Inc. in Hoboken, New Jersey.

Finally, I would like to thank my many friends and colleagues at the CANMET Materials Technology Laboratory, where it has been my privilege to work for the past 32 years.

R. Winston Revie

INTRODUCTORY NOTES ON CLIMATE CHANGE, LIFE-CYCLE DESIGN, AND CORROSION OF STEEL

T. Murata
Japan Science & Technology Agency, Saitama, Japan

A. CLIMATE CHANGE

Climate change is attributed mainly to increased CO_2 in our atmosphere because of anthropogenic activities and is expected to increase as much as 50% by 2030 compared to the concentration in 2005, that is, 359 ppm [1, 2]. Such a change will affect the corrosion of carbon steel through acidification due to increased concentration of HCO_3^- and Ca^{2+} in waters at temperatures a few degrees Celsius higher than those in 1990. In addition, other influential factors that will arise from climate change include the following:

1. Increase in precipitation
2. Formation of aerosols with CO_2 emission
3. Increased SO_x emissions caused by the use of sulfur-bearing coal due to oil shortages
4. Enhanced biological growth in waters

For these reasons, the corrosivity of environments in the future will be complex, and a simple acidification model will not be adequate. To predict the effects of climate change on corrosion, computational analyses and systematic corrosion studies are required to develop models based on projected climate change.

"Time of wetness" is universally considered to be a key corrosion index for atmospheric corrosion. In recent years, weather instability has led to changes in global rainfall distribution, changes that could lead to new and different predictive indices for atmospheric corrosion. For corrosion in waters, microbiological factors are expected to increase in importance with the changing climate. In contrast to the environmental factors that pertain to corrosion in air and water, the heterogeneous distribution of chemicals in contaminated soils in industrialized areas results in nonuniform soil corrosivity. Dynamic corrosion models are required with on-site monitoring systems.

B. LIFE-CYCLE DESIGN

To minimize the environmental burden and to attain a sustainable society, life-cycle design of steel structures is required to ensure safety, reliability, durability, and the best use of materials and energy throughout the life cycle. The life-cycle concept will be required for future design and construction of social as well as industrial infrastructure. For example, in developing a life-cycle design for weathering steels, discussed in Chapter 48, reliable corrosion data for long-term service and a systematic approach to minimize both corrosion damage and social costs are necessary.

In general, corrosion is studied using a set of parameters under simplified or fixed conditions. In the real world, in response to constantly changing environmental parameters, corrosion behavior also changes. For this reason, an understanding of corrosion dynamics is required, and the corrosion protection models that are implemented must have a capacity to reflect dynamic environmental conditions that are subject to constant change.

A. INTRODUCTION

Are failure analyses useful? The answer is an emphatic *Yes*. There are many reasons to perform a failure analysis; the most common one is to help prevent future failures. To ensure that corrective actions will be effective, it is necessary to understand why failures have occurred in the first place. Otherwise, any design or manufacturing changes that are implemented may not be effective or simpler ways to prevent future failures may be overlooked. Another common reason for performing a failure analysis is to establish responsibilities for the mishap. For instance, an insurance company may want to determine if an event is covered by the policy or not or financial responsibilities must be established for the resolution of a lawsuit.

There is always value in performing some level of failure analysis, even if it seems that it would be better to try something new rather than finding out exactly what went wrong. A tremendous amount of information can be gleaned from understanding how things fail, and this knowledge is invaluable in making things (equipment, machines, and processes) work better in the future. There is a natural tendency to move past the setback of a failure, maybe to avoid dwelling on unpleasant facts or assuming that nothing can be learned from something that did not work out. However, much can be learned from understanding what went wrong, and a good learning opportunity should not be thrown away with the failed parts.

The end point of a failure analysis depends on the specific circumstances and the type of answers needed. In some cases, it may be enough to rule out a specific failure mode, rather than establishing exactly what happened. In an industrial setting, the goal may be to understand the failure enough to be able to identify corrective measures or to determine if a product recall is required. Finally, in serious accidents an exhaustive failure analysis may be necessary for insurance, legal, or safety reasons.

B. FAILURE ANALYSIS PROCEDURES

The analysis of corrosion failures is not fundamentally different from any other failure analysis. Although some

Uhlig's Corrosion Handbook, Third-Edition, Edited by R. Winston Revie

unique techniques may be used and the failure modes are specifically related to corrosion, the methodology used is much the same for every type of failure analysis. Failure analysis follows the scientific method. Typically there is a question to be answered, such as "How or why did this failure occur?" Hypotheses are proposed to answer the question or questions. The hypotheses are checked against facts, experiments, and analyses. In the end, some hypotheses are ruled out and others are confirmed.

In practice, there may be many hypotheses put forward to explain a failure, some likely and others very unlikely. Conducting an efficient failure analysis means that most effort is spent proving the hypothesis that ultimately turns out to be the correct explanation while dismissing early (but with good reason) those hypotheses that turn out to be unfounded. Thus it is important to identify the relevant information early on, even though one cannot be sure of what information is ultimately going to be relevant. Performing a failure analysis results in an interplay between hunches, developing likely hypotheses, testing them rigorously, dismissing other hypotheses for good cause, and keeping an open mind for other possible scenarios if the ones that appeared likely at first turn out to not fit all of the facts.

C. GENERAL APPROACH FOR CONDUCTING A FAILURE ANALYSIS

There is no firm set of rules to conduct a correct failure analysis, but the following approach will help. Gather some general information, formulate hypotheses, and then use these hypotheses to gather more targeted information. Use this targeted information from observations, testing, and analyses to validate or rule out the hypotheses.

C1. Gather General Information

The first step of a failure analysis should be to understand the role of the failed component and its environment. Is the failed part available for examination? Does a cursory examination provide some clues as to why it failed? By definition, the failure was not desired, so were any steps taken in the design or operation to prevent it? Was the part or equipment that failed a recent design, had it been modified recently, or did it have a long history of good service? Does the manufacturer, designer, operator, eyewitnesses, or end user have any hypotheses about the cause of this failure? All these questions will help orient the investigator at the start of a failure analysis.

C2. Formulate Hypotheses

It is important to formulate hypotheses early in a failure investigation, because they will guide the collection of further information. Without some hypotheses, relevant information may be overlooked, or to the contrary too much information will be gathered in an effort to be inclusive, which may also impair getting to the truly important facts. One should also think about hypotheses that have to be considered even if they may be ruled out in the end. For instance, if the corrosion failure involves dissimilar metals, galvanic corrosion should be investigated because it is an obvious possibility, even if other aspects of the situation make it unlikely.

C3. Gather Further Information

The hypotheses will help the investigator gather relevant information. It is important to collect facts that may tend to disprove a given hypothesis as well as those that may support it. One of the traps to be avoided is to bias the information collected toward proving one particular scenario.

The Royal Society's motto *Nullius in verba*, roughly translated as "Take nobody's word for it," is a valuable principle to follow when gathering information. Reported observations, hearsay ("Joe told me that…"), and sweeping generalizations ("This has never happened before") should be noted but not considered reliable until they have been checked for accuracy. Often the simple act of verifying information will separate fact from fiction and considerably clarify a picture that may have appeared confused at first.

C4. Validate or Reject Hypotheses

It is very important that hypotheses be tested or validated in some fashion; without this step they are nothing more than speculation. The validation may be very simple in some cases or it may require extensive analysis in other cases, but this step should never be overlooked. The validation process must be based on physical and engineering principles, not merely on a process of elimination based on commonalities and differences. Sometimes a failure analysis proceeds by listing common factors and differences between failures and instances of successful operation. This method may be useful as a guide to formulate hypotheses (although not as useful as trying to understand the physical factors affecting a failure), but it should not be used as the exclusive means to validate or reject any hypothesis.

The validation of hypotheses must not be biased in favor of a specific scenario. It is not always easy to recognize that a hypothesis that looked promising at first should actually be rejected or modified, but one should remain alert to this possibility if the validation does not turn out as expected.

D. TECHNIQUES TYPICALLY USED TO INVESTIGATE CORROSION FAILURES

Corrosion failures often involve the use of some specific information or techniques. Several guidance documents

suggest checklists or procedures that are specific to corrosion failures, for instance the American Society for Testing and Materials (ASTM) has issued a *Standard Guide for Corrosion-Related Failure Analysis* [1]. These guides supplement the general failure analysis process and adapt it to corrosion failures. A few topics that recur regularly in corrosion failures are discussed here, but the reader may wish to consult some of the extensive literature on failure analysis [1–14].

D1. Sampling and Collecting Corrosion Evidence

Sampling and collection of corrosion evidence are often key steps in corrosion failure analysis. Sampling should be done carefully because corrosion products and deposits often contain valuable information that can be easily damaged or contaminated. For example, if microbial activity is suspected, samples should be collected in sterile containers under appropriate conditions to avoid contamination by other microorganisms. These live samples should be analyzed promptly. If the pH or dissolved oxygen level of the aqueous environment may help to explain the corrosion, field measurements should be made of these parameters as they can change rapidly during storage. Samples should be protected from contamination by other debris and stored such that they will be protected from further corrosion damage.

In addition, samples must be representative. In many cases a few well-chosen samples will be enough. The investigator may easily choose a few "typical" samples from the affected and nonaffected areas. However, in cases where one must assess the condition of a large number of items (e.g., to assess the extent of damage), a statistically valid sampling method must be used. There is no sampling method that always produces a "statistically valid" sample, so the sampling must be defined for each case with the help of a competent statistician.

D2. Determining Corrosion Rates

A question often arises about the timing of some corrosion event. For instance, one may want to know for how long some corrosive conditions have been present or how long before some corrosion will result in a leak or vessel rupture. Unfortunately, corrosion rates are notoriously variable, and in some cases it is nearly impossible to make precise predictions. However, corrosion rates have been published for many combinations of materials and environment and they can be useful if their limitations are understood. These rates are typically averages over many samples or observations; although the performance of any single sample may deviate significantly from the average, in aggregate these rates can be useful. In general, corrosion rates tend to slow down with time, so it is usually important to know the time period over which the rate was measured because linear extrapolation cannot be used in most cases.

Direct measurements of corrosion rates in the laboratory usually take a long time, which may not be practical in the context of the failure analysis. Where this is not possible, accelerated corrosion tests are sometimes performed; however, it is generally quite difficult to determine the acceleration factor over the actual environment. When possible, long-term monitoring of the corrosion process in service is the best way to obtain relevant rates, and this monitoring should be started as soon as possible after the equipment, product, or process is placed in service.

D3. Characterizing the Form of Corrosion

Various types of corrosion have been defined, based generally on morphology or mechanism. Authors differ on this classification, but generally some variation of the following eight categories of corrosion are used: (1) uniform, (2) galvanic, (3) crevice, (4) pitting or localized, (5) intergranular, (6) dealloying, (7) erosion–corrosion, (8) environmentally assisted cracking (EAC), or stress corrosion cracking (SCC) [15]. Other named forms of corrosion such as microbiological-induced corrosion (MIC), filiform corrosion, and liquid-metal embrittlement are typically covered as subcategories of these types. In this chapter we discuss corrosion failures of various types and illustrate them with case histories where applicable.

D3.1. Uniform Corrosion. Uniform corrosion, also known as general corrosion, is a very common corrosion type where the metal is corroding more or less uniformly. Most often, this type of corrosion is easily investigated, since it occurs whenever a susceptible metal is in contact with an aggressive environment: Leave a nail in water and it will corrode. Questions that are more difficult to answer may include the rate at which the corrosion damage occurred, for instance, why the corrosion was particularly rapid in a specific case. In other cases, the key may be to find out how the environment came into contact with the susceptible metal. Finally, questions may arise regarding the effect of corrosion on the strength or other properties of the corroding material.

D3.1.1. Corrosion Rates. Although corrosion rates are extremely variable, they are useful to indicate the average behavior of many samples. They are also useful as a broad indicator of the intensity of corrosion: In cases where the observed rates are far different from the published ones, there should be some explanation of the difference.

Case Study: Corrosion Rates Indicate That Product Is Not Suitable for Intended Use. A company decided to manufacture a copper-covered stainless sheet to make roof panels, gutters, and flashing products. In this process the stainless steel was electroplated with copper on both sides: 10 μm on the side expected to be exposed to the weather and

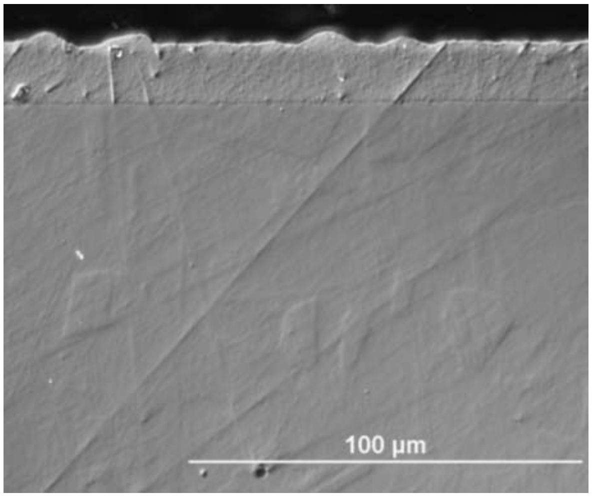

FIGURE 1.1. Copper-coated stainless steel (thick side).

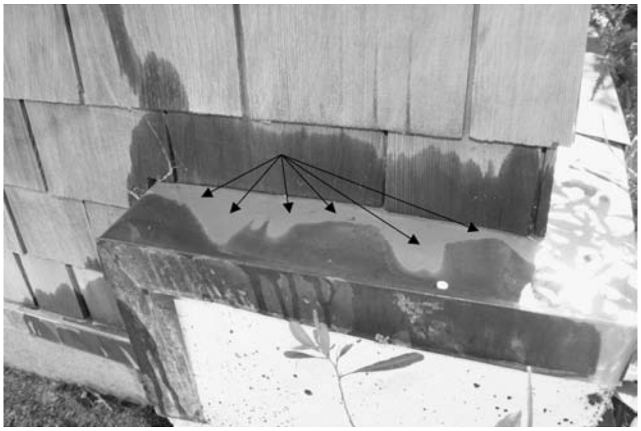

FIGURE 1.2. Rapid corrosion of copper coating from areas underneath wood shake. Arrows indicate bare stainless steel exposed after the copper layer has corroded away.

3 µm on the other (see Fig. 1.1). Atmospheric exposure tests performed by the manufacturer and others indicated a corrosion rate of the order of 1 µm per year for coastal marine atmospheric environments. At this rate, the copper coating would have been consumed in about 10 years (or 3 years if the wrong side of the sheet is exposed to atmospheric corrosion), well short of the 30-year life that was contemplated for this product and somewhat shorter than the time to form a patina. Once the copper layer is removed, the roof looks like stainless steel rather than the intended copper patina, and furthermore the now-exposed stainless steel may pit. Although this material may perform well in dry and noncoastal marine climates, it was clearly not suitable for general use under all outdoor atmospheric corrosion conditions.

The field experience indicated that after less than one year of service there were complaints of excessive corrosion. The copper layer was completely removed from areas of severe exposure, such as in chimney flashings exposed to the acidic flue gases or from the water runoff from wood shakes (see Fig. 1.2). Even though most of the installations had not failed after a few years, the occurrence of several early failures corroborated the reported corrosion rates and indicated that the coatings were too thin for this application. By comparison, a similar product with 50 µm of copper roll bonded to both sides of stainless steel sheet has demonstrated good performance for more than 20 years of service.

Case Study: Extraordinarily High Corrosion Rates. Dilute nitric acid can be extremely corrosive to carbon steel, but concentrated nitric acid passivates carbon steel. This passivation is temporary and can be reversed. A well-known experiment illustrates this behavior: A nail is placed in a test tube and concentrated nitric acid is added to cover about half the nail. Nothing happens because the nail is passivated by the acid. Water is added slowly so that it forms a separate layer on top of the nitric acid. Nothing happens at first, but after a minute or so, corrosion starts at the interface where water dilutes the nitric acid. The passivation breaks down and the corrosion reaction becomes extremely violent.

This experiment was repeated unwittingly inside a nitrogen tetroxide (N_2O_4) tank car through a series of errors [16]. The carbon steel tank car was used to carry N_2O_4 that was being used in a paper plant. The N_2O_4 will react with water to form nitric acid. This N_2O_4 tank car had been involved in an earlier incident in which a significant amount of water had entered it undetected. Sometime later, the presence of water was detected and it was decided to drain the car of the nitrogen tetroxide and nitric acid that had formed. After draining some material, the car was erroneously thought to be nearly empty and water was added to dilute what was thought to be a small "heel" of liquid but was in fact a significant amount of nitric acid and nitrogen tetroxide. The operation was repeated twice in the following days, every time with the same result. Each time, a complicated process of mixing and diluting was taking place inside the car: The inflow of water may have stirred the car's content, but water, concentrated nitric acid, and nitrogen tetroxide tended to separate in layers because of their different densities. The result was unpredictable and at some point the carbon steel passivation broke down. Very rapid corrosion occurred, a massive release of nitrogen oxides overwhelmed the venting capacity of the pressure relief valve, and the tank car ruptured. There were three distinct corrosion bands on the inside of the car where severe loss of material had occurred in a matter of hours or days.

D3.1.2. Cosmetic Corrosion Failure. Sometimes, uniform corrosion does not affect the structural properties of the corroding part and the only effects are cosmetic. Whether or not this represents a failure depends on the circumstances.

If the appearance of the part is of no concern, a slight corrosion may be acceptable; otherwise corrosion may be deemed a serious concern well before any structural failure may occur.

Case Study: Atmospheric Corrosion on the Underside of Roofing Panels. The roof of a California building was made of steel panels with a thick coating on the external side. The underside, which was exposed to an attic space, was left with a thin shop primer coating because there were no concerns about its appearance. After a few years in service, the structural performance of the panels was called into question, in part because the underside had visibly corroded. Some atmospheric corrosion had appeared in spite of the shop primer. Cross sections of the corroded areas demonstrated that the depth of corrosion was minimal and that, at the observed rate, perforation of the roofing panel would not occur during the expected lifetime of the building. Consequently, this was an instance where corrosion was not a failure.

Case Study: Atmospheric Corrosion of Terne-Coated Roof. In two buildings, one located in Alaska and the other in Louisiana, roofs made from lead–tin (terne)–coated stainless steel became severely discolored instead of developing the dull gray appearance typically associated with lead roofs. Metals such as copper and lead used for roofs develop a patina or surface film on exposure to the atmosphere; the patina for terne is usually dull gray. However, in these two instances, the roofs developed irregular patterns of reddish-yellowish corrosion patterns (Fig. 1.3). Our investigation showed that the discoloration of the terne-coated roofs was not caused by rusting of the stainless steel substrate. Rather, it resulted from the normal patination of the terne coating being disrupted due to adverse environmental conditions. The sequence of patina formation is orthorhombic lead oxide (PbO, yellow) → basic lead carbonate → normal lead carbonate → lead sulfite → lead sulfate. If access to the air is restricted, there may not be enough carbon dioxide to form the basic lead carbonate, so the yellow lead oxides remain. There was no attack of the stainless steel substrate and no risk of leaks from the roof corrosion, so this was purely a cosmetic failure. However, this is an example where the appearance of the roof was important—the terne coating had been chosen for its color—so this was indeed a corrosion failure.

D3.2. Galvanic Corrosion. Galvanic corrosion is a common failure mode. It occurs where a less noble metal is in electrical contact with a more noble metal in an electrolyte. ASTM standard G71 provides a test procedure to evaluate the potential for galvanic corrosion [17].

A related failure mode, but not strictly galvanic corrosion, occurs when the source of potential difference results from

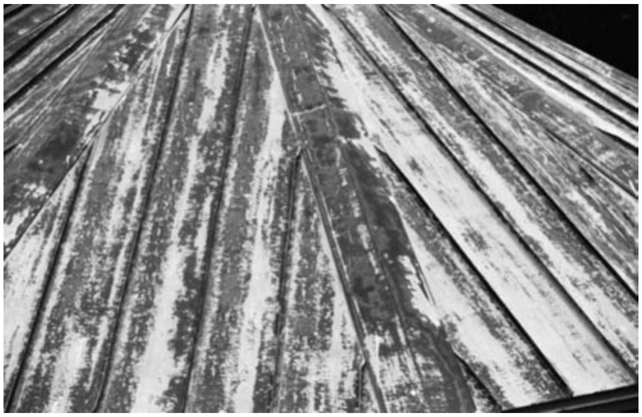

FIGURE 1.3. Terne-coated roof showing severe reddish-yellowish discoloration instead of the expected gray patina.

a difference in the electrolyte composition between two zones. For instance, differences in oxygen concentration can accelerate corrosion of the area depleted in oxygen. Yet another source of potential differences may be electrical currents generated by some external cause, for instance, stray ground currents from large electrical equipment.

Typically, galvanic corrosion results in fairly rapid attack. But potential differences may be used to protect a piece of metal by forcing the corrosion to occur on a sacrificial anode. This, of course, is the principle of cathodic protection. However, the cathodic protection may not perform as anticipated, leading to corrosion failures.

Case History: Ineffective Cathodic Protection. In some small ships, the propeller shafts are enclosed in stern tubes that are part of the hull. The inside of the stern tubes is exposed to the seawater whereas the outside is dry, being in the hold of the ship. In a specific model of ships, the propeller shafts are made of stainless steel while the stern tubes and the hull are made of low-carbon steel. The shafts are supported by three bearings in the tubes: one aft, one midlength of the tubes, and one that is part of the forward end of the tubes. The hull is painted and there are zinc anodes on the hull and propeller for cathodic protection. However, severe corrosion was observed after less than one year in service on the inside of the stern tubes, particularly at their forward end, which is the farthest from the aft opening of the tubes (Fig. 1.4).

The corrosion pattern was typical of painted low-carbon steel exposed to aerated seawater without cathodic protection. Potential measurements on a boat in service confirmed that the steel was not cathodically protected in the forward region of the stern tube. This is not surprising: There were no zinc anodes inside the tubes and the "throwing power" of the anodes on the outside of the hull was simply not enough to reach the inner surface at the forward end of the tubes, especially given the shaft bearing supports that are in the way. Further, the stainless steel shaft, sealing flange, and

FIGURE 1.4. Severe corrosion of the inside of a stern tube. The pattern of general corrosion with some deeper pits is typical of low-carbon steel in seawater.

rotating seal were likely to have anodically polarized the steel tubes, accelerating the corrosion. Under these conditions, any small defect or holiday in the paint coat (and the inside surfaces of the tubes are difficult to paint) would lead to the observed corrosion. It was recommended that zinc anodes should be placed on the inside of the tubes for effective cathodic protection.

Case History: Thermogalvanic Corrosion. A relatively uncommon source of potential difference between two electrodes is a difference in temperature. The electrode potential of a metal piece in an electrolyte depends in part on the temperature, but temperature effects are usually small and negligible. However, in some cases these temperature differences lead to significant failures. A common occurrence is the potential difference between the hot and cold water lines in homes when the copper pipes are buried under a concrete slab. In several residential developments in the western United States, the hot and cold water lines were buried under the home cement slab foundation. The temperature difference between the hot and cold copper water lines provides a potential difference, which in some environments results in the hot line being anodic to the cold. The soil and soil moisture provide the electrolyte. The result is pitting corrosion on the outside of the hot water lines. This failure mode happens more often on homes with hot recirculation pumps. These pumps keep hot water circulating constantly in the lines, so that there is almost instantly hot water at the faucets when they are open. The result is that the lines are hot 24 hours a day, whereas without recirculation pumps the lines would be cold most of the time.

In this situation, statistical methods can be used to predict future leaks based on prior experience. The Weibull distribution is commonly used to model failures. In a particular development, the number of leaks in homes with recirculation pumps could be modeled accurately by a three-parameter Weibull distribution (Fig. 1.5) whereas the homes without recirculation could not be easily characterized without accounting for home location or hot water usage.

D3.3. Crevice Corrosion. Crevice corrosion is a type of localized corrosion at an area that is shielded from full exposure to the environment. This type of attack is usually associated with small volumes of stagnant solution caused by holes, gasket surfaces, lap joints, surface deposits, and crevices under bolt and rivet heads. This form of corrosion is sometimes also called deposit or gasket corrosion [15]. ASTM provides a guide for evaluation of the crevice corrosion resistance of stainless steel and nickel-based corrosion-resistant alloys in chloride-containing environments [18].

Crevices are formed in a variety of design situations. For instance, aircraft skin panels are joined by lap splice joints, where moisture and corrosive atmospheric gases can become trapped between the two panels, resulting in crevice corrosion [19, 20]. This mechanism was blamed for the 1988 Aloha Airline accident in which a 20-year-old Boeing 737 lost a major portion of the upper fuselage at 25,000 ft [19, 21, 22]. In this particular instance, crevice corrosion resulted in the formation of voluminous hydrated aluminum oxides which acted to separate the two skin panels, stressing the rivets and resulting in fatigue failures.

D3.4. Pitting. Alloys that maintain their resistance to corrosion through the formation of a protective passive layer, such as stainless steels, aluminum alloys, and titanium alloys, generally do not suffer from uniform corrosion; rather they will usually corrode as a result of the localized breakdown of a small region of the passive film. Corrosion occurs rapidly at this defect compared to the surrounding material covered with the passive film, resulting in the formation of a pit. ASTM has a standard that helps to characterize the nature of pitting [23].

Case History: Pitting Corrosion of Aluminum Due to Copper-Containing Fungicides. Irrigation pipes used in several California farms suffered from rapid pitting corrosion starting on the inside of the pipe. The pipes are used to irrigate crops and spray fungicide and other chemicals. The pipes that experienced severe pitting were used to spray copper-based fungicides.

A literature review indicates that dissolved copper (in the form of copper hydroxide, the active ingredient of the fungicides) is not enough to promote severe pitting of aluminum alloys; there must be some chlorine and bicarbonate ions as well. The pitting mechanism has not been identified in detail, but it probably involves penetration of the aluminum oxide layer by chloride ions, plating of copper on the exposed aluminum surface, and starting the formation of corrosion products nodules over the corroding areas. Once

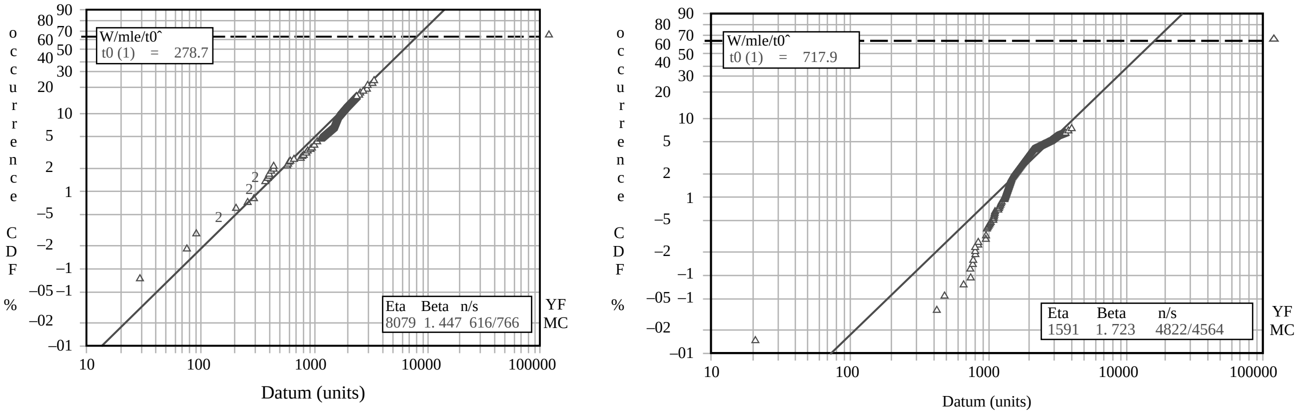

FIGURE 1.5. Three-parameter Weibull distribution fits very well the cumlative failure distribution of homes with recirculation pumps (left), but homes without pumps cannot be characterized with a two- or three-parameter Weibull distribution without accounting for geographic distribution or other effects such as hot water usage (right).

the nodules are formed, they set up concentration cells and severe pits grow under the nodules.

Experiments confirmed that all three ions were necessary for severe pitting. Aluminum pipes exposed to fungicide dissolved in deionized water were slightly attacked, with few shallow pits forming. Similarly, pipes exposed to farm water (containing bicarbonate hardness as well as about 9 ppm chlorides) without fungicide experienced mild pitting. Only the combination of farm water and fungicides caused severe pitting, comparable to the damage observed in the irrigation pipes on the farms (Fig. 1.6).

D3.5. Dealloying. Dealloying (also known as selective dissolution) includes two commonly occurring phenomena known as graphitic corrosion of cast irons and dezincification of brasses. These are two related corrosion modes, in which one of the components of an alloy leaches out selectively, leaving behind a spongy and weak matrix. In dezincification, zinc leaches out of the brass, leaving behind a copper matrix. In graphitic corrosion of cast irons, the iron corrodes away, leaving behind a porous and weak graphite matrix.

This dealloying corrosion may not be easily recognized by a simple visual examination; frequently the matrix does not look appreciably different from the intact material. A metallographic cross section may be required to identify this type of corrosion and determine its extent.

Case History: Graphitic Corrosion of a Sewer. A fire protection water main at a restaurant failed. As part of the repairs, slurry comprised of cement and pea gravel was pumped under the restaurant foundation to fill the void that was created from water gushing out of the ruptured

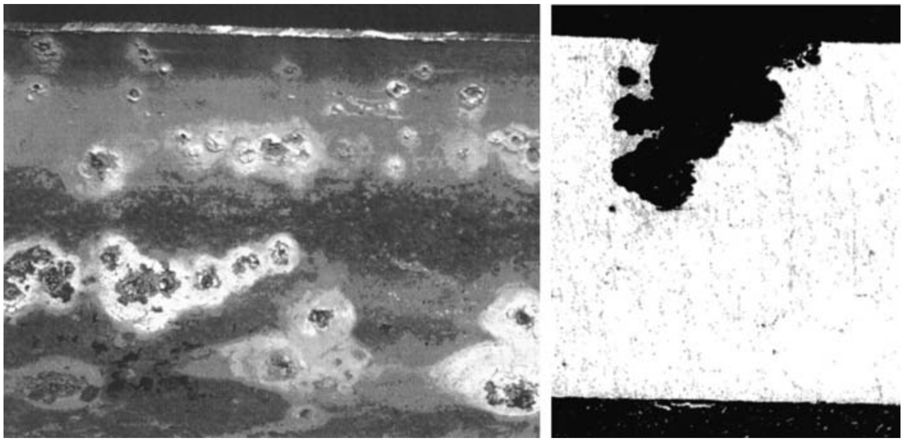

FIGURE 1.6. Pitting observed on the inside surface of an aluminum irrigation pipe (left) and cross-section of a pit in a laboratory sample of aluminum pipe exposed to copper-containing fungicide (right).

fire main. The contractor performing the repairs then found that the sewer line was plugged with this slurry. Further inspection found the sewer line was corroded and the contractor thought that perhaps his cement had corroded the pipe. The insurance for the restaurant ordered an investigation into the cause of the sewer line failure. The piping is shown in Figure 1.7.

It was immediately clear that pumping the slurry was not likely to have corroded the sewer line, as cement is not corrosive to ferritic materials. Inspection of the gray cast iron sewer line showed severe graphitic corrosion: substantial wall thinning, holes, and selective leaching of iron from the cast iron matrix. The corrosive attack was primarily on the sewer pipe inner surface, with little or no corrosive attack from the outside. The graphitic corrosion was extensive, indicating that the sewer may have been leaking for a long time, probably years. The most severe corrosion, including holes in the sewer line, was near the foundation on the south side of the restaurant where the fire protection water main entered the building. Examination of the fire main showed that it had failed due to weakening of the pipe wall from external corrosion. Thus, it is likely that the sewer line leak was the source of moisture that caused the external corrosion damage to the fire protection water main.

D3.6. Erosion–Corrosion. Some metals corrode more rapidly when exposed to flowing water. A good example is copper: Corrosion is much accelerated when exposed to water flowing at more than about 1 m/s past the surface. These conditions may be found in home plumbing systems with hot recirculation lines, as shown below.

Case History: Erosion–Corrosion of Copper Hot Recirculation Lines. Some homes have hot recirculation lines; that is, the hot water lines form a loop in which a small pump keeps a constant flow of water. This allows hot water to flow almost instantly from any tap in the home. However, the constant flow and high temperature could lead to severe corrosion. In a recent residential development where these loops were installed in fairly small homes, the available pumps were oversized with respect to the pipes, resulting in a constant high-velocity flow of hot water. Localized corrosion developed in a few years at areas where the flow was disrupted, such as elbows and tees. The corrosion pattern showed deep, well-defined eroded areas looking like sand dunes or river erosion patterns, indicative of erosion–corrosion (Fig. 1.8).

D3.7. Environmentally Assisted Cracking. EAC/SCC is a frequent cause of corrosion failures because it tends to be unexpected. Many early corrosion failures occurred in situations where SCC was unknown or unexpected at the time. For instance, the Silver Bridge at Point Pleasant, West Virginia, was designed in 1927 at a time when SCC was not known to occur under rural atmospheric conditions in the classes of bridge steels used for construction [24–26]. Yet SCC developed in an eyebar suspension link and led to the catastrophic collapse of the bridge after 40 years in service. Similarly, the Flixborough explosion of 1974, which killed 28 people in Great Britain when 50 tons of cyclohexane was released in a chemical plant, was (in part) a result of nitrate SCC and liquid metal embrittlement [27, 28].

Generally, SCC requires a specific combination of stress, material, and environment. Since the fundamental mechanisms for SCC are not always well understood, new combinations that can cause SCC are unfortunately found by accident.

Case History: Room Temperature Transgranular SCC of Austenitic Stainless Steel. Austenitic stainless steel, such as type 304 or 316, is known to be susceptible to transgranular SCC (TGSCC), but it was thought that this required exposure to concentrated chloride environments above 60°C. However, there have been several recent reports of such SCC at room temperature. For instance, SCC has been observed in permanent anchors used for rock climbing in Thailand (Fig. 1.9), in limestone formations at sea level [29].

After a few years, some of the anchors developed extensive cracking, to the point that they broke under normal climbing loads. Examination of the broken pieces showed

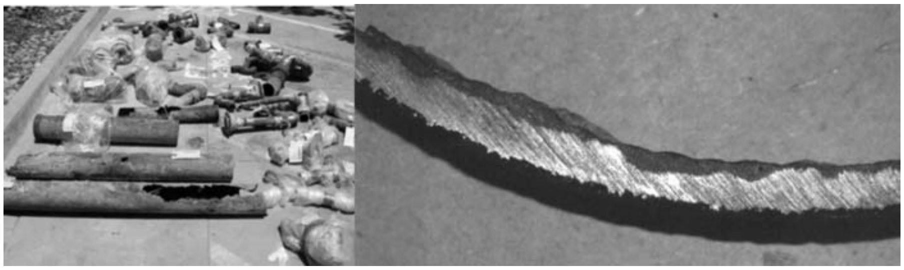

FIGURE 1.7. Fire main and sewer piping from restaurant (left) and graphitic corrosion on inner surface of sewer piping (right).

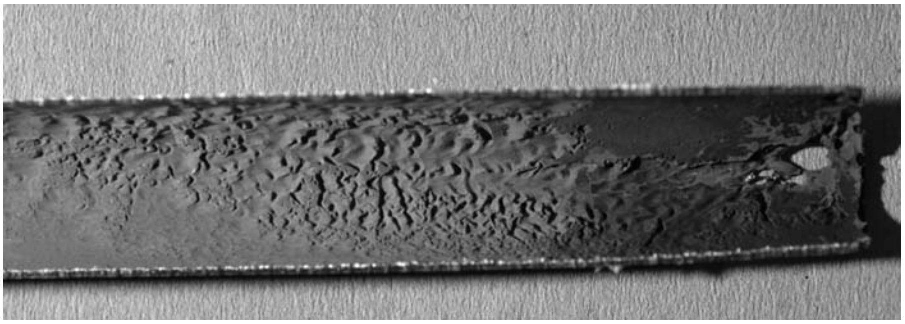

FIGURE 1.8. Copper hot recirculation line showing signs of erosion–corrosion.

pervasive intergranular SCC and the fracture surfaces contained a high concentration of magnesium, rather than the sodium that would be expected in a marine environment. Review of the known cases of room temperature transgranular SCC showed that the climbing anchors are in an environment that combines known promoters of TGSCC. Essentially, this type of SCC requires that the steel be exposed to very high concentrations of chlorides, which are promoted by salts such as magnesium or calcium chlorides, and by low relative humidity (a high relative humidity tends to dilute any salt water film on the metal). The climbing cliffs are located on tower karsts, which get their characteristic steep sides because of very active dissolution and redeposition of the limestone. Thus the climbing anchors can be exposed to calcium and magnesium salts as well as sodium chloride from the ocean. Although the environment is usually very humid, there are times where the relative humidity is fairly low, concentrating any solution that has formed on the stainless steel. Thus the climbing anchors are exposed to an environment that is extremely severe for transgranular chloride SCC.

D4. Complex failure analysis

Sometimes the incident under investigation is particularly complex or involves significant costs, either human or financial. In these instances, it is more important than ever to perform the failure analysis in a careful manner, separating various issues that may be involved and thoroughly validating hypotheses before coming to final conclusions. Such an example is described here.

Case Study: Chlorine Release at a Manufacturing Facility. A massive amount of chlorine gas was released to the atmosphere at a chemical plant making chlorine from calcium chloride [30, 31]. In the plant, the chlorine gas is liquefied before transport by railcar. In the liquefaction process, the chlorine gas is first compressed, then cooled down in a shell-and-tube heat exchanger, in which the chlorine flows inside tubes while chilled calcium chloride brine at about $-23°C$ ($-10°F$) circulates on the outside of the tubes. The liquefied chlorine is sent to a storage tank via a long transfer pipe containing several tees and elbows. The release

FIGURE 1.9. Typical 316L rock climbing bolt (left) installed permanently on climbing routes in cliff formations located on Thai beaches (right).

occurred through a large corrosion hole in an elbow in the transfer line between the liquefier and the storage tank.

Early indications showed that the hole in the elbow was due to severe general corrosion on the inside surface. Dry chlorine is not corrosive to the steel elbow, but addition of water to the chlorine could make the mixture extremely corrosive. Potential sources of water included the chlorine liquefier: If there was a leak in the tubes, brine solution could enter the chlorine stream. The liquefier was pressure tested and several tubes were found to be leaking.

The liquefier was cut open to expose the leaking tubes. To the general surprise, an old rag was found stuck in the shell of the liquefier, right at the brine inlet piping. It appeared that the rag had been there for a long time, most probably from the time of installation of the liquefier, some 25 years earlier. The rag partially blocked the brine flow path, resulting in accelerated flow in the areas that remained unobstructed. The leaking tubes were found in the area of accelerated brine flow.

With these early findings, the following scenario was hypothesized: The rag had been in the liquefier since installation, leading to increased brine flow rates over some tubes. This eroded the tubes, and, after about 25 years, one or more tubes were perforated. The brine flowed into the chlorine, creating a very corrosive mixture that corroded through the elbow in the transfer line within a few days, before the water contamination of the chlorine could be detected. Each step in the scenario was validated with tests and analyses.

1. *The rag increased the flow rate over some tubes in the bundle*. A fluid flow finite-element analysis of the liquefier inlet section was performed. With the cloth, the brine velocity in the area of the holes was about 3.94 m/s, whereas without the cloth it would have been only 1.27 m/s, or about one-third.
2. *This increased flow rate led to through erosion of the tube in about 25 years*. The observed corrosion rate of the tubes in areas where the brine flow was not accelerated by the cloth was very slow, about 10 μm per year. At this rate, it would take over 200 years to puncture a tube, so the design and operation of the liquefier were not the cause of the tube leak. The corrosion rate of the tube material exposed to brine flowing at high velocities was measured in a test bed in which chilled brine of various pH values was flowed over dummy tubes at various velocities. For a brine solution at its natural pH (no chemical additions), flowing at about 4 m/s, the interpolated corrosion rate would lead to through-wall erosion in about 22 years, very close to the actual service life of 25 years.
3. *Once the tube was perforated, brine flowed into the chlorine stream*. This conclusion was actually not immediate, because both the brine and chlorine systems were pressurized to roughly the same value. A careful pressure drop analysis of both the chlorine and the brine systems, coupled with review of plant data and some actual measurements made on a mock-up of the brine system, confirmed that the brine pressure was likely higher than that of the chlorine, so that brine would be entrained into the chlorine stream.
4. *The transfer line elbow corroded mostly from the inside out*. This was not immediately obvious, as both the inside and the outside of the elbow were severely corroded. The outside surface may have suffered from underinsulation corrosion during its life, and perhaps more rapid corrosion had occurred during the incident, when liquid chlorine was released from the leak site, but the extent of damage on the inside and outside needed to be compared accurately. A cross section of the failed elbow was traced over the outline of an undamaged elbow; this illustrated clearly that most of the corrosion had occurred on the inside surface (Fig. 1.10).
5. *The corrosion rate at the elbow was high enough to lead to a leak in a few days*. It is likely that the brine leak in the chlorine liquefier occurred relatively shortly before the incident, because it is likely that small amounts of water in the chlorine would have been detected prior to distribution. The best estimate of the start of the brine leak was a few days before the incident. The elbow was about 5.3 mm thick originally, so the corrosion rate would have to be extraordinarily high for through-wall attack in a few days. A related observation that required explanation was that the corrosion at the leak site was much more severe than

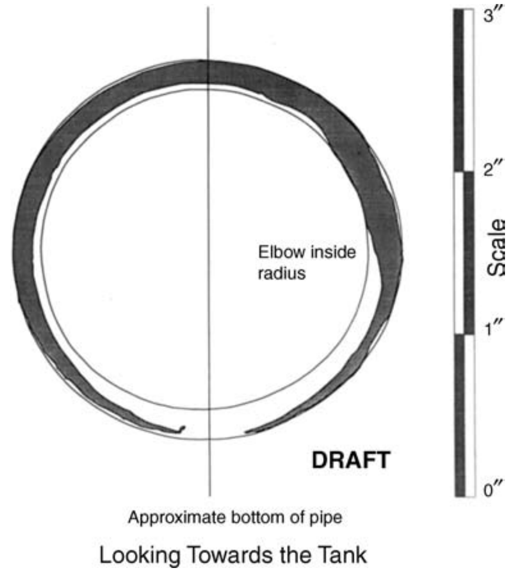

FIGURE 1.10. Erosion–corrosion wall loss of liquefied chlorine run down elbow compared to exemplar elbow.

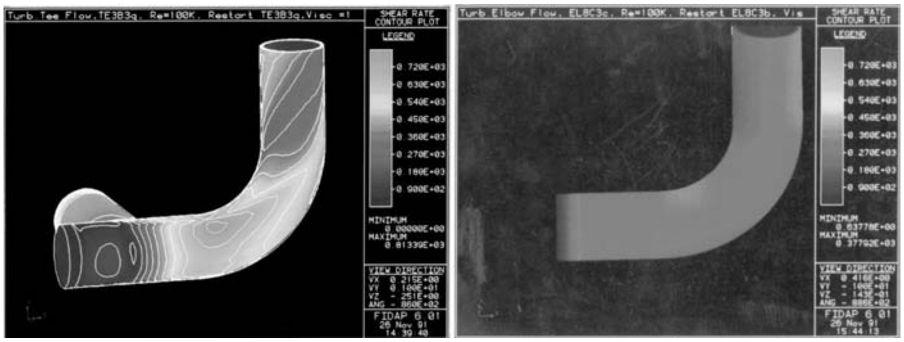

FIGURE 1.11. CFD calculated shear rate of (a) failed elbow-tee configuration and (b) elbow closest to storage tank without tee.

elsewhere in the transfer line, even though the line contained at least one other elbow. This was investigated by a combination of tests and analysis. The failed elbow happened to be located immediately after a T fitting, so that the flow went through two changes of direction in rapid succession. A computer fluid dynamics (CFD) model showed that the flow velocity and the shear rate in this elbow were much higher than in the other elbow in the transfer line, explaining why the corrosion was so much more severe at the leak point (Fig. 1.11). Actual corrosion rate measurements with several mixtures of brine and chlorine, both static and flowing, showed very high corrosion rates, but not quite high enough to achieve penetration in less than seven days. However, given the variability of the measured rates and the uncertainty about the flow conditions and the composition of the corroding mixture, it was concluded that the elbow most likely corroded in a few days after the tubes had started leaking.

The hypothesized scenario was thus validated step by step. This was a very serious incident, in which the stakes were high enough that a thorough failure analysis had to be performed, and the resources were available. Most failure analyses cannot be this detailed, but the basic steps must be the same: gather initial information, formulate hypotheses, and, most importantly, validate these hypotheses with the level of detail appropriate for the conclusions to be reached.

A. INTRODUCTION

Metallic corrosion seriously affects many sectors of a nation's economy or, on a vastly smaller scale, the design choices made by an engineer. This finding is so because corrosion and protective measures to control corrosion result in the utilization of materials, energy, labor, and technical expertise that would otherwise be available for alternative uses. Corrosion causes users of metal products to incur added expenses such as more costly corrosion-resistant materials, painting and other corrosion-protective measures, earlier replacement of capital goods, increased spare-parts inventories, and increased maintenance. Some of these costs are avoidable and could be lowered by applying the economically best available corrosion prevention technology. However, decreasing the presently remaining unavoidable costs would require advances in technology.

The cost of the corrosion of metals will be considered from two standpoints: the cost to the economy of a nation and the cost of selected corrosion control measures. The main basis for the discussion of the cost to a nation will be the study published in 1978 [1] that the U.S. Congress directed the National Bureau of Standards (NBS; currently National Institute of Standards and Technology, NIST) to undertake. This study was, and still remains, probably the most comprehensive investigation of the full extent of corrosion on the economy of a nation. The analysis required was contracted out to Battelle Columbus Laboratories (BCL). The NBS–BCL study, unlike previous ones (B3), was based upon a solid technical–economic method that attempted to evaluate, in a rigorous way, all costs of corrosion, direct and indirect, over the entire economy and to evaluate the uncertainties in these cost estimates. "A significant feature of the study was that the method employed—input/output analysis—provides a methodological framework that permits comprehensive treatment of all elements of the costs of corrosion: production costs, capital costs, and changes in useful lives, for example. The input/output model allows analysis of interindustry relationships in the national economy and attribution of relative costs to specific segments of the economy" [1a, p. 30].

To carry out the second aspect of this discussion, a National Association of Corrosion Engineers (NACE) Recommended Practice [2] and a more recent NACE update [3] will be the source of the discussion of the economic appraisal of a selected corrosion control method.

B. ECONOMIC EFFECTS OF METALLIC CORROSION IN THE UNITED STATES

The NBS–BCL study [1] of metallic corrosion costs in the United States in 1975 employed a modified version of the BCL National Input/Output (I/O) model. A series of articles giving a detailed discussion of the NBS–BCL study [4] was published in the more available corrosion literature.

B1. Approach

B1.1. Elements of Corrosion Costs Used in the BCL I/O Model. The BCL I/O model using 130 sectors of the U.S. economy included the following as costs associated with corrosion: (a) material and labor expenditures associated with the protective measures of painting, applying cathodic protection, coatings, and use of inhibitors; (b) the expenses arising from the extra material and labor for prevention; (c) the partial corrosion losses that result in replacement costs and lost production; and (d) the expenses incurred by using information, technology transfer, research, development, and demonstration of methods to cope with the destructive effects of metallic corrosion.

A basic factor to be considered in measuring macrocorrosion costs in a sector of an economy was the lifetime and replacement value of a given component that could suffer from corrosion damage. Table 2.1 gives some of the elements of the costs of corrosion used in the BCL I/O model.

Corrosion costs used in the I/O approach can be either direct or indirect. The NBS report [1a, p. 11] describes these in the following way: Direct costs include all reductions in the requirements for inputs for production which would become possible if there were no corrosion. These include flow inputs (e.g., pig iron into steel), capital inputs for expansion and replacement of capacity (e.g., blast furnaces for steel), and value added. The direct flow effects include reduced maintenance costs and the use of less expensive materials for embodiment in outputs. Among the direct capital effects are the reduced need for equipment due to less time down for maintenance and the lower replacement cost because of increased equipment life. The value-added effects include reduced costs of labor and lower depreciation allowances for the smaller capital requirements. The indirect effects include two elements: (1) In addition to the reduced input requirements, the inputs also cost less, because of savings in their own and earlier production processes: (2) the general interactive effects of reductions in production levels on one another.

Value added is the additional value accruing to a product's ingredients as they are fashioned into the product itself. It includes wages, salaries, rents, profits, interest, taxes, and depreciation. It can also be defined as the value of the productive factors contributed by the industry itself, rather than those purchased from other industries.

TABLE 2.1. Some Elements of the Costs of Corrosion[a]

Capital costs	
	Replacement of equipment and buildings
	Excess capacity
	Redundant equipment

	Corrosion control
Design costs	
	Materials of construction
	Corrosion allowance
	Special processing
Associated costs	
	Loss of product
	Technical support
	Insurance
	Parts and equipment inventory

[a]See [1a, p. 10].

B1.2. Scenarios for the I/O Model. Three scenarios were developed and used in the I/O model to quantify corrosion costs: Three "worlds" were formulated: *world I*—the real-world economy in 1975, *world II*—an imaginary corrosion-free world, and *world III*—a hypothetical world in which everyone applies the best economically practical corrosion control measures. The scenarios used in the model involved the gross national product (GNP—a more recently used term is gross domestic product, GDP). Three sets of these worlds were (a) world II minus world I is *the total national cost of corrosion* and represents resources that are wasted because of corrosion; (b) world III minus world I is *the total national avoidable costs* of corrosion and represents resources that would be available if economically best preventive practices were used throughout the economy; and (c) world III minus world II measures *presently unavoidable costs*.

B1.3. The I/O Model. To describe the BCL I/O model, it is best to quote directly from the NBS report [1a, p. 12]: "A number of characteristics make input–output analysis, pioneered by W. W. Leontief, and the modified Battelle model well suited for use in estimating the total direct and indirect costs of corrosion. The model is quite detailed. In this study, it has 130 economic sectors and each is represented by a production function consisting of the respective inputs from that sector plus value added. As a result, relatively detailed industry corrosion cost data may be incorporated into the model for simulation purposes. The complex structure serves as a guide for the precise analysis of corrosion costs and a means for integrating the results."

"The model is comprehensive. It has sufficient components to allow all the contributions to corrosion costs (production expenses, capital cost, reductions in replacement, and excess capital capacity, for example) to be considered in the analysis. Because of the model's structure, all of these

aspects, and their interactions, may be evaluated in a coordinated and systematic manner."

"The model is simultaneous and, therefore, able to account for both direct and indirect effects of certain changes in the economy. This is critical to estimating the total costs of corrosion to society."

"Because the model simultaneously determines equilibrium values, comparative static analysis (i.e., comparison of alternate growth scenarios at the same moment in time) is an obvious application. For example, the costs of corrosion in the existing world (World I) are compared to those in each of the two hypothetical worlds mentioned previously—World II in which no corrosion exists and, thus, the costs are zero, and World III in which 'best practice' corrosion control methods are employed."

B2. Results

If we use the approach outlined above, the NBS–BCL study separates the total costs of corrosion into two costs: (a) *avoidable costs*, which are costs that can be reduced "by the most economically effective use of presently available corrosion technology," and (b) *unavoidable costs*, which result from "presently unavoidable losses." For the study's base year 1975, total costs of metallic corrosion (materials, labor, energy, and technical capabilities) were estimated by the BCL I/O model used in the study to be \$82 billion, 4.9% of the \$1677 billion GNP. Approximately 40% of this (\$33 billion, 2.0% of the GNP) was estimated to be avoidable. Combining the BCL results and the NBS detailed analysis of the uncertainty, the total national yearly cost of metallic corrosion was reported to be about \$70 billion (4.2% of GNP), with an uncertainty of ≈±30%. The NBS report found the 1975 avoidable cost of corrosion was roughly 15% of the total, but it estimated that it could have a range of 10–45%. An analysis of the errors, especially the estimates of the avoidable costs, led to the conclusion in the NBS report that the values cited above were reasonable.

Table 8 of the NBS report [1a] lists the total costs that were allocated to the 130 economic sectors of the United States that were produced by the BCL I/O model. This table gives corrosion losses on a dollar basis and as cost per unit of sales for the total and avoidable costs of both direct and direct plus indirect costs.

In addition to the 130 sectors of the economy provided by Table 8 of this report, the following special area costs were covered in more detail in the NBS report:

(a) U.S. federal government—total costs attributable to corrosion were estimated to be 2% of the federal budget with 20% of this total being judged to be avoidable.

(b) Personally owned automobiles—total expenses of corrosion in the ownership of an automobile were found to be \$6–14 billion, 1975 dollars, with avoidable costs being \$2–8 billion.

(c) Electric power—total direct costs arising from the effects of corrosion on the operation of power generation plants were estimated to be \$4.1 billion with avoidable costs of \$120 million (3% of total costs).

(d) Fossil fuel energy and materials—total costs arising from the additional energy and materials losses resulting from corrosion were estimated to be \$1.4 billion, with avoidable costs of \$248.5 million for energy, and \$1.705 billion, with avoidable costs of \$212 million, for nonrenewable raw material sectors.

B3. 1995 Update of the NBS–BCL Study

The Specialty Steel Industry of North America engaged Battelle to produce a report [5] updating the NBS–BCL study [1, 3] and reflecting the changes resulting from economic growth, inflation, and 20 years of scientific research and technological advances. In Table 2.2, the revised estimates for 1995 are compared to the 1975 BCL values—not taking the NBS uncertainty analysis into consideration. In part, the Battelle panel that produced the report attributed the 1995 reductions in the percent of GNP to the following factors: (a) the anticorrosion technology of the motor vehicle industry (the most significant factor); (b) increased use of stainless steels, coated metals, and more protective coatings; (c) substitution of material to reduce weight; and (d) reclassification of unavoidable costs as avoidable.

In a more recent study, the annual direct cost of corrosion to industry and to governments in the United States was estimated to be approximately \$276 billion, or 3.1% of the GDP [5a].

TABLE 2.2. Metallic Corrosion in the United States[a]

	1975 (billions of current dollars)	1995

C. CORROSION COSTS IN VARIOUS COUNTRIES

The fact that many countries have attempted to assess their national corrosion costs points up the worldwide awareness that corrosion can be a serious economic concern. It is useful to compare the United States results to those obtained in various industrial countries where such assessments of national corrosion costs were undertaken (including other past U.S. studies). These other studies of corrosion losses either involved major data gathering and interpretation efforts, which were the results of the analysis by a single authority of the country's corrosion costs in terms of the knowledge of the best presently available corrosion control measures and industrial practices, or, simply, assertions by an author with no reference as to how the costs were computed. This is the rationale for using the NBS–BCL study as the major focus of this discussion, because it looks at the entire economy of a nation and seeks to estimate the uncertainties in the numbers reported. Because of this more rigorous approach, the results of the NBS–BCL analysis gave higher total costs of corrosion but, surprisingly, agreed qualitatively with those found in previous studies as discussed in the NBS report. In 1986, a more recent examination of corrosion costs in various countries was the topic of an NACE symposium entitled "International Approaches to Reducing Corrosion Costs" [6]. The NBS study considered the following countries.

C1. United Kingdom

In 1969, a major data-gathering and interpretation endeavor, which was the precursor to the NBS–BCL U.S. study and unlike the less meticulous efforts of the countries described below, was initiated in the United Kingdom with the appointment by the Minister of Technology of a 25-member committee headed by one of the leading corrosionists in the United Kingdom, T. P. Hoar, to determine the cost of corrosion [7].

The committee contacted 800 industries in the country, all government departments, corrosion protection companies, and corrosion consultants. They were to gather from these sources information on the effects of corrosion, including the amount of shutdowns, rejection of product losses, structural failures, and the loss to industries from these. The committee added to these losses the costs of items replaced because of corrosion, expenditures on corrosion protection, and information services, research, and development in the various industries. Using these collected data, the Hoar committee arrived at an industrywide estimate of the cost of corrosion [7].

The Hoar report reported losses to the United Kingdom (Table 2.3) of £1.365 billion ($3.2 billion, 1969 U.S. dollars) for 1969–1970. This amounts to ≈3.5% of the GNP of the United Kingdom for that period. In addition, the committee found that some £310 million, or 23% of this total figure, was potentially avoidable. The estimated potential savings were £310 million, or 22.7% of the GNP. They suggested approaches toward achieving these savings, such as improved materials selection, specification and control of protective measures, improved awareness of corrosion, especially in design, and greater use of cathodic protection. An informal conference was held in 1971 as a supplement to the Hoar report to discuss the findings. Six sessions were held, one for each section of the report [8].

TABLE 2.3. National Cost of Corrosion and Corrosion in the United Kingdom[a]

Industry or Agency	Estimated Cost (£M)
Building and construction	250
General engineering	11
Marine	280
Metal refining and semifabrication	15
Oil and chemical	180
Power	60
Transport	350
Water	25
Total	1365

[a]See [7].

C2. German Federal Republic

Behrens [9] estimated that total losses for the period 1968–1969 were 19 billion DM ($6 billion, 1969 dollars), with avoidable costs of 4.3 billion DM ($1.5 billion, 1969 dollars). No details were given as to what these figures include or how they were computed. Total costs were reported to be about 3% of the West German GNP for 1969, and avoidable losses were roughly 25% of total costs. These figures, with respect to GNP and percentage of avoidable cost, are in good agreement with figures found for other nations.

C3. Sweden

A partial study of corrosion costs in Sweden by Trädgåidh [10] in which painting expenditures to combat corrosion were analyzed for the year 1964 found these costs to be 300–400 million crowns ($58–77 million, 1964 dollars) with between 25 and 35% being avoidable.

C4. Finland

Costs to Finland for the year 1965 have been estimated by Vläsaari [11] to be 150–200 million markaa ($47–62 million, 1965 dollars). Linderborg [12], referring to these losses, described the factors that must be taken into account in

assessing corrosion costs to the Finnish nation. He recognized that an important factor was the variable lifetimes for a variety of items using the specific example of the automobile.

C5. Union of Soviet Socialist Republics (Now Russia)

Kolotyrkin [13] reported in 1969 that corrosion costs were $\approx$2% of the GNP, or 6 billion rubles ($6.7 billion, 1969 U.S. dollars), giving no indication as to what this figure includes or how it was computed.

C6. Australia

The direct costs of corrosion in 1973 were estimated by Revie and Uhlig [14] to be A$470 million ($550 million, 1973 dollars). The authors decided that these costs are "probably too low" considering the factors they used to develop this figure. Some additional direct costs—mostly labor—for the mining, transportation, and communications industries were unavailable. Only muffler corrosion was considered as contributing to automobile losses. Lifetimes were not taken into account quantitatively. The amount of $470 million was 1.5% of Australia's GNP for 1973. However, since indirect costs may equal or exceed this figure, total corrosion costs to Australia were estimated to be $\sim$3% of GNP. No quantitative effort was made to assess uncertainties or to separate these costs into avoidable and unavoidable components.

C7. India

For the period 1960–1961 Rajagopalan [15] estimated the cost of corrosion to India was 1.54 billion rupees ($320 million, 1961 dollars). He calculated the expenditures of certain measures to prevent or control corrosion, including direct material and labor expenses for protection, additional costs for increased corrosion resistance or redundancy, costs of information transfer, and funds spent on research and development. No quantitative estimate of uncertainty was attempted nor were avoidable and unavoidable costs broken down.

C8. Japan

A survey [16] conducted from 1976 to 1977 in Japan found that the annual direct cost of corrosion was 2500 billion yen ($9.2 billion, 1974 dollars), which amounts to 1.8% of the Japanese GNP. If the indirect costs were included, the total would increase severalfold.

C9. Previous U.S. Studies

Probably the first itemized measure of the costs of corrosion in the United States was carried out by Uhlig [17], who arrived at a value for the total direct corrosion losses of $5.5 billion for the late 1940s. A more recent study was carried out by NACE [18]. This study, based on replies of 1006 persons to a questionnaire, estimated the cost to NACE members of direct expenditures of corrosion control measures to be $9.67 billion for 1975.

D. COST OF SELECTED CORROSION CONTROL MEASURES

In order for the corrosion engineer to select the economically optimum corrosion control measure for a given specific problem, it is necessary that the corrosion engineer recognize the pertinent economic factors that bear on the choice of appropriate corrosion technology. To address this need, NACE Technical Unit Committee T-3C on Economics of Corrosion produced and issued in 1972 the Recommended Practice NACE Standard RP-02-72, "Direct Calculation of Economic Appraisals of Corrosion Control Measures" [2]. In 1994, the NACE Task Group T-3C-1 issued a technical report [3], "Economics of Corrosion," to replace, the simpler and less rigorous from an accounting practice standpoint, RP-02-72. The objectives of the 1994 report were(1) present the economic techniques in a form that can be readily understood and used by engineers as a decision-making tool; (2) facilitate the communication of decisions between the corrosion technologist and management; and (3) justify investments in anticorrosion methods that have long-term benefits.

The 1994 report used more advanced and standardized accounting notation and terminology that was based on American National Standards Institute (ANSI) standard Z94.5 entitled "Engineering Economy" [19]. Another more accessible source of the calculational techniques that enable an economic appraisal of corrosion control measures has been published by Verink [20]. A useful feature of the report (also present in the 1972 document) was a section devoted to worked examples and applications using the calculational techniques in the report to select process equipment and the best alternate cathodic protection proposal.

A. INTRODUCTION

Over $220 billion is lost to corrosion in the United States each year, according to government and industry studies. This corrosion cost is equivalent to 3 or 4% of the gross national product (GNP). The real tragedy of this annual corrosion cost is that ~ 15% or more could be saved by the application of existing technology to prevent and control corrosion. The existing technology includes the following methodologies to prevent and control corrosion: proper design, selection of materials, coatings and linings, cathodic protection, and inhibitors. Standards, reports, books, and thousands of technical articles attest to the successful use of the existing technology to prevent and control corrosion and thus to reduce the annual losses to corrosion.

B. CORROSION—AN ECONOMIC PROBLEM

Corrosion is essentially an economic problem. It is vitally important that engineers and engineering managers be aware of the economic impact their decisions have on the ability of a business to meet its corporate goals. A discipline that assists in the measurement of the economic impact of such decisions is called "engineering economy."

Engineering economy is concerned with money, both as a resource and as the price of other resources. Business success is dependent on the prudent and efficient use of all resources, including money. The principles of engineering economy permit direct comparisons of potential alternatives in monetary terms. In this way, they encourage efficient use of resources.

The economics of corrosion evaluation involves the assessment of the technical validity and economic justification of each alternative. Corrosion technologists generally spend much effort exploring the technical validity of materials or processes. However, each corrosion problem may have more than one material or process that could satisfactorily solve the technical problem. Each candidate material or process probably has a unique stream of investment and operating

or maintenance costs while providing equivalent technical benefits. Indeed, once the technically viable alternatives are chosen and their respective costs and performance characteristics are isolated, the technologist's decision becomes one of financial analysis because almost all of the factors in the decision process can be reduced to the magnitude and timing of cash flows.

The purposes of this chapter are:

1. To present the economic techniques in a form that can be readily understood and used by engineers as a decision-making tool
2. To facilitate the communication of decisions between the corrosion technologist and management
3. To justify investment in anticorrosion methods that have long-term benefits

B1. Basics—Money and Time

Consider the effects of time and earning power on $20.00. If $20.00 is placed in the bank and earns interest at a rate of 5% per year, it grows to $21.00 when the interest, $1.00, is paid at the end of the year. Thus, $20.00 today at 5% is equivalent to $21.00 a year from now. Stated another way, in order to have $21.00 one year from now, only $20.00 has to be deposited today if the interest rate is 5%. The $20.00 is called the "discounted present value" of the $21.00 needed one year hence.

The initial deposit as well as the earned interest left in the account have earning power because the interest is compounded, which means that it is computed on both the principal and the accrued interest.

Suppose the $20.00 were used to pay four equal annual installments of $5.00 each. Without interest, the $20.00 would be exhausted after making the last payment. If the $20.00 is deposited in the bank at 5% interest, it will be worth $21.00 at the end of the first year. Paying out $5.00 would leave $16.00 to be held at 5% interest for the second year. The $16.00 invested at 5% will earn $0.80 in one year. Subtracting $5.00 from $16.80 leaves $11.80 to be held at 5% interest for the third year. The $11.80 will earn $0.59 by the end of the third year at 5%. Another annual payment of $5.00 leaves $7.39 to earn interest during the fourth year. Adding the $0.37 interest earned during the fourth year and subtracting the final $5.00 annual payment leaves a balance of accrued interest of $2.76.

The earning power of money permits another strategy. If the initial deposit were reduced to $17.73 at 5% interest, $5.00 could be paid out each year for four years and nothing would be left. This example illustrates the distinction between the terms "equivalent" and "equal." The $20.00 is equal to four payments of $5.00 each. It also would be equivalent to four $5.00 annual payments (only) if the interest rate were zero. The $17.75 is not equal to the sum of four payments of $5.00 each. However, when $17.73 is invested at 5%, it is equivalent to four annual payments of $5.00.

The term "equivalent" implies that the concept of the time value of money is applied at some specific interest rate. Therefore, for an amount of money to have a precise meaning, it must be fixed both in time and amount. Mathematical formulas and tables are available to translate an amount of money at any particular time into an equivalent amount at another date.

Many kinds of translations are possible. For example, a single amount of money can be translated into an equivalent amount at either a later or an earlier date. This is accomplished by calculating the present worth (PW) or the future worth (FW) as of the present date. Single amounts of money can be translated into equivalent annuities (A) involving a series of uniform amounts occurring each year. Conversely, annuities can be translated into equivalent single amounts at either an earlier or a later date. The present worth of an annuity (P/A) is the single amount of money equivalent to a future annuity. The single amount equivalent to a past annuity is referred to as the future worth of an annuity (F/A).

It is also possible to calculate the amount of money that would be equivalent to a nonuniform series of cash flows. Two types of nonlinear series that find application are an arithmetic progression, in which the series changes by a constant amount, and a geometric progression, in which the series changes by a constant rate. The arithmetic progression is considered to be representative of variable costs, such as maintenance costs, which may increase as equipment ages. The geometric progression is used to represent the effects of inflation or deflation.

C. NOTATION AND TERMINOLOGY

The American National Standards Institute (ANSI) standard Z94.5 titled "Engineering Economy" consists of a compilation of the symbology and terminology of the field so that the improved communication benefits of standardization are available to practitioners [1]. With the development and publication of this standard and its adoption by the Institute of Industrial Engineers and the Engineering Economy Division of the American Society of Engineering Education, it is expected that future books and articles will utilize these symbols common to engineering economy because they represent the consensus choice of the prominent modern authors and educators in this field. This would avoid one of the significant previous deterrents to the use of these methods in the past.

The reader is referred to ANSI standard Z94.5 for further details, including functional forms and uses of compound interest factors, and formulas involving annual compounding and others involving continuous compounding [1].

The basic form of the notation used for all time value factors consists of a ratio of two letters representing two amounts of money (e.g., P/A or F/P) plus an interest rate ($i\%$) and a number of periods (n). The customary manner of writing these is

$$(\mathrm{P/A}, i\%, n)$$

or

$$(\mathrm{F/P}, i\%, n)$$

The present worth (P) of a known annuity (A) can also be expressed as follows:

$$\mathrm{P} = \mathrm{A}(\mathrm{P/A}) \tag{3.1}$$

or the future worth (F) of a known present amount (P) is

$$\mathrm{F} = \mathrm{P}(\mathrm{F/P}) \tag{3.2}$$

Other forms also are common, such as PW(·) or FW(·), which are called "operators" because they represent some computational operation, such as the PW or the FW of whatever is inside the parentheses.

It should be evident that (F/P) is the reciprocal of (P/F) and that (F/A) and (A/F), and so on, also are reciprocals. This observation is useful because it means that only three time value factors need to be tabulated in order to conduct six operations.

Another algebraic relationship shows that if two time value factors are multiplied, the product is a third time value factor. For example,

$$(\mathrm{A/F}) \times (\mathrm{P/A}) = (\mathrm{P/F}) \tag{3.3}$$

D. METHODS OF ECONOMIC ANALYSIS

Economic analysis methods that are concerned with the entire service life sometimes are called "life-cycle cost" methods. Those that lead to single-measure numbers include:

(a) Internal rate of return (IROR)
(b) Discounted payback (DPB)
(c) Present worth (PW) method, also referred to as the net present value (NPV)
(d) Present worth of future revenue requirements (PWRR)
(e) Benefit–cost (BCR) ratios

All five methods employ the concept of PW. While each method has certain advantages, the individual methods vary considerably with respect to their application and complexity.

The IROR method compares the initial capital investment with the PW of a series of net revenues or savings over the anticipated service life. Expenses include all operation, maintenance, taxes, insurance, and overheads but do not include return on (or of) the invested capital. From an economic standpoint, IROR consists essentially of the interest cost on borrowed capital plus any existing (positive or negative) profit margin. The disadvantage of this method is that it ignores benefits extending beyond the assumed life of the equipment and thereby may omit a substantial part of the actual service life. This may lead to unnecessarily pessimistic measures of long-range economy.

The PWRR method is particularly applicable to regulated public utilities, at which the rates of return are more or less fixed by regulation. It is particularly applicable when it has already been determined by IROR analysis that a project is economically viable, and the engineer wishes to determine which is the most economic alternative under circumstances wherein several alternatives produce the same revenue but some of them create less expense (requirement for revenue) and consequently a greater profit margin (or lower losses) than others. The principal objection to the PWRR method is that it is inadequate when alternatives are competing for a limited amount of capital because it does not identify the alternative that produces the greatest return on invested capital.

The DPB method is somewhat more complicated than the PWRR method. The BCR method is similar to the IROR method because both methods involve assessment of alternatives, not only for economic measures compared with a "do-nothing" scenario, but also for incremental measures associated with incremental capital investments.

The PW method, also referred to as the NPV method, is considered the easiest and most direct of the five methods and has the broadest application to engineering economy problems. Many industries refer to this method as the "discounted cash flow" method of analysis. This method often is used as the "referee" method to test the results of other methods of analysis. Under the circumstances, it is not surprising that there is a preference for this method and that primary attention is given to this method in this chapter. Those interested in exploring the other methods are referred to standard texts on the subject.

D1. Annual Versus Continuous Compounding

Because actual cash flow (both inward and outward) is continuous, it appears that continuous compounding is the more accurate assumption for engineering economy studies. However, although the overall cash flows tend to be continuous, the cash flow data seldom are sufficiently precise in economy studies to take full advantage of continuous

compounding. It is also true that the normal purpose of the economy study is to analyze some specific event that will occur at a specific time, so a procedure that is readily associated with a specific time is usually the most appropriate. For these reasons, and because annual compounding is conceptually easier to understand and apply, annual compounding is the method primarily used in this chapter. The PW method is a form of discounted cash flow (DCF), wherein cash flow data, which include dates of receipts and disbursements, are discounted to PW. Before applying these methods, a management judgment is made as to the desired life (usually expressed as a number of years, n) and the minimum acceptable rate of return (ROR) on invested capital for a project (expressed in terms of the effective interest rate, i, or the nominal rate of return, r). Rates of return (before taxes) vary among industries, ranging from 10–15%, where obsolescence is not high, to 25–40% (or perhaps higher) for dynamic industries. Obviously, it is convenient if the minimum acceptable ROR is known before making engineering economy analyses. However, it is not always easy to learn what is considered an acceptable ROR. Under such circumstances, it has been helpful to prepare a series of economic alternatives in which the ROR is varied so that management can make a choice.

An example illustrates the features of the method. In this case, the "longhand" method is used. In practice, there are several shortcuts.

Should an expenditure of $15,000 be made to reduce labor and maintenance costs from $8200 to $5100 per year? Money is worth 10% and the life of the project is 10 years. For simplicity, the effects of taxes and depreciation have been neglected in this example.

Table 3.1 shows the projected pattern of cash flow for the "defender" (the present method) and the "challenger" (the proposed method) over the life of the project. A minus sign means that money leaves the "bank," whereas a plus sign means that the "bank balance" increases in size. The net cash flow for each year appears in the right-hand column under the heading "B − A."

TABLE 3.1. Tabulation of Cash Flow

Period (year)	Plan A (dollars) (Defender)	Plan B (dollars) (Challenger)	B − A (dollars)
0	—	− 15,000	− 15,000
1	− 8,200	− 5,100	+ 3,100
2	− 8,200	− 5,100	+ 3,100
3	− 8,200	− 5,100	+ 3,100
4	− 8,200	− 5,100	+ 3,100
5	− 8,200	− 5,100	+ 3,100
6	− 8,200	− 5,100	+ 3,100
7	− 8,200	− 5,100	+ 3,100
8	− 8,200	− 5,100	+ 3,100
9	− 8,200	− 5,100	+ 3,100
10	− 8,200	− 5,100	+ 3,100
Totals	− 82,000	− 66,000	+ 16,000

Source: E. Verink, "Corrosion Economic Calculations," ASM Handbook, Vol. 13, 9th ed., Corrosion, ASM International, Materials Park, OH, 1987, p. 372 (Table 4).

It is apparent that selection of the challenger (plan B) results in a net positive cash flow. That is, the net amount of money in the bank is increased over the life of the project when plan B is selected. Before reaching a conclusion regarding implementation of plan B, these cash flows are reduced to a common basis for comparison and to determine whether the objective of a 10% ROR has been achieved. The PW (or present value) of these cash flows provides such a basis. The ROR for plan B is calculated by iteration using interest tables and interpolating between values.

D1.1. First Iteration. Assume a rate of return of 10% and refer to Table 3.2:

$$(\mathrm{PW}) = -15{,}500 + 3100(\mathrm{P/A}, 10\%,\ 10\,\mathrm{years}) \quad (3.4)$$

$$= -15{,}500 + 3100(6.145) = +\$4047.95 \quad (3.5)$$

The ROR for which the discounted cash flow is equal to zero (i.e., the first term on the right of the above expression is balanced by the second term) is the actual rate of return. From the first iteration, it already is evident that plan B returns more than 10% because the net cash flow is positive. Thus, plan B, the challenger, is the more economical. The numerical value of the actual rate of return can be determined by additional iterations. Such an exercise reveals that the ROR in this case is 16.1%.

In this example, plans A and B could represent alternative materials of construction having different corrosion rates, with the annual dollar difference being related to the consequences of corrosion on maintenance costs. This presupposes the availability of corrosion data that can be used to estimate expected life, maintenance costs, and so on. Other examples illustrate how to account for the effects of salvage value, taxes, and depreciation.

E. DEPRECIATION

Depreciation has been defined as the lessening in value of an asset with the passage of time. All physical assets (with the possible exception of land) depreciate with time. There are several types of depreciation. Two of the more common types are physical depreciation and functional depreciation. Accidents can also cause loss of value, but this cause is often accommodated in other ways (i.e., insurance or reserves) and is not considered here.

Physical depreciation includes such phenomena as deterioration resulting from corrosion, rotting of wood, bacterial

action, chemical decomposition, wear and tear, and so on, which can reduce the ability of an asset to render its intended service.

Functional depreciation results not from the inability of an asset to be available to serve its intended purpose, but rather from the fact that some other asset is available that can perform the desired function more economically. Thus, obsolescence and/or inadequacy, or inability to meet the demands placed on the asset, lead to functional depreciation. Technological advances produce improvements that often result in obsolescence of existing assets.

The manner in which depreciation is accounted for is largely a tax question. The language of the tax laws specifies the procedures that are permissible. Tax laws change from time to time, so procedures that are attractive under a given set of circumstances may become unattractive (or even forbidden) under other circumstances. Some of the more common methods of depreciation include:

1. Straight line
2. Declining balance
3. Declining balance switching to straight line
4. Sum of the year's digits
5. Accelerated cost recovery system

E1. Straight-Line Method

The straight-line depreciation method assumes that the value of an asset declines at a constant rate. If the asset originally cost \$6000 and had a salvage value of \$1000 after five years' life, the annual depreciation would be (\$6000 – 1000)/5 = \$1000/year. Symbolically, this can be expressed

$$\text{Annual depreciation,} \quad D = \frac{P - S}{n} \tag{3.6}$$

The "book value" of the asset would decrease at the end of each year by the amount of the annual depreciation until, at the end of the fifth year, the book value would be the same as the salvage value.

E2. Declining-Balance Method

The declining-balance method assumes that the asset depreciates more rapidly during early years than in later years. A certain percent of depreciation is applied each year to the remaining book value of the asset. Under these circumstances, the size of the depreciation declines each successive year until the asset is fully depreciated. When the declining-balance method is used, the maximum rate that has been permissible for tax purposes is double the straight-line rate. This accounts for the term "double-declining balance."

E3. Declining Balance Switching to Straight Line

Prior to 1981 in the United States, it was allowable to depreciate an asset using declining-balance depreciation for the early years and then switch to straight-line depreciation when the allowable depreciation (using declining balance) falls below the amount permissible under straight-line depreciation. Switching to straight-line depreciation permits the book value to go to zero eventually. The declining-balance method switching to straight line has been incorporated in part of the 1986 version of the ACRS depreciation method discussed below.

E4. Sum-of-the-Year's-Digits Method

The sum-of-the-year's-digits method assumes that the value of an asset decreases at a decreasing rate. Assume an asset has a five-year life. The sum of the year's digits equals 1 + 2 + 3 + 4 + 5 = 15. For the \$6000 asset mentioned above, which has a salvage value after five years of \$1000, the first year's depreciation would be (\$6000 – 1000)(5/15) = \$1666.67. The second year's depreciation would be (\$6000 – 1000)(4/15) = \$1333.33, and so on, until the asset is fully depreciated. This method is no longer permitted in the United States for new assets.

Most of the property acquired before 1981 is still being depreciated by one of the methods mentioned above. Each of these (pre-1981) methods involves the taxpayer estimating a "useful life" either on the basis of experience or based on a guideline from the U.S. Internal Revenue Service in Washington, DC. The guidelines are presented as ranges of values in the class life asset depreciation range (ADR) system. The midpoint of the range is referred to as the "ADR life."

E5. Accelerated Cost Recovery System Method

For property placed in service after 1981, the accelerated cost recovery system (ACRS), which is a part of the Economic Recovery Act of 1981, prescribes a different method for recovering the cost of depreciable property. The Tax Reform Act of 1986 revamped the ACRS enacted in 1981. The 1986 act generally is less generous than the prior law, which combined ACRS with investment tax credit (ITC). While ACRS was originally designed primarily as an incentive for investment, the new rules are intended to provide a more even match between the class lives of particular assets and their useful lives. Nonetheless, deductions are more accelerated than under pre-1981 law.

The principal differences between the prior version of ACRS and the new law are in the class lives of assets and the methods of recovering their costs. As in the prior law, salvage continues to be disregarded. The new system is generally effective for assets placed in service after 1986, but by special election, property placed in service after July 1, 1986, also may qualify under the new rules.

TABLE 3.3. Recovery Property

ACRS Class and Method	ADR Midpoint	Special Rules
3-year, 200% DB	4 years or less	Excludes cars, light trucks
5-year, 200% DB	> 4 to <10 years	Includes cars, light trucks, semiconductor manufacturing equipment, qualified technical equipment, R & D property, and so on
7-year, 200% DB	10 to <16 years	Includes agricultural, horticultural structures, and RR track. Property with no ADR midpoint
10-year, 200% DB	16 to <20 years	None
15-year, 150% DB–SL	20 to <25 years	Includes sewage treatment plants, telephone, data, and voice communication
20-year, 150% DB–SL	25 years or more	Excludes real property with ADR midpoint 27.5 years or more. Includes municipal sewers
27.5-year, SL	N/A	Residential rental property
31.5-year, SL	N/A	Nonresidential real property

Note: DB—declining balance; SL—straight line; N/A—not applicable.

Assets are assigned to one of six classes of depreciable property or to one of two classes of real property. The ACRS classes are tabulated in Table 3.3. Costs in the more short-lived classes (e.g., 3-, 5-, and 10-year classes) are recovered using double-declining-balance depreciation. It is permissible to optimize deductions by switching to straight-line depreciation when this becomes advantageous. The 15- and 20-year classes recover using the 150% declining-balance method, switching to the straight line when the depreciation based on the straight-line method (for the remaining years of depreciable life) is greater than the declining-balance amount. All real estate is depreciated by the straight-line method.

The new law does not provide statutory cost recovery allowances; therefore, averaging conventions are used. Generally, a half-year convention applies for the first-year and last-year allowances for depreciable property, and the midmonth convention applies to real property. A special rule provides that when more than 40% of asset additions in any year are placed into service in the last quarter of the taxable year, a midquarter convention is used to compute the allowances for all additions during the year. Under prior ACRS rules, a half-year convention was built into the statutory allowance for the first year of service, but the cost of three-year property, for example, still was "recovered in three years. Under the new statute, the half-year convention for personal property effectively adds another year to the cost recovery period because for the same three-year asset the half-year convention applies to the first year; a full allowance applies to years 2 and 3, and the remainder is recovered in the fourth year. Thus, the deductions are spread over four years although the recovery period is considered to be three years.

E6. Alternate Cost Recovery System

The 1981 statute provided a variety of alternate cost recovery options. By contrast, the 1986 statute unifies into one alternative cost recovery system several variations of ACRS enacted for various purposes. The alternative system provides longer lives for assets (i.e., slower rates of depreciation) and utilizes straight-line depreciation. The alternative system life is its ADR midpoint life. For real property, the ADR midpoint life is 40 years. If there is no ADR midpoint for personal property, a 12-year life is assigned.

There also have been changes in ACRS class for particular assets. Under prior law, cars and light trucks were 3-year property. Now they are classified as 5-year property, as listed in Table 3.3. Similarly, most equipment that was not a public utility property was in the 5-year class. Now many types of equipment are classified as 7- or 10-year equipment.

Notwithstanding these general rules, there are several assets for which there are special rules. These are listed in Table 3.4.

Taxpayers may elect the alternative system of determining the applicable depreciation allowance, or they may elect to use the straight-line method over the ACRS life. Either election is made on a class-by-class basis and, once made, is irrevocable. For example, for property put into service in a given year, a taxpayer may choose the regular system for the three- and five-year property, while choosing the alternative system for the seven-year property put into service that year. Property put into service the subsequent year is subject to a new election (on a class-by-class basis).

TABLE 3.4. Special Alternative ACRS Lives

Type of Property	Alternative Class Life (years)
Semiconductor property	5
Telephone central switching equipment	9.5
Railroad track	10
Single-purpose agricultural structures	15
Municipal wastewater treatment plant	24
Telephone distribution plant and equipment	24
Municipal sewers	50

The 1986 act repeals the ITC. Assets placed into service after December 31, 1985, are not eligible for ITC. A transition rule is provided to permit credit for assets for which binding contracts existed on this date. The transition rule requires that the asset must be placed into service by a specific date based on the property's depreciation recovery class. The ITC carryovers that had not expired as of December 31, 1985, are preserved and may be used in 1986 (and thereafter); however, they are reduced by 35%.

For detailed information, readers are referred to the act itself or to explanatory treatises [2].

F. GENERALIZED EQUATIONS

Generalized equations that simplify the solution of a large percentage of engineering economy problems have been set up. These equations take into account the influence of taxes, depreciation, operating expenses, and salvage value in the calculation of present worth and annual cost. Using these equations, an individual problem can be solved merely by entering data into the equations with the assistance of the compound interest tables and solving for the unknown value. The tax rate, t, is expressed as a decimal. Operating expense is represented by X. The letter S represents salvage value.

For straight-line depreciation

$$(\mathrm{PW}) = -P + \frac{t(\mathrm{P}-\mathrm{S})}{n}(\mathrm{P/A},\ i\%, n) - (1-t)(X)(\mathrm{P/A},\ i\%, n) + \mathrm{S}(\mathrm{P/F},\ i\%, n) \quad (3.7)$$

In this expression for the present worth, the first term, P, is the cost at "time zero" of the initial investment. The value at time zero is a definition of PW (at time zero). Hence, it is not necessary to translate this amount to another date because evaluation is made at time zero. Because the investment involves flow of money out of the bank, the sign of this term is minus.

The second term is concerned with depreciation. The depreciation method influences the mathematical formulation of this term. The annual amount of tax credit permitted by this method of depreciation, in this case, straight-line depreciation, is expressed by $[t(\mathrm{P}-\mathrm{S})/n]$. These equal annual amounts are translated back to zero time by converting them to present worth using (P/A, i%, n). The ACRS depreciation methods allow specific straight-line depreciation options. When one of these options is chosen, the formulation of this term remains the same as shown above with the exception that salvage is ignored. If the straight-line option is not chosen, this term in the generalized equation becomes a series of terms each having the tax rate multiplied by the appropriate depreciation percentage of the initial cost multiplied by the appropriate single-payment present worth factor (P/F) for the applicable year and interest rate. The sum of these terms represents the effect of depreciation on PW.

The third term in the general equation actually consists of two terms. One is $[(X)(\mathrm{P/A}, i\%, n)]$, and it represents the cost of items properly chargeable as expense. Examples include such things as cost of maintenance or insurance, cost of inhibitors, and so on. Because this term involves expenditure of money from the bank, it carries a minus sign. The term $[t(X)(\mathrm{P/A}, i\%, n)]$ accounts for the tax credit for this business expense. Because it represents a saving, the sign is plus.

The fourth term translates the anticipated (future) value of salvage to present value. This is a one-time event rather than a uniform series; therefore, it involves the single-payment present-worth factor. As noted above, the ACRS depreciation method ignores the salvage value of an asset, so when using the ACRS method, the fourth term is zero.

Present worth can be converted to equivalent annual cost by use of the following equation:

$$\mathrm{A} = (\mathrm{PW})(\mathrm{A/P},\ i\%, n) \quad (3.8)$$

Alternative materials having the same life can be compared from an engineering economy standpoint merely by comparing the magnitude of their present values. However, if the candidate materials have different life expectancies, it is necessary to convert present worth to equivalent annual cost, A, to compare the materials from an engineering economy standpoint. The material with the lowest annual cost is the material of choice.

G. WORKED EXAMPLES AND APPLICATIONS

Example 3.1. Process Equipment. A new heat exchanger is required in conjunction with rearrangement of existing facilities. Because of corrosion, the expected life of a carbon steel exchanger is 5 years. The installed cost is \$9500. It is proposed to substitute a Unified Numbering System (UNS) S31600 [American Iron and Steel Institute (AISI) 316 stainless steel] exchanger having an installed cost of \$26,500, and an estimated life of 15 years, written off in 11 years. Which is the more economical choice based on annual cost? The minimum acceptable rate of return is 10%, the tax rate is 48%, and the depreciation method is straight line.

Because the lives of the alternatives are unequal, the economic choice cannot be based merely on the discounted cash flow over a single life of each alternative. Instead, comparison is made on the basis of equivalent uniform annual costs, commonly referred to as "annual cost," as mentioned above. Referring to the generalized equation (3.7), data in this example are available for only the first two terms of the equation. The third term, which involves

maintenance expense, and the fourth term, involving salvage value, are both assumed to be zero.

The first step is to compute the discounted cash flow over one life span for each alternative. This involves the calculation of the PW for each material:

$$(\mathrm{PW})_{\mathrm{steel}} = -\$9500 + \frac{0.48(9500-0)}{5}(3.791) = -\$6043 \tag{3.9}$$

$$(\mathrm{Pw})_{316} = -\$26,500 + \frac{0.48(26,500-0)}{11} \tag{3.10}$$

To compare the two alternatives, the discounted cash flows (PWs) each are converted to annual costs:

$$\mathrm{A}_{\mathrm{steel}} = -\$6043(0.2638) = -\$1594 \tag{3.11}$$

$$\mathrm{A}_{316} = -\$18,989(0.1540) = -\$2924 \tag{3.12}$$

Therefore, the carbon steel heat exchanger, which has the lower annual cost, is the more economical alternative under these conditions.

Example 3.1a. Process Equipment. If the carbon steel exchanger were to require \$3000 yearly maintenance (e.g., painting, use of inhibitors, and cathodic protection), would carbon steel still be the preferred alternative?

Maintenance costs are treated as expense items with one-year life (end-of-year costs). This particular exercise involves the third term in the generalized equation shown above. In Example 3.1, the annual cost without the yearly maintenance cost has already been computed, so in this case the annual cost including maintenance (stated to be \$3000 per year) is obtained simply by subtracting the after-tax maintenance costs from the result given in Example 3.1:

$$\mathrm{A}_{\mathrm{steel}} = -\$1594 - (1-0.48)(\$3000) = -\$3154 \tag{3.13}$$

Because this is an after-tax cash flow, the quantity (1 – 0.48) (\$3000) is the after-tax maintenance cost where 0.48 equals the tax rate expressed as a decimal. The \$3000 is the present value of the first year's maintenance, so no further discounting is necessary in this case.

By comparing this result with the annual cost of UNS S31600 in Example 3.1, it is evident that if \$3000 is required each year to keep the carbon steel unit operative, the UNS S31600 unit would be more economical.

Example 3.1b. Process Equipment. Under the conditions described in Example 3.1, if it is not certain that a five-year life will be attained for unprotected carbon steel, at what life (for carbon steel) is it economically equivalent to the UNS S31600 heat exchanger?

The carbon steel heat exchanger will be economically equivalent to the UNS S31600 heat exchanger when their annual costs are equal. Therefore, the problem can be solved by determining how many years of life for steel is equivalent to an annual cost of \$2924. Trial-and-error methods are useful for such problems.

Trying $n = 3$ years

$$(\mathrm{PW})_{\mathrm{steel}} = -\$9500 + 0.48\,\frac{9500-0}{3}(2487) = -\$5719 \tag{3.14}$$

$$\mathrm{A}_{\mathrm{steel}} = -\$5719(0.40211) = -\$2300 \tag{3.15}$$

Trying $n = 2$ years

$$(\mathrm{PW})_{\mathrm{steel}} = -\$9500 + 0.48\,\frac{9500-0}{2}(1.736) = -\$5542 \tag{3.16}$$

$$\mathrm{A}_{\mathrm{steel}} = -\$5542(0.57619) = -\$3319 \tag{3.17}$$

Thus, a carbon steel heat exchanger must last more than two years but is economically favored in less than three years under the conditions given.

Example 3.1c. Process Equipment. Under the described conditions, how much product loss, X, could be tolerated after two of the five years of anticipated life (e.g., from roll leaks or a few tube failures) before the selection of UNS S31600 is justified?

Equating

$$\mathrm{A}_{316} = \mathrm{A}_{\mathrm{steel}} + \mathrm{A}_{\mathrm{product\ loss}} \tag{3.18}$$

$$-2924 = -1594 + [(1-0.48)(X)(0.8264)][0.2638] \tag{3.19}$$

Solving for X

$$-1430 = 0.1134(X) \tag{3.20}$$

$$X = -\$12,610 \tag{3.21}$$

The term 1–0.48 is recognized from term 3 of the general equation (3.7) as $1 - t$, wherein t is the tax rate. The quantity 0.8264 is the single-payment PW factor (P/F, 10%, 2 years) and translates the product loss, X, to its present worth at time zero. The quantity 0.2638 is the uniform series capital recovery factor (A/P, 10%, 5 years) and translates the present worth of the product loss to annual cost so that it can be added to the annual cost of steel for comparison with the annual cost of UNS S31600. If production losses exceed \$12,610 in year 2 (no losses in other years), the UNS S31600 heat exchanger is justified.

Example 3.2. Cathodic Protection. It is proposed to cathodically protect an underground pipeline installation, assuming the following: $i = 10\%$, $t = 34\%$, straight-line depreciation. Three proposals have been made:

1. Anodes, 4250 at \$100,000, installed. Useful life, 10 years.
2. Thirty (30) rectifiers with groundbeds at \$100,000, installed. Expected life, 20 years with annual maintenance cost of \$5900.
3. A "mixed" system involving rectifiers (\$18,000 installed plus \$1200/year maintenance for 20-year life) plus anodes (\$82,000 installed for 10-year life).

For proposal 1,

$$(\mathrm{PW})_1 = -100{,}000 + (0.34)\frac{100{,}000 - 0}{10}(6.1446) = -\$79{,}108 \tag{3.22}$$

$$\mathrm{A}_1 = -79{,}108(0.1628) = -\$12{,}879 \tag{3.23}$$

For proposal 2,

$$(\mathrm{PW})_2 = -100{,}000 + (0.34)\frac{100{,}000 - 0}{20}(8.5136) - (1 - 0.34)(5900)(8.5136) = -118{,}679 \tag{3.24}$$

$$\mathrm{A}_2 = -118{,}679(0.1175) = -\$13{,}945 \tag{3.25}$$

For proposal 3, for the anode portion,

$$(\mathrm{PW})_3 = -82{,}000 + (0.34)\frac{82{,}000 - 0}{10}(6.1446) = -\$64{,}869 \tag{3.26}$$

$$\mathrm{A}_3 = -118{,}679(0.1628) = -\$10{,}561 \tag{3.27}$$

For the rectifier-driven portion,

$$(\mathrm{PW})_3 = -18{,}000 + (0.34)\frac{18{,}000 - 0}{20}(8.5136) - (1 - 0.34)(1200)(8.5136) = -\$22{,}138 \tag{3.28}$$

$$\mathrm{A}_3 = -22{,}138(0.1175) = -\$2601 \tag{3.29}$$

$$\mathrm{A_T} = \mathrm{A}_3(\text{anodes}) + \mathrm{A}_3(\text{rectifiers}) = -10{,}561 - 2610 = -\$13{,}162 \tag{3.30}$$

Under these particular conditions, proposal 1 is calculated to be the least expensive alternative on the basis of lowest annual cost, followed by proposal 3.

A. BACKGROUND

Predicting the performance of materials in operating environments can be approached by an orderly stepwise procedure; this procedure is described in this chapter and examples are given. Before describing this procedure, it should be understood that all engineering materials are reactive chemicals. As table salt dissolves in water, so any engineering material can dissolve rapidly and completely in some environments. In view of this inherent reactivity, the surprise is not that materials fail; the surprise is that they work.

For metals in aqueous solutions, the barrier that prevents inherently reactive materials from dissolving is a thin insoluble compound on the surface between the reactive metal and the chemical environment. Such a barrier or film is called a "passivating film" because it passivates the inherent reactivity and because the term "film" implies thinness and fragility. Thus, predicting and assuring reliable performance need to be undertaken with great care and with full understanding of both the inherent reactivity of metals and the fragility of the thin barriers that provide protection. Similar patterns of reactivity and self-protection apply to all solids. Figure 4.1 shows the relative thinness of protective films on iron alloys in neutral aqueous solutions.

Much of this discussion is oriented toward large systems since these are the most complex, and it is often thought that predicting their corrosion-affected lifetimes either is not possible or must necessarily be guessed. This is not true, and a straightforward approach to predicting the corrosion behavior of complex systems is described in this chapter. Simpler systems can be approached using the same methods, but shortened.

In this chapter, while predicting performance is the nominal topic, "assuring performance" is implicit within the same framework. In this discussion, "predicting" carries with it the responsibility of "assuring." For simplicity in this chapter "predicting" is used, but it should be understood that "assuring" is implied.

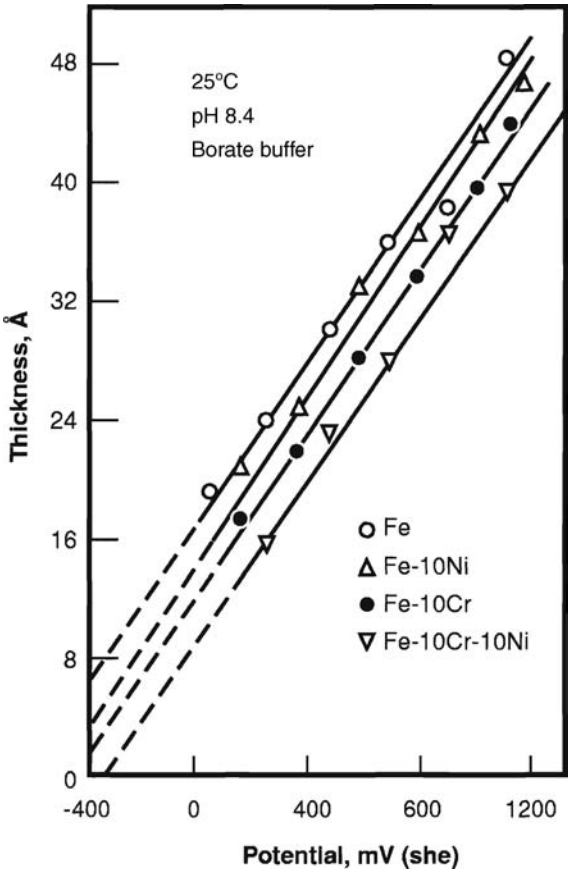

FIGURE 4.1. Film thickness versus electrochemical potential for Fe, Fe–10 Ni, Fe–10 Cr, and Fe–10 Ni–10 Cr alloys after 1 h of polarization at 25°C measured in pH 8.4 in borate buffer solution. (After Goswami and Staehle [9].)

The approach of this chapter follows the corrosion-based design approach (CBDA) [1, 2]. This is based on the idea that the subject of corrosion is a design science; the specific study and subject of corrosion would not be important except as it relates to assuring the reliable performance of equipment. The CBDA is not directly related to designing components for their functions; it is the purpose of the CBDA to assure that components work reliably in their intended applications and for their intended lives.

This chapter should be as useful to designers as to specialists in corrosion. This chapter is organized mainly around the design process and associated decision making. Lists and charts are included for identifying issues that need to be dealt with and for measuring progress toward achieving goals. This chapter also recognizes that much of design is a feedback process. As new information is acquired, it can be introduced into the design and operations.

While predicting performance and assuring reliability, as discussed here, follow an underlying theme that is related to degradation of materials, dealing with predicting the performance of large systems is not included here. Such a broader subject embraces prediction and assurance procedures such as HAZOP (hazard and operability) and HAZAN (hazard analysis). The former is concerned with "what if" kinds of questions that are traditionally more related to system design and arrangement of components; the latter is concerned with mathematical analyses and is often called probabilistic risk assessment (PRA) or quantitative risk assessment (QRA). These approaches and similar ones are dealt with comprehensively in a series of texts published by the American Institute of Chemical Engineers (AIChE) and others, including Kletz [3–8].

It is not the province of this chapter to consider whether pipes in a complex chemicals plant are connected properly or whether a given check valve is inserted in the wrong direction; such subjects are the province of other methodologies such as HAZOP. Operator error is not a part of the present discussion except as it may relate to factors that affect degradation. On the other hand, many failures that lead to the shutdowns of plants result from degradation that is not traditionally included (but should be) in such methodologies as HAZOP and HAZAN.

The degradation of materials generally occurs via three well-known avenues: corrosion, fracture, and wear. Corrosion is traditionally related to chemical processes that break chemical bonds; fracture is related to mechanical processes that break bonds; and wear is related to relative motion that breaks bonds. These are, to some extent, separate considerations, but they are also interconnected. Chemical environments accelerate fracture; chemical environments accelerate wear and vice versa as wear products produce deposits that accelerate corrosion; and fracture processes can permit one component to contaminate another. It is not possible in this chapter to deal with the three traditional subjects of degradation or with their interactions except for stress corrosion cracking (SCC) and corrosion fatigue (CF), both of which are traditionally considered to be part of corrosion. The subject generally understood as corrosion is the focal point of this chapter. However, the procedures developed herein are generally applicable to the three general modes of degradation.

There are some nomenclature problems here. "Corrosion" is often considered to be what happens to metals, whereas the subject of "durability" is often considered to embrace the chemical degradation of concrete. Degradation of polymers is often considered as "bond breaking." No effort is made here to deal broadly with the degradation of all types of materials and with their respective historical terminology. However, the chemical-, mechanical-, and wear-type degradations occur in all solids, and the treatment of all of these can be readily embraced in the framework of this chapter. However, most of the examples here are based on the behavior of metallic materials in aqueous solutions, and many of the examples are taken from the nuclear industry.

Regardless of whether corrosion, fracture, or wear is considered individually or as their interactions (i.e., corrosion-accelerated wear) the generic subject covered here is "degradation." However, the term "corrosion" is more general, as it is derived from the Latin word that means "to gnaw," and this term is used.

This chapter takes a bottom up approach. Here, predictions start with individual materials in individual components as these materials sustain different environments on their surfaces. Such an approach is characteristic of corrosion problems; they must be dealt with specifically at the interfaces between materials and environments. In contrast, other approaches to reliability (e.g., HAZOP) ask the questions about the performance of components as they interact to produce a reliable system. Unfortunately, many of these approaches ignore questions of the chemical and mechanical stability of materials, and the conclusions of these exercises are often incomplete since the degradation of materials was not considered.

Predicting the performance of materials in components usually involves more than one possible mode of failure in more than one location. Figure 4.2 illustrates different submodes* [9] of corrosion that have occurred at different locations on an example U-tube in a recirculating steam generator of a pressurized water nuclear power system. Here, at seven different locations, eight modes and submodes of corrosion have occurred. For a prediction of performance in the application typified in the case of Figure 4.2, the seven different locations have to be identified explicitly together with the possible modes and submodes which can occur at each of the locations. A complete consideration of possible failures in the case of Figure 4.2 would require a matrix of 56 different possible interactions; approaching such apparent complexity is dealt with in this chapter. Each combination of locations and modes which is analyzed for corrosion in this chapter is called a "mode–location" case.

Generally, in predicting corrosion performance, the best guidance is obtained from applicable and prior engineering experience. Such experience provides bases for determining what mode–location cases should be considered and where additional research is necessary. Engineering experience may also be misleading in the sense of providing unwarranted confidence; small changes of environments in new applications often produce enormous differences in corrosive conditions, especially where concentration processes occur. Also, the experience obtained from several units operating for relatively short times is often mistakenly used to assure long-time experience. In developing predictions, the CBDA method includes both engineering experience and potentially important effects that may not have been obvious in previous applications.

Predicting the performance of materials as a part of a larger system of components is not accomplished with a single model for a single process. Predicting performance is more generally a "bookkeeping" problem as described here. Predicting performance requires, above all, both accounting for numerous possible circumstances that can produce failure and developing explicit responses. Some of these responses that describe specific mode–location cases can be intensely mathematical but as parts of this larger framework. The bookkeeping approach described here requires that explicit decisions be made either to include or to neglect considerations of certain possible failure conditions. Such decisions can become part of the design assumptions and part of the written record of the design.

The approach taken here considers "design" to embrace the full set of factors that affect reliable performance. Thus, considerations of corrosion, as they affect reliability, are as important as the product meeting its initial commitments to functions. Design, then, should include the elements of the CBDA.

The CBDA is based on the premise that materials have properties that depend on their environments. For example, the strength of a stainless steel listed in a reputable handbook may be useless in the presence of chloride ions since the useful strength is no longer the handbook strength but rather is the threshold stress for the occurrence of stress corrosion cracking, SCC†; this threshold strength may be 10% of the yield stress. The same is true for nominally high strength materials; in the presence of small defects, the actual strength of these materials decreases with increasing strength when exposed to many common environments. This modified strength is called "situation-dependent strength" and has been described in detail [11].

Predicting performance should also be considered in the context of the "cause" and "mode" of failure. The cause of failure is what has to be fixed and is generally in the realm of institutional and economic decisions. The mode of failure refers to the process by which failure occurs. For example, SCC occurs via the mode of a chloride- and oxygen-containing aqueous environment being exposed to austenitic stainless steel. How this process occurred, the sources of chloride, oxygen, temperature, and stress relate to the mode. The cause of this failure may be related to the choice of stainless steel for reasons of false economics, lack of instrumentation (or maloperation or lack of redundancy) to detect the conductivity that results from chloride leaking from a condenser, or lack of training of operators. The emphasis in the present

*The concept of "modes" and "submodes" is explained in Section E. The mode is a generic term (e.g., SCC), and submodes of SCC have, respectively, different dependencies.

† The abbreviation SCC is used throughout for "stress corrosion cracking." Also, the abbreviation. IGC and CF are used, respectively, for "intergranular corrosion" and "corrosion fatigue." The terms IGSCC and TGSCC refer similarly to "intergranular SCC" and "transgranular SCC."

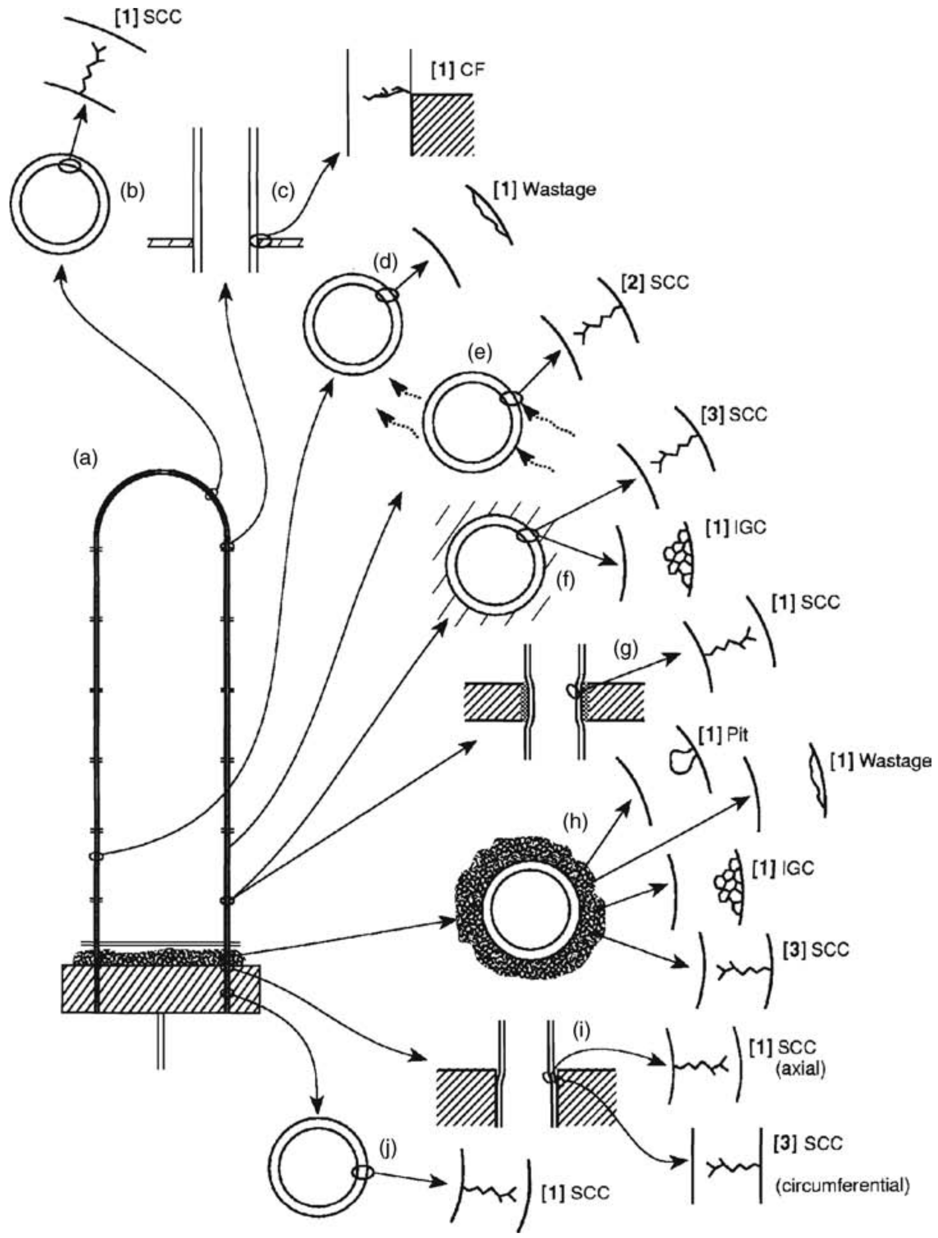

FIGURE 4.2. Schematic relationship of location to possible mode–location cases of corrosion for a U-tube steam generator used in pressurized water nuclear reactor systems. Tube sheet shown at bottom. Full-width tube support shown above tube sheet; other periodic locations of tube sheets noted. (a) Single tube of U-tube in steam generator of pressurized water reactor (PWR) systems. (Numbers in brackets indicate similar submodes although they may occur at different stresses or temperatures. Curved vignettes indicate that the view is perpendicular to the axis of the tube; straight vignettes indicate that the view is parallel to the axis of the tube.) (b) High stress from bending and forming in U bend produces axial SCC, **[1]**, from primary side. (c) Immediately above the tube support with circumferential corrosion fatigue, **[1]**, from secondary side. (d) Free span from secondary side with, **[1]**, wastage on cold leg. (e) Free span from secondary side with axial SCC on hot leg side, **[1]**. (f) Tube at tube support with axial SCC, **[3]**, and IGC, **[2]**. (g) Denting at intersection of tube support and tube gives stresses in tube which produce axial SCC, **[1]**, from the primary side. (h) Tube inside sludge pile above the tube sheet with corrosion on secondary side: pitting **[1]**; wastage, **[2]**; IGC, **[1]**; axial SCC, **[1]**. (i) Roll transition with circumferential SCC, **[3]**, on secondary side and axial SCC, **[1]**, on the primary side. (j) Expanded tube in tube sheet with axial SCC, **[1]**, from primary side. (After Staehle [10].)

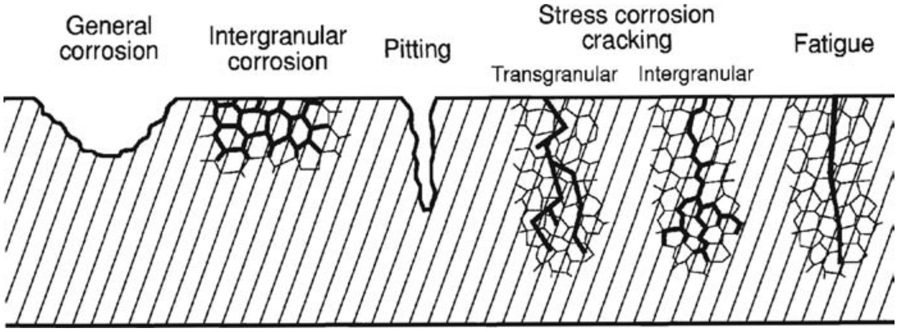

FIGURE 4.3. Schematic views of five intrinsic modes of corrosion penetration: general (including wear, erosion, and fretting), intergranular, pitting, SCC, and fatigue cracking.

approach to prediction is upon using a format that requires explicit considerations of all the possible modes by which failure can occur. Avoiding serious consideration of a mode–location case for reasons of economics or haste is a "cause" of failure.

There is an approach to analyze failures used in some industries called "root-cause" analysis. This is a misnomer since these exercises usually deal with mode and not cause. Furthermore, these exercises almost never get to a root of anything. In many cases, identifying real cause would embarrass the responsible organization.

The comprehensive approach to predicting and assuring lifetime used here is based on the CBDA. This CBDA is implemented according to the following steps*:

[**1**] *Environmental Definition*. Defining the environment involves specifying the conditions in which a material is required to perform reliably. The most broadly acknowledged "environments" are usually chemical, but environment should be considered more broadly to include, for example, thermal conditions and conditions of stressing as described in Sections C3 and C4.

[**2**] *Material Definition*. Defining a material involves more than specifying, for example, a stainless steel of some well-known composition and properties; the reactivity of even well-known materials is affected by seemingly subtle processes such as the preferential concentration of impurities at grain boundaries. Defining a material means to define it with respect to its reactivity as such reactivity may be exacerbated, for example, by the composition of grain boundaries, second phases, cold work, or particular combinations of impurities.

[**3**] *Mode Definition*. Defining the mode of corrosion means to define the morphology of the degradation, or the avenues followed by the degradation and their dependence on the "principal variables" (for metals in aqueous environments the principal variables are potential, pH, species, temperature, stress, alloy composition, and alloy structure). When there is more than one occurrence of a mode, and the dependencies of such occurrences (e.g., alkaline and acidic SCC) on the principal variables are different such different occurrences are called "submodes." Figure 4.3 shows schematically the morphologies of the intrinsic† modes of degradation.

[**4**] *Superposition*. Superposition involves comparing, for a specific material, the various possible modes of degradation and their dependencies with the prevailing environments identified in the "environmental definition." If the modes of degradation can occur within these environments for a defined material, then further work may be required to analyze performance, or the conditions of the overlap should be avoided and the design should be changed. At this point, it is common to add inhibitors to the environment or change the material, change the operating conditions (e.g., lower the temperature), lower the mean stress, minimize residual stress, change aspects of the design, eliminate crevices, or eliminate stress intensifications.

[**5**] *Failure Definition*. Defining failure means to define the objectives of the prediction. Failure implies quite different outcomes in different industries as well as within even a single component, depending on requirements for reliable performance and/or safety. Failure in the food or the architecture industries may involve the appearance of rust on steel parts, although

* In this text, boldface numbers in brackets are used to indicate an action or an event that requires checking or action as opposed to a numerical list of aspects or features.

† The term "intrinsic" refers to modes thai are sustained by the material regardless of the geometric features of die environment. For example, "crevice corrosion" is not a mode of corrosion but rather is general corrosion that occurs inside a crevice just as the same general corrosion could occur outside the crevice. Similarly, "microbiological corrosion" is not a mode of corrosion but an environment that can produce any of the intrinsic modes.

there is little loss of material; in other industries, while a crack may exist and may be propagating, it is not considered a failure until it approaches some fraction of K_{I_c}.* Failure may involve the perforation of a single tube in a heat exchanger consisting of several thousands of tubes; on the other hand, failure may not be defined until some larger fraction, say 10%, of the tubes are failed and plugged. (Although individual tubes would have been plugged at early outages.) Furthermore, failure or approaching the possibility of failure implies certain responses and actions; developing or defining such action levels is also a part of defining failure.

[6] *Developing a Statistical Framework.* All degradation phenomena are inherently statistical, even under ideal conditions, owing to the multiple pathways by which a single corrosion mode can proceed. Furthermore, even when the same nominal materials are used (but with different vendors and different times of manufacturing), subtle and not so subtle differences occur among them (e.g., heat-to-heat variations). Finally, the properties of environments vary even, again, under ideal conditions. Thus, to account for these intrinsic and extrinsic variabilities, it is necessary to treat the properties of materials and environments in a statistical framework. It should be recognized that failure does not usually occur when the mean or median of failure is reached (e.g., failure of half the tubes in a condenser); by this point the equipment is generally decimated. Rather, failure occurs when possibly 0.01 or 0.1% of subcomponents (e.g., tubes, welds, and area) fail. Thus, it is usually necessary to predict the very earliest failures; such predictions are necessarily based on statistical methods.

[7] *Accelerated Testing.* Since most equipment is intended to perform for many years, whereas the tune available for prior testing is short, some accelerated testing may be necessary. Accelerated tests are invoked for obtaining quantitative predictions or at least some indication of the capacity of materials to endure extended circumstances. Results from such testing provide credibility to predictions. Acceleration is achieved through the use of various "stressors" (higher temperatures, higher stress, lower pH, higher chloride concentration, and cold work of the material) that can be used to intensify the exposure; using several different stressors helps to confirm that correlations being used are credible. The essential requirement of accelerated testing is that the acceleration produce the same mode of failure that is expected under the nonaccelerated nominal and longer term conditions.

* See Section C5 for a discussion of K_{I_c}.

[8] *Prediction.* In predicting performance, the foregoing seven steps are integrated to determine when failure can occur and how such failures would relate to the criteria for failure.

[9] *Monitoring, Inspection, and Feedback.* Perfect predictions could require generally large efforts and possibly prohibitively long times; further, some eventualities cannot be readily predicted. Most engineering systems can be monitored and inspected, and the data can be "fed back" to designers and operators. This feedback process is implicit in prediction although there are some engineering circumstances (storage of radioactive waste) where feedback from inspection and monitoring is not practical over the life of the project.

[10] *Modification in Design, Materials, Manufacturing, Operation, Monitoring, and Inspection.* Data taken from operation, including failures, can be compared with predictions and design life objectives to determine what changes need to be made in the design, materials, manufacturing, operation, monitoring, and inspection.

This chapter describes the implications and implementation of these 10 steps of the CBDA. Certain of these steps (e.g., environmental definition) is emphasized in proportion to their importance to reliable performance.

B. SCOPE OF PREDICTION

B1. Chronological Stage

It is often assumed that prediction applies mainly to steady-state operation of equipment Actually, failure can occur at any time in the life of a component starting from the earliest stages of manufacturing. The stages at which degradation can occur, and therefore needs to be considered, are identified in Figure 4.4; examples of failures at these various stages are well known. The stages in Figure 4.4 apply to complex equipment. Less complex equipment and products may involve fewer stages, but analyzing the successive stages, as in Figure 4.4, is still incumbent upon designers.

B2. Hierarchical Levels

Often, a single failure in a component causes an entire system to be shut down. On the other hand, the failure in this single component may result from ingesting chemicals produced in another part (although connected) of the system. Furthermore, any system contains many subsystems, components, and materials all of which are vulnerable to failure one way or another. Thus, in general, predicting failure means considering a larger system than a single component and a single material. While such a comprehensive approach may not

Stages for Analysis (Chronological)

Before Startup	After Startup
[1]. Manufacture	[8]. Startup
[2]. Testing (e.g., hydrotest)	[9]. Steady State Operation
[3]. Storage at Manufacture	[10]. Shutdown (planned and forced)
[4]. Shipping	[11]. Maintenance During Shutdown
[5]. Site Storage	[12]. Cleaning During Shutdown
[6]. Installation	[13]. Inspection During Shutdown
[7]. Prestart Testing	[14]. Startup During Shutdown
	[15]. Long Time Operation

FIGURE 4.4. Schematic illustration of the 15 stages in the chronology of equipment. Stages separated in two categories according to whether they relate to conditions before startup or after. At each of these stages the possibility of aggressive degradation has to be considered.

always be necessary, it needs to be considered, and the relevant parts of connected systems need to be identified. Such an integrated consideration involves eight hierarchical levels:

[1] *Stage [SG_j].* * The chronological or sequential stages which need to be considered are enumerated in Figure 4.4. Analysis needs to be carried out at each of the chronological stages with the extent appropriate to the stage. Failures caused at early stages in the chronology of Figure 4.4 are sometimes helpful in refining the manufacturing process or in reacting to fullscale testing. More important is the possible initiation of failure that develops during the early stages and that produces eventual failures during steady-state operations (e.g., improper processing, machining lubricants that contain MoS_2, or cleaning operations that contain HF where subsequent rinsing has been inadequate).

[2] *Site [ST_j].* An overall site may include several systems. A power station contains the transmission equipment, electrical transformers, power plant, fuel handling, and others.

[3] *System [SY_j].* A single system may have a higher priority for analysis. This is often the power plant in a power station. The overall analysis of a system is usually the province of HAZOP- and HAZAN-type analyses.

[4] *Subsystem [SS_j].* Within a power plant there are numerous subsystems. These would include, with their connected parts, turbine, primary water system, secondary cooling water system, and tertiary cooling system.

[5] *Component [CM_j].* Within a subsystem [SS_j] there are numerous components. For example, a secondary system of a pressurized water nuclear power plant includes a steam generator, condenser, feedwater heaters, and turbine.

[6] *Subcomponent [SC_j].* In a particular component there are subcomponents. For example, in a nuclear steam generator there are tubes, vessel walls, steam separators, baffles, tube supports, and tubesheets.

[7] *Locations for Analysis [LA_i].* At the LA_i the analysis begins. An LA_i is a location where failure is likely and should receive careful considerations. Such locations are usually identified by some combination of corrosion-prone materials, locally high stresses, stress intensifications, high heat transfer rates, high flows, and/or the occurrences of crevices and deposits. At an LA_i it is possible to be specific and consider the surface of a material with respect to predicting its performance. However, as described in Section C.3, the possible failure at any LA_i may be influenced by factors such as corrosion products from other components within the proximate system or from other systems (copper from condensers, leaks through turbine seals, insoluble iron products from piping). Further, there may be multiple LA_i on a single component as noted in the example of Figure 4.2.

[8] *Modes and Submodes of Degradation [MD_j, SD_j].* The MD_j or SD_j are illustrated in Figure 4.3. The full set of MD_j, or SD_j need to be identified as they apply to each of the LA_i. At this point, the analysis begins and may include either approximate correlations or detailed

* In each of the hierarchical levels, the subscripts *i* and *j* arc used since there may be multiple elements. The subscript *j* is used when the elements have a horizontal character; *i* is used when the elements have a vertical character.

mathematical models as they are required to describe a given mode–location case.

B3. Mode–Location Approach: Explicit Considerations

The central activity of the CBDA involves identifying and analyzing specific combinations of locations and modes called "mode–location" cases. The details of how locations and modes are identified is discussed in Sections C and E. Figure 4.2 shows examples of 14 mode–location cases on a single subcomponent. The specific steps in implementing the mode–location approach follow:

[1] *Identify reference subcomponent for analysis.*

[2] *On the reference subcomponent, identify the LA_i.* At this step, it is necessary to recognize that there may be multiple LA_i on a single component, as shown in Figure 4.2. While they may vary depending on how failure is defined (see Section G) and with other considerations in the overall system, the LA_i are selected by identifying where failure, or aggressive conditions, are reasonably most likely. LA_i include locations, for example, where:

a. Chemical environments are the most aggressive, most concentrated, at the extremes of pH, include geometries that produce deposits, involve electrochemical cells, or have crevices.

b. Stresses are high due to combinations of applied and residual contributions, and stress intensifications are present.

c. Thermal conditions provide the highest stresses, highest surface temperatures, and highest heat fluxes.

d. Flows are highest, flows change direction, flows are stagnant, or flows are erosive.

e. Other aggressive conditions.

Identifying such locations, generally, is based upon the judgment of experienced engineers but needs to include considerations of disciplines familiar with special inputs such as stress analysis, fabrication, material properties, and corrosion. Initially, it may be useful to select more locations rather than fewer since predicting failure is the inverse of justice: guilty until proven innocent.

[3] *Identify the set of modes, MD_j, and submodes, SD_j, that may reasonably occur over the range of LA_i.* Disciplines that are knowledgeable in such modes should be involved.

[4] *Develop a matrix where the relevant LA_i and MD_j/SD_j can be related.* Such a matrix together with examples of LA_i and MD_j/SD_j is shown in Figure 4.5(a and b). Here, for the steam generator component that connects the primary (inside of tubes) with the secondary (outside of tubes) system, the significant locations for analysis are shown in Figure 4.5(a). For each of these locations, the possible modes and submodes of degradation are also shown in Figure 4.5(a). Figure 4.2 provides perspective for Figure 4.5.

In Figure 4.5(b), a table is shown where the locations for analysis, LA_i, are listed in the vertical column and possible modes, MD_j, and submodes, SD_j, are shown along the horizontal axis. Also, in the second and third columns, the locations on the inside (primary) and outside (secondary) of the tubes where the LA_i, are relevant are noted. The table in Figure 4.5(b) is the focal point of analysis in the CBDA.

[5] *Define specific actions that might be taken at each cell of Figure 4.5b.* Figure 4.6(a) shows the explicit actions that can be considered for each of these matrix elements defined by LA_i and MD_j/SM_j. For example, in the $j = 13$, $i = 2$ cell, no action is necessary because wear at this location is not reasonable; also fatigue in the sludge, $j = 12$, $i = 5$, can be rejected. On the other hand, wastage in the sludge pile, $j = 10$, $i = 5$, can occur and needs to be considered as a possible failure mode at that location.

Continuing to consider how the chart of Figure 4.5(b) might be used, after substituting a new alloy such as alloy 690 for the older alloy 600 in the steam generator shown in Figure 4.5, the mode of LPSCC, $j = 1$ can be omitted from consideration at all locations on the primary side, $i = 1, 3, 6, 10$; and pitting, $j = 11$, might be eliminated from the primary and in some instances from the secondary side. The justification for eliminating other cells is based on likely risks. Figure 4.6 shows how the mode–location chart might appear for two different alloys in Figure 4.6(b).

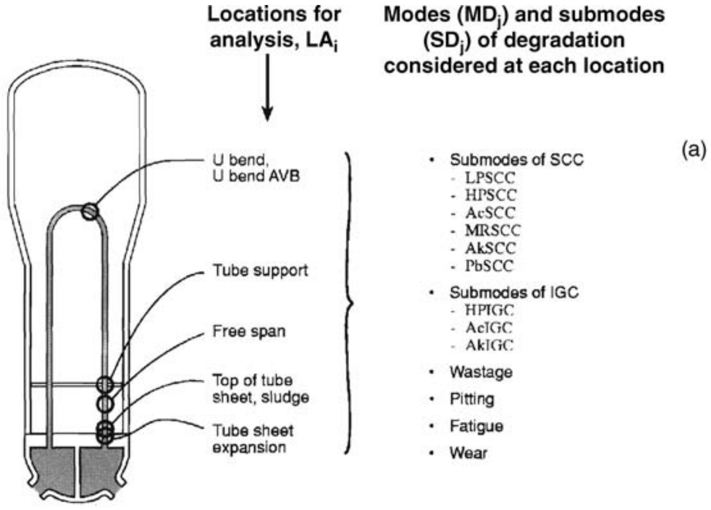
[6] *Develop quantitative models for each of the mode–location cells.* Many of the cells in Figure 4.5(b) can be modeled by well-known relationships. While there is always an academic interest in modeling phenomena such as those in the cells of Figure 4.5(b) using relationships developed from first principles, such relationships are rarely better or more general than good correlations. Further, the development of such fundamental models after requires more than the available time.

For most of the SCC submodes, the mean-value data might be modeled with a simple equation of a power law-exponential type as shown in Eq. (4.1):

$$x = A[\mathrm{H}^+]^n[\chi]^p\sigma^m e^{E - E_0/\beta} e^{Q/RT} t^q \qquad (4.1)$$

Pitting might be modeled as Eq. (4.2):

$$x = B[\mathrm{H}^+]^n[\chi]^p e^{E - E_0/\beta} e^{Q/RT} t^{1/3} \qquad (4.2)$$



(b)

Locations for Analysis, LA_i	Tube Side		Submodes of SCC						Submodes of IGC						
	ID	OD	LPSCC (j=1)	HPSCC (j=2)	AcSCC (j=3)	MRSCC (j=4)	AkSCC (j=5)	PbSCC (j=6)	HPIGC (j=7)	AcIGC (j=8)	AkIGC (j=9)	Wastage (j=10)	Pitting (j=11)	Fatigue (j=12)	Wear (j=13)

Modes (MD_j) and Submodes (SD_j) To Be Considered

FIGURE 4.5. Bases for mode–location analysis. (a) Schematic view of steam generator with different locations for analysis, LA_i, and possible modes, MD_i, and submodes SD_i noted for a single tube (out of several thousands), (b) Chart for aggregating mode–location cells as applied to a steam generator in a pressurized water nuclear power plant. The prefixes LP, HP, Ac, MR, Ak, and Pb for SCC and ICG refer to "low potential," "high potential," "acidic," "mid-range pH," "alkaline," or "lead" for "stress corrosion cracking" and "intergranular corrosion."

Linear processes such as wastage might be modeled as Eq. (4.3):

$$x = C[H^+]^n[\chi]^p e^{E - E_0/\beta} e^{-Q/RT} t \qquad (4.3)$$

where

A, B, C, n, p, m, β, q = constants unique to specific correlations
x = depth of penetration
H = hydrogen ion concentration
χ = concentration of relevant species (e.g., chloride)
σ = stress
E = electrochemical potential
E_0 = equilibrium or corrosion potential
Q = apparent activation energy
R = gas constant
T = absolute temperature
t = time

The constants in Eqs. (4.1)–(4.3) can be determined often from previous engineering experience or from laboratory experiments; these values might also be determined by extrapolations from accelerated tests as described in Section I. Depending on what constitutes failure (Section G), various statistical functions (Section F) can be inserted into these cells as described in Section H.

[7] *Develop statistical expressions.* Developing statistical expressions for describing failure data is described in Section H. However, how such expressions are developed depends on what constitutes failure.

For example, if a description of the mean behavior is acceptable for the application, equations like (4.1)–(4.3) are adequate. However, if an application fails when 0.01 or 0.1% of the elements fail, then a statistical interpretation is necessary for quantifying the cells in Figure 4.5(b), and this is discussed in Section **H**.

B4. Explicitness and Simplification

There may be practical limits to the extent of work that can be undertaken in responding to the cells in Figure 4.5(b). To some extent the process can be simplified since many of the modes follow the same general patterns as shown in Eqs. (4.1)–(4.3). Also, some of the cells can be neglected, as in Figure 4.6, as

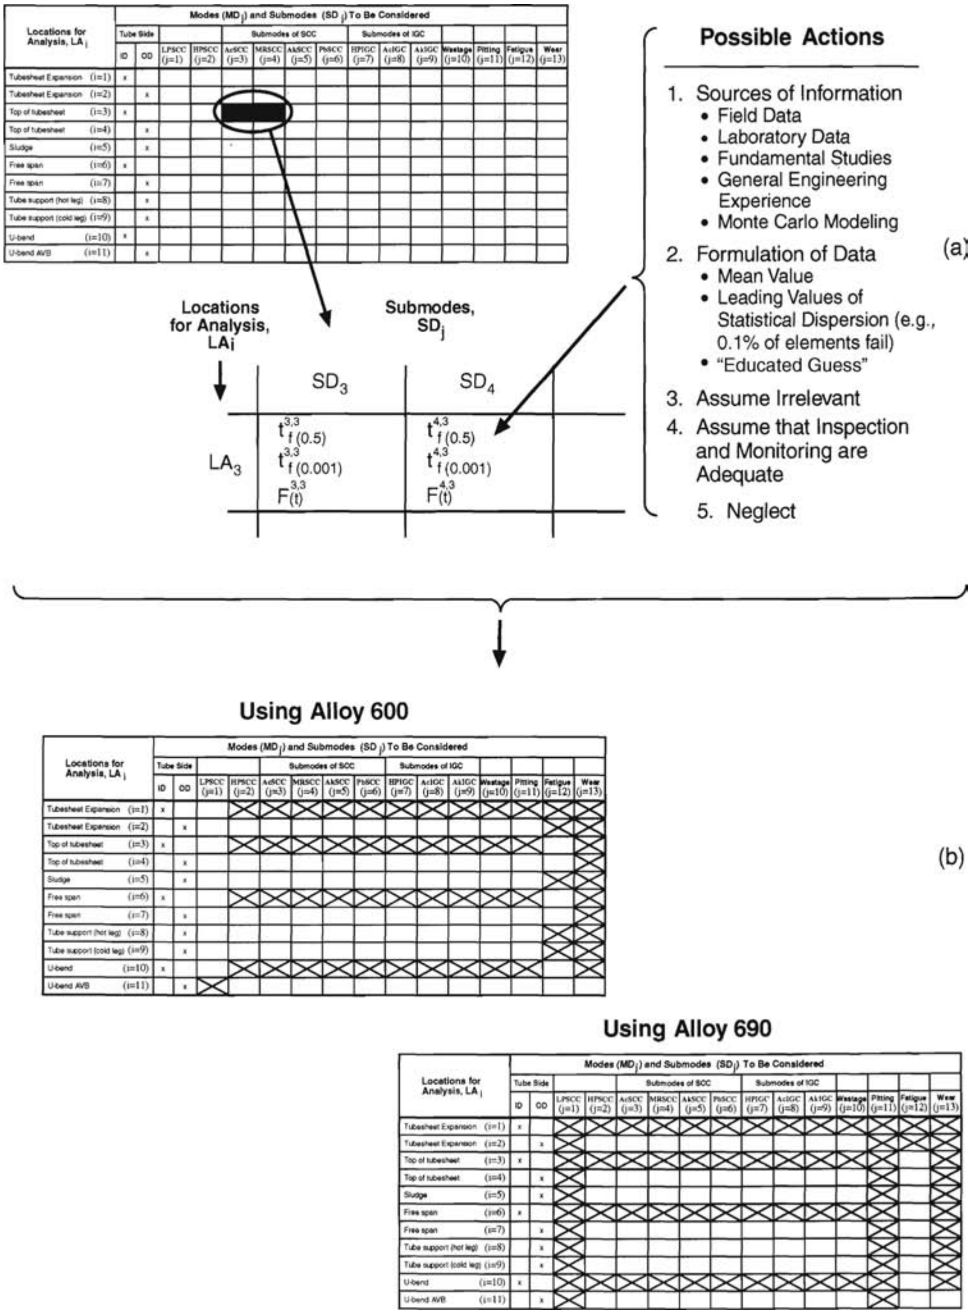

FIGURE 4.6. Possible actions and results for preparing mode–location charts. (a) Possible actions for each cell. The use of statistical results is discussed in Section H and Figure 4.30. Here the time to fail at a cumulative fraction failed of 0.001 is noted. Also, the cumulative expression $F(t)$ is inserted. (b) Examples of possible charts where two different alloys, alloy 600 (76 Ni–16 Cr–7 Fe) and alloy 690 (60 Ni–30 Cr–10 Fe), are applied to the pressurized water nuclear steam generator application shown in Figure 4.5. Where a cell can be neglected, it is noted as crossed out.

irrelevant to the specific application, that is, mechanical wear may not occur at the free span.

The mode–location matrix shown in Figure 4.5(b) provides a simple but rigorous basis for prediction in that it requires explicit considerations of each cell. Thus, explicit action has to be taken for each mode–location cell, and possible explicit actions are described in Figure 4.6(a). These actions can include developing a specific experimental program to develop the necessary correlation, or they may include deciding to not consider or include the cell. Such decisions could then become a matter of record, the wisdom of which can be reviewed over time.

Once the array of necessary information is defined from explicit consideration of the cells in Figure 4.5(b), a program of experiments and/or review of engineering experience can be organized to obtain the information in some efficient way, that is, some of the cells may depend on the same or similar variables or exhibit similar dependencies.

Responses to completing the information for each cell depend on the application. For example, failure (as defined in Section G) may occur when 10% of tubes in a heat exchanger fail. Thus, the information needed in a cell is the time to fail 10% of tubes. In other cells, the time to penetrate 50% of the wall is the appropriate information. In the case of welded pipes, failure can occur when one weld out of 1000 fails (0.1%). Thus, the information to be gathered for each of the cells could be different possibly even in the same subcomponent and would depend on the definition of failure from Section G.

C. CBDA STEP [1]: ENVIRONMENTAL DEFINITION

C1. Perspective

The environments to which materials are exposed dominate considerations in predicting and assuring their reliable performance. Further, defining environments is often the most poorly treated part of design. Environments, at best, are difficult to define, and their broad and uncertain variability increases the difficulty of prediction. Environments include a broad array of chemical and nonchemical considerations as noted in Section C2. In addition, environments that constitute aggressive conditions are not always obvious; for example, many corrosion reactions that proceed by complexing in the liquid or gas state are not commonly appreciated (e.g., the SCC of zirconium alloys in dilute iodine gas and the SCC of titanium in alcohols). Sometimes, pure environments (e.g., pure water) are very corrosive, as for the case where pure water produces SCC of alloy 600 in the range of 250–400°C. For these reasons, special emphasis is placed on step 1 of the CBDA, environmental definition.

Environments of concern are local environments on the surface, and their characters are often quite different from bulk environments. Such differences are produced, for example, by heat transfer, evaporation, flow, and electrochemical cells. Differences between bulk environments and the surface environments, where corrosion actually occurs, are illustrated in Figure 4.7(a).

Environments act in corrosion when the necessary conditions are simultaneously present in time and are congruent is location. An environment that promotes SCC is significant only when the necessary stress is also present at the same time (the principle of "simultaneity"). An environment that promotes SCC in sensitized stainless steel may be significant only when it is exposed to welds where the heat-affected zones have been sensitized, and the stresses are high (the principle of "congruence"). These conditions are illustrated in Figures 4.2 and 4.7.

As shown in Figures 4.2 and 4.5(a), multiple and different environments can occur on the same subcomponent (e.g., "multiplicity" of environments). Thus, to have evaluated the environment at one crevice location, for example, a tube sheet crevice noted in Figure 4.5(b), may have nothing to do with the sludge crevice owing to the different chemistries in the two cases.

The discussion in Section B1 concerning chronological stages indicates that length of exposure and the circumstances associated with each of the stages are important in predicting and assuring performance. Also, time spent within a stage affects environments on surfaces owing to possible gradual buildup or changes in the identity of chemicals.

In addition to the stages shown in Figure 4.4 having different conditions, the compositions of environments, even in the steady state, change with time. Such changes involve, for example, accumulations of chemicals and the buildup of deposits, as shown schematically in Figure 4.8. For example, during steady state, the depth of a sludge pile shown in Figure 4.5(a) increases with time, as shown in the three stages of Figure 4.8. In tube sheet crevices, the concentration of chemicals increases with time as more solution enters the crevice and is evaporated by the high heat flux. In the case of reinforced concrete, the original pH is in the range where iron is maximally corrosion resistant (pH of 12–13); however, with time, CO_2 enters the concrete and causes the pH to be lowered through a process called "carbonation" [12]. This lower pH surrounding the steel accelerates its corrosion and the consequent degradation of the reinforced concrete.

Environments are also changed, and made possibly more aggressive, as inhibitors are added to mitigate corrosion. For example, chemicals such as ammonia or phosphate are often added to control the pH; hydrazine or sulfite may be added to minimize the oxygen concentration. These species together with their possibly aggressive byproducts need to be considered in predicting corrosion performance. Ammonia from hydrazine may accelerate the corrosion of copper alloys;

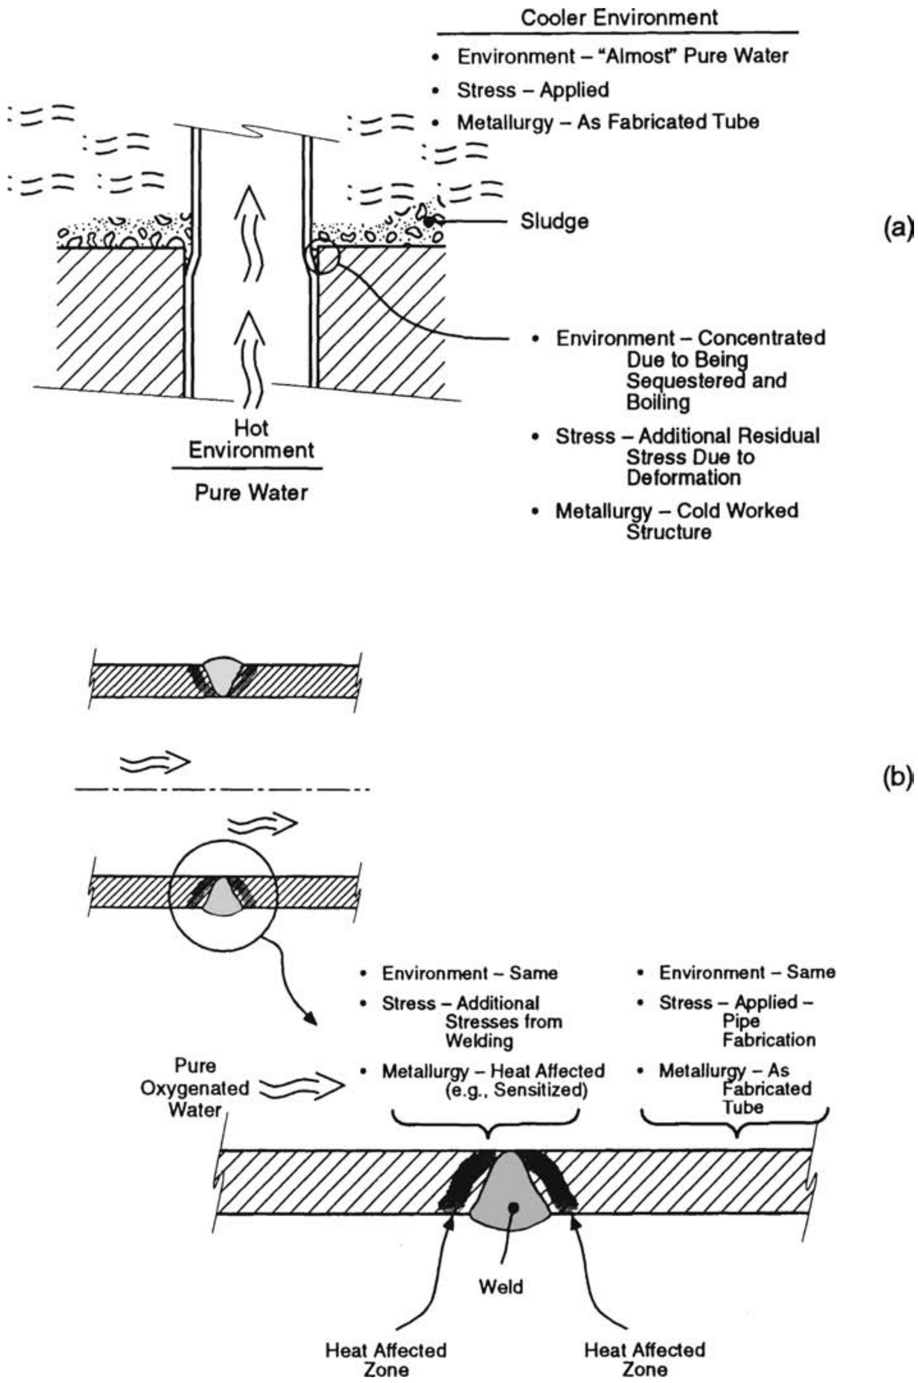

FIGURE 4.7. Schematic views showing that, for corrosion to occur, (1) the local environment needs to be specifically considered and (2) the chemical environment, the stress, and the corrosion-prone metallurgy must occur at the same locations at the same time. (a) Tube expanded into a tube sheet with surrounding sludge. (b) A welded pipe with heat-affected zone and welding stresses at the same location but with an environment the same on both welded and nonwelded regions.

sulfite may be reduced to sulfide, which accelerates the corrosion of iron-based alloys; precipitation of phosphate compounds above the retrograde temperature produces phosphoric acid.

C2. Components of Environment

As conceived by those who think about the subject of corrosion, "the environment" is often thought to be the

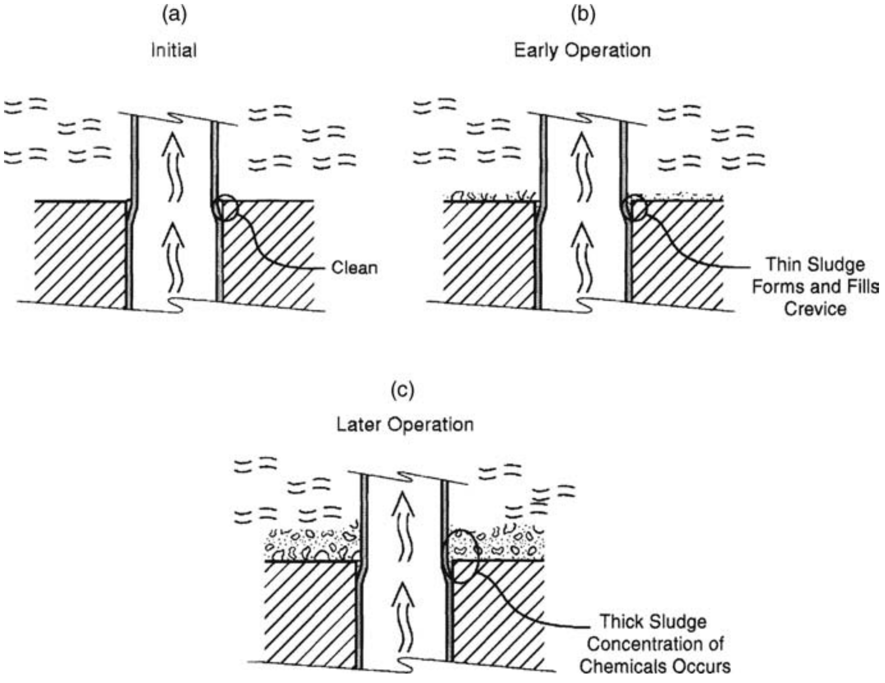

FIGURE 4.8. Schematic view showing how local environments, such as depths of deposits, change with time during steady-state operation: (a) initial condition; (b) after short-time operation; (c) after longer time operation.

chemical environment; this is an inadequate conception. Rather, considerations and components of the environment that affect degradation and that need to be included in predicting are the following:

[**1**] *Environmental type* refers to whether the environment is aqueous, organic, molten salt, liquid metal, hot gases of various types (oxygen, chlorine, sulfur species), electrolytes, and nonelectrolytes. The environments of principal practical interest are usually aqueous or high-temperature air, and the examples in this discussion are taken from such environments, mainly aqueous. However, the framework provided by the CBDA applies to predictions in all environments.

[**2**] *Chemical composition* is the chemistry of the environment on the surface at a specific LA_i, as shown in Figure 4.7. It is not the chemical composition of the bulk, although this is useful in assessing eventual chemical composition at an LA_i. The chemical composition includes the major and minor species in their dissolved, gaseous, or solid forms.

Figure 4.9 shows a schematic view of the chemical composition in a tube-to-tubesheet crevice of a steam generator of the type shown in Figure 4.5(a) where the bulk environment was virtually pure. These chemicals have concentrated as a result of the high temperature in the crevice within a lower temperature enclave on the secondary side. This high temperature and lack of flow in the secondary crevice concentrate even the most dilute chemicals from the bulk environment. Figure 4.9 emphasizes that the environment, which is relevant to corrosion, at the location of tube support crevices is not the very dilute bulk environment but the very concentrated environment in the heat transfer crevice. Figure 4.9 also shows the chemical and physical complexity of this heat transfer crevice. Numerous chemicals are present and can transform to complex compounds and different soluble chemicals. Furthermore, four local gradients cause movement and reactions: electrochemical potential, temperature, concentration, and density.

[**3**] *Electrochemical composition* is both the chemistry of those species and the geometric conditions that affect the electrochemical parameters mainly of potential and pH or equivalent properties. In aqueous environments, this includes oxygen as it increases the potential or hydrazine as it decreases the potential. The electrochemical potential produces a powerful effect on chemical reactions and is the product not only of environmental chemistry but also of separated electrochemical cells, especially where the relative areas of anodes and cathodes are different.

[**4**] *Microbiological species* [13] include organisms that metabolize the surrounding chemistry to produce

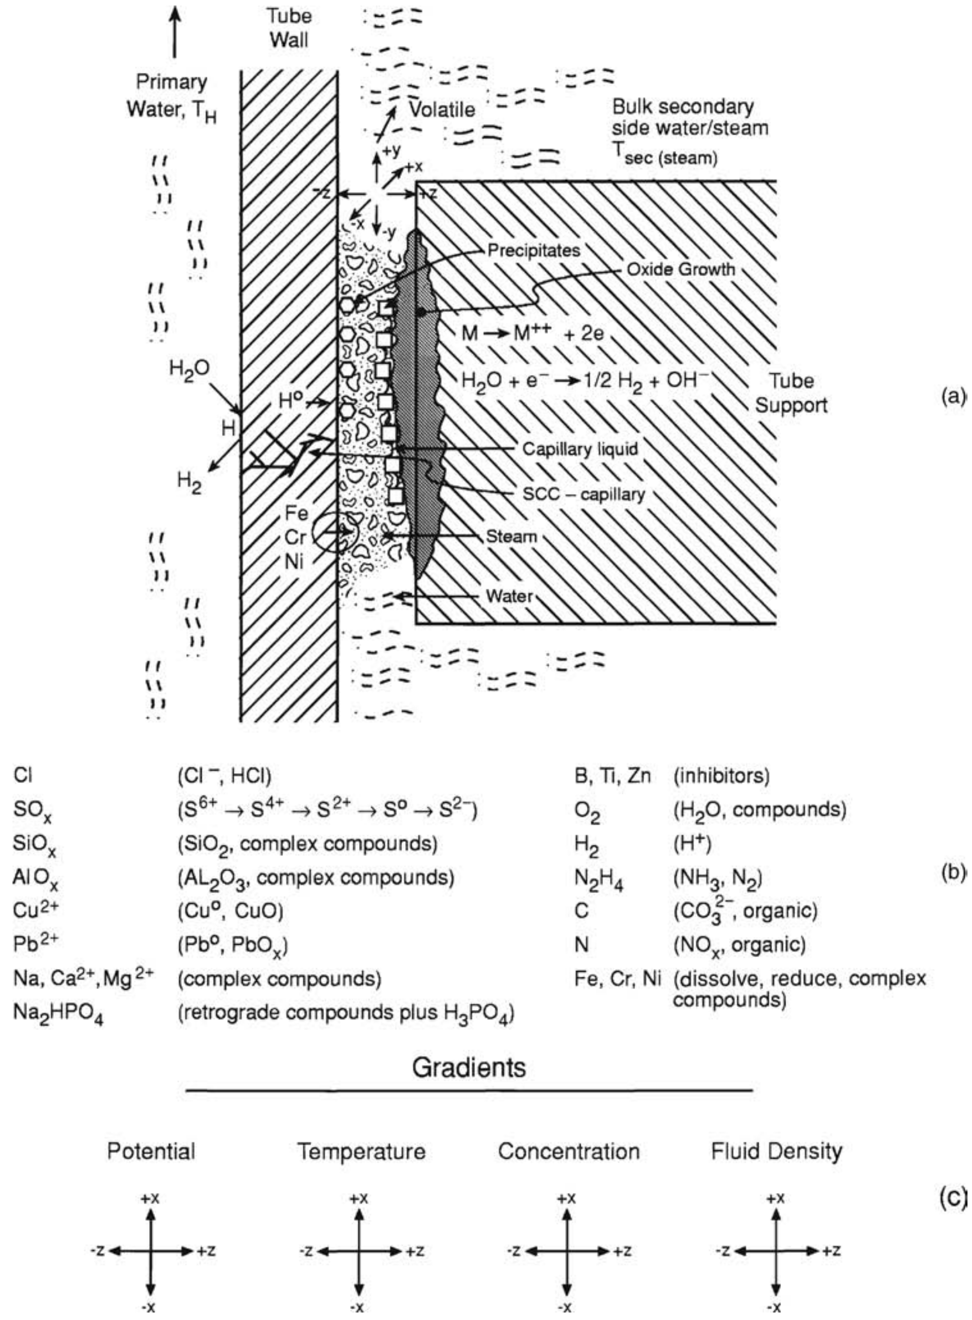

FIGURE 4.9. Schematic illustration of chemical processes that can occur in heat transfer crevices at the intersection of tubes and tube supports on the secondary side of steam generators used in pressurized water nuclear reactors, (a) The crevice geometry occurs between a tube containing hotter water than the secondary side and a tube support that is cooler, (b) Chemicals concentrate and react in the sequestered geometry. Typical species of products are shown. (c) Inside the crevice, gradients in potential, temperature, concentration, and density occur; these cause movements, further concentrations, and electrochemical cells.

different and possibly corrosive species. Some species, for example, metabolize SO_4^{2-} to produce sulfide; others metabolize oils and greases to produce organic acids. Microbial colonies, owing to their geometry alone, can produce sequestrations that accelerate localized corrosion. These microbiologically induced transformations lead to local environments that are often very corrosive, producing all the modes of

corrosion identified in Figure 4.3. Effects of microbial species on corrosion are more pervasive than are commonly recognized.

[5] *Surface alterations* involve exterior coatings of organic and inorganic materials as well as changes in the substrate produced by carburizing/decarburizing, dealloying, surface machining, and adsorbed contaminants (e.g., fluorine remaining from pickling processes). Each of these surface alterations involves its own chemistry and sequestration (e.g., some organic coatings permit filiform corrosion).

[6] *Flow (chemical and erosive effects)* [14–16] affects the rates of reduction and oxidation reactions as it affects the boundary layer thickness; mixing inside pits and SCC depending on the axis of flow relative to the surface axis especially of SCC; cavitation and associated mechanical damage; deposits of suspended solids that result when flow is reduced; erosion due only to the fluid velocity when it is locally very high (e.g., wire drawing); gradients in electrochemical potential produced by flow-induced streaming potentials; and erosion due to the presence of abrasive particles. Examples of effects of flow on electrochemical parameters, flow-assisted corrosion (FAC) and sequestered geometries, are shown in Figure 4.10.

[7] *Phase* of the environment refers to there being gas, liquid, or solid but also to two phase circumstances such as at liquid–gas interfaces (water lines), solid–liquid–gas interfaces (such as at deposits), nucleate boiling, and film blanketing.

[8] *Geometrically induced chemical environments* are those due to crevices, deposits, heat transfer crevices, galvanic juxtapositions, differences in pH of nearby areas, relative area ratios, and gravitational effects (accumulation of deposits). This category includes what, in the past, have been called crevice corrosion and galvanic corrosion.

[9] *Temperature effects (affect chemical environments)* are those related to reaction rate, surface temperatures, heat flux and associated surface concentrations, and temperature gradient chemical transfer.

[10] *Stress environments* are those related to applied and residual stresses "together with variations in time" that affect cyclic stresses, *R* ratio, frequency, randomness, and wave shape. Here, the importance of residual stresses is always and greatly underestimated; over 50% of all SCC is related to residual stresses [18]. Considerations of differences due to plane stress and plane strain are included here, although their distinction is usually small relative to environmental effects.

[11] *Stress environments affected* by (a) fluid flow that produces stresses owing to differences in velocity and produces vibrations in certain critical ranges; (b) temperature gradients that produce stresses and very rapid rates of temperature change that produce thermal shock; (c) geometric effects that intensify stresses at sharp comers, crack tips, irregular shapes such as threads, and corrosion pits.

[12] '*Relative motion of adjacent surfaces* produces wear, fretting, galling, and seizing. Wear and fretting may be greatly influenced by the chemical environment.

[13] *Neutron flux* (mainly relevant to nuclear reactors) produces several different effects on materials: First, neutrons, depending on their energies, produce transmutations or changes in chemical identities of many isotopes. Such transmutations may be chemically significant. For example, iodine produced in the fission of uranium produces SCC of zirconium alloy fuel elements in nuclear reactor cores. Second, neutrons, especially at higher energies, displace atoms from their lattice sites and produce hardening of the material. This hardening increases the strength and, thereby, increases the proneness to SCC. Third, the often large concentrations of vacancies that are produced in the displacement of atoms lead to vacancy condensation with consequent increases in volume; this increase in volume leads to the inevitable stresses and dimensional incompatibilities in adjoining subcomponents [19]. Fourth, neutrons produce the well-known fissioning of uranium, thorium, and plutonium with the consequent fission fragments of greatly different chemistries and increase in volume.

[14] *Electromagnetic radiations* such as gamma rays, X rays, and solar rays produce some important effects: First, gamma rays produce internal heating depending on their energy, intensity, absorption rate, and geometry of the subcomponent. Second, solar rays produce degradation of some polymers such as crazing and forms of SCC. Third, electromagnetic radiations catalyze some chemical reactions.

[15] *Charged particles* such as alpha particles (helium nuclei) and beta particles (electrons) can displace atoms in materials and can produce transmutations.

Thus, when environments are defined at any LA_i in the chart of Figure 4.5(b), items **[1]**–**[15]** need to be considered. In subsequent sections, only a few of the 15 environments are considered. However, the list of 15 provides a more general view of environments than the only chemical ones that are often considered These environments affect the modes and submodes differently. For example, the stresses noted in Section C5 and the accompanying Figure 4.13 are relevant not usually to general corrosion but mainly to SCC and CF. Neutrons, energetic electromagnetic radiation (gamma rays), and other energetic particles are not relevant except in applications involving nuclear reactors.

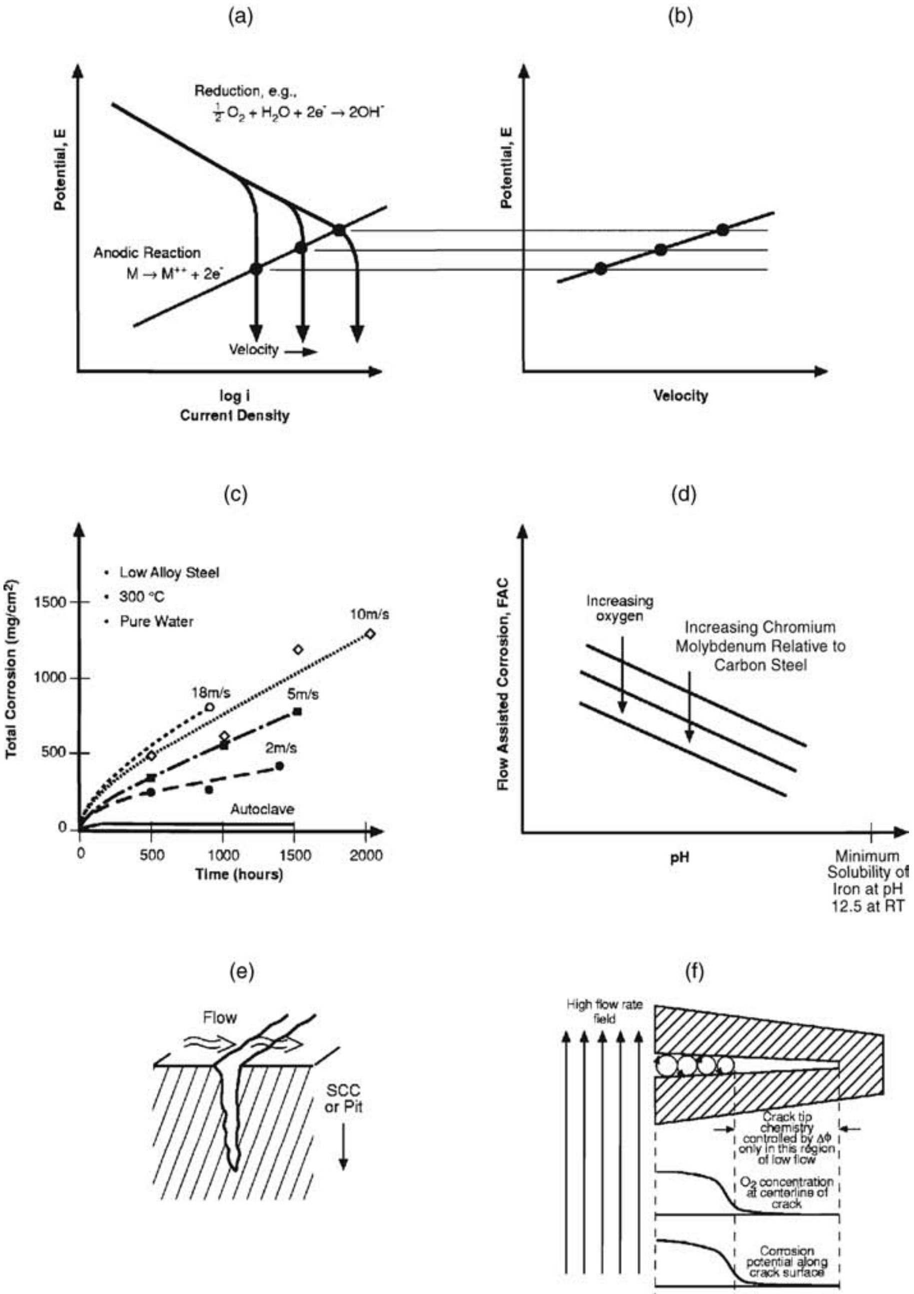

FIGURE 4.10. Three different effects of flow on corrosion. (a) Increasing flow accelerates the rate of the reduction of reducible species such as oxygen. Schematic polarization curves representing increasing velocities of flow are shown, (b) Corrosion potential versus velocity is shown corresponding to the effects of velocity on the polarization behavior in (a). (c) Total corrosion versus time for low-alloy steel exposed in 300°C pure water exposed to increasing velocities. (After Berge [17].) (d) Schematic relationship between FAC and pH, increasing oxygen concentration, and increasing chromium and/or molybdenum added to low-alloy steels. (e) Schematic view of advancing SCC (could be pitting) exposed to flow. (f) Schematic view of effects of flow on convection inside an advancing SCC. Here, the effective "electrochemical mouth" of the advancing SCC is moved inward as a result of mixing induced by external flow. (After Andresen and Young [14].)

C3. Chemical Environment

The "chemical environment" as described here is that identified in item **[2]** of Section C2. Figure 4.11 illustrates schematically how to approach defining the chemical environment. The objective noted in Figure 4.11 is to develop the chemical conditions at the LA_i (i.e., the *i* column of Figure 4.5(b) and **[8]** in Figure 4.11). Defining the chemical environment starts, **[1]**, with defining the major and minor species in "nominal chemistry" as they occur at the specific surface of an LA_i. Major species include water molecules and whatever is intentionally dissolved; minor species may include impurities, such as those in tap water. Considering the prior chemistry history, **[2]** supplies information on possible contaminants that may have formed on surfaces that would affect the LA_i either directly or as these species may dissolve and find their way to the LA_i. **[2]** refers generally to contaminants that may preexist in the system from construction (e.g., lead hammers left in the system), contaminants from cleaning operations, or defects produced by prior corrosion.

System sources, **[3]** in Figure 4.11, refer, for example, to copper that is released from copper alloy tubed condensers and then deposits on other surfaces in a secondary system to accelerate localized corrosion such as pitting. Species enter turbines from steam sources that are contaminated by river water that leaks into condensers. Oxygen enters through leaks in turbine seals. Chloride may be leached from platinum catalysts that have been prepared with chloroplatinate. System sources, **[3]**, then are those that are not normally expected to be produced or related to the component but may be transported from other parts of the system. These can be readily identified and in most cases predicted.

Physical features, **[4]**, refer to crevices, deposits, flow, phases, and local electrochemical cells that influence the chemistry of an LA_i. An LA_i with a crevice involves a quite different situation from the nominal chemistry of the bulk, as indicated in Figures 4.7, 4.8 and 4.9. An LA_i involving a waterline involves an electrochemical cell that changes the local oxidizing conditions.

Transformations, **[5]**, involve changes in chemical identity: for example, the process of microbes changing a hydrocarbon to an organic acid. Another transformation might involve the reduction of a sulfate (SO_4^{2-}) to a lower valence such as thiosulfate or bisulfide in a low-potential environment such as one containing hydrogen or hydrazine. These lower valences of sulfur are usually more chemically aggressive and, in some cases, accelerate hydrogen entry leading to SCC; sulfate by itself is not so aggressive.

Concentration, **[6]**, involves the concentration of species usually from the bulk; thus, whereas the bulk may contain chloride at a few parts per million (ppm) or even a few parts per billion (ppb), heat transfer crevices such as shown in Figure 4.9 or evaporation or a wicking process may concentrate the environment at an LA_i. Thus, the environmental species can attain concentrations much greater than the bulk; often such local concentrations are fully saturated.

Inhibition, **[7]**, involves chemical species added to minimize corrosion usually by affecting the pH, lowering the oxygen, or preferentially blocking anodic sites. Depending on the nature of the environments, as noted in Section C2, there are many possible approaches to inhibition. Adding inhibitors needs to be undertaken with the recognition that inhibitors may produce undesirable and possibly aggressive byproducts. For example, phosphate that is added to buffer and control pH can undergo a precipitation, as temperatures are increased, through a retrograde insolubilization process that produces local phosphoric acid. Using hydrazine for lowering the concentration of oxygen sometimes accelerates

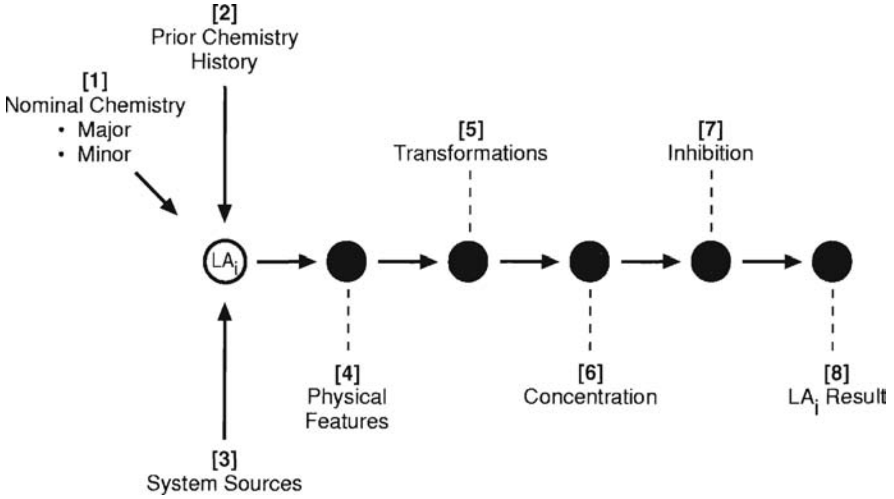

FIGURE 4.11. Analysis sequence for determining chemical environment at a location for analysis, LA_i.

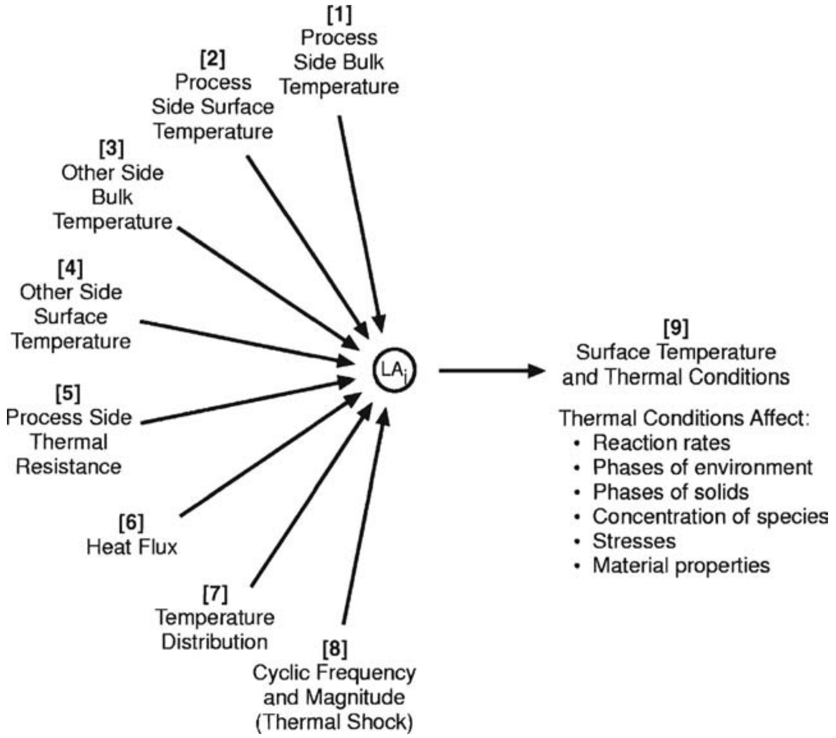

FIGURE 4.12. Analysis sequence for assessing effects of thermal environment on a location for analysis, LA_i.

the corrosion of copper-based alloys through the complexation of the copper with the ammonia produced in the decomposition of hydrazine.

Consideration of items **[1]**–**[7]** together provides the bases for defining the chemical environment at a single LA_i at **[8]** and in Figure 4.5(b).

C4. Thermal Environment

Figure 4.12 shows factors of the thermal environment which affect the conditions for a given LA_i. Temperature enters this discussion first because of its direct proportionality to some function of the rate of most corrosion reactions noted in Eqs. (4.1)–(4.3). Temperature gradients affect corrosion reactions as heat fluxes concentrate environments and produce thermal stresses.

For this illustrative discussion, corrosion on the process side is discussed. The temperature of the process side is usually lower than the other side as noted in **[3]** and **[4]** of Figure 4.12.* This means that the temperature on the surface of the process side is higher than that of the surrounding bulk environment. The process side is chosen for discussion since it is usually the side where chemicals concentrate on surfaces or in heat transfer crevices; furthermore, the thermal stresses on the process side are generally tensile, providing that the process side is cooler.

The process side bulk temperature, **[1]** in Figure 4.12, is cooler than the surface, **[2]**; however, corrosion occurs at the temperature of the surface and not at the bulk so that degradation is occurring at **[2]**. This difference is exacerbated when the bulk environment is a gas where the resistance to heat transfer is higher. Regardless, the temperature of main interest for corrosion is at the surface and not the bulk.

At the process side, the next important factor is the heat flux [6] which influences the concentration of species as well as affects the surface temperature. Such a concentration is illustrated in Figure 4.9. Increasing heat fluxes tend to concentrate species, especially when the surface may be sequestered by a crevice or a deposit. Such concentrations change the local environments and need to be accounted for in Section C3.

Temperatures influence the onset of retrograde solubilities where increasing temperature may cause some phases to precipitate and produce simultaneously new compositions of supernatant liquids. In the case of the retrograde precipitation from phosphate solutions, phosphoric acid may be produced adjacent to the precipitated compounds.

Temperature enters the chemical aspect of corrosion at LA_i as temperature gradients. For example, thermal gradients produce tensile stresses on the process side (if cooler); thermal gradients in exothermic hydrogen-occluding

* Not all "process sides" are at the lower temperature side of a tube.

metals cause hydrogen to redistribute to the colder locations, thereby increasing brittleness. Thermal cycling produces fatigue effects as the associated stresses are cycled, and a very high rate of temperature change produces thermal shock.

C5. Stress Environment

The stress environment is usually considered to be the province of mechanical engineering and mechanics as they analyze stresses for the purpose of sizing components. These disciplines are also interested in cyclic stressing as it affects dry fatigue and design life. However, the stress analysis and corrosion communities have common interests in stresses as related to SCC and CF. Analyses by both communities are affected by residual stresses which, while difficult to analyze and predict, cause a large fraction of all failures by SCC [18].

Figure 4.13 shows how factors of the stress environment combine to produce conditions at an LA_i.

Generally, the applied stresses, **[1]**, are well defined and are produced by the usually obvious pressures, bending, tensile loads, flow, and temperature gradients. Applied stresses include those due to cyclic stressing, including various *R* ratios, cyclic frequencies, and wave shapes. Less well defined but often the critical contribution to modes of corrosion such as SCC are residual stresses **[2]**. Whereas the applied stresses are usually required to be something less than half the yield stress or lower, residual stresses are usually in the range of the yield stress. Residual stresses result from fabrication processes such as welding, cold deformation, and surface machining. Quantifying such residual stresses is often omitted in design with the erroneous conclusion that such stresses are irrelevant to design and performance.

"Other stresses" **[3]** result from sources such as corrosion products forming in restricted geometries where the specific volume of the corrosion product is greater than that of the metal that is corroded [20]. Such stresses can cause cracks to initiate and grow, as shown in Figure 4.14(a). Here, the stresses to cause SCC have been produced in a crevice between an insert and a notched specimen. These cracks then continue after the insert is removed, thereby indicating that the stresses to propagate SCC are totally due to the action of expanding corrosion products inside the advancing cracks.

Stresses from expanding corrosion products can readily cause adjacent metals to flow plastically as occurs in nuclear steam generators; this process, called "denting" [21], is illustrated schematically in Figure 4.14(b). Here, corrosion of the adjacent tube support produces corrosion products that expand and begin to strangle the tube. The chemistry that produces such corrosion is described also in Figure 4.9. This process is called "denting" since, when seen from the inside

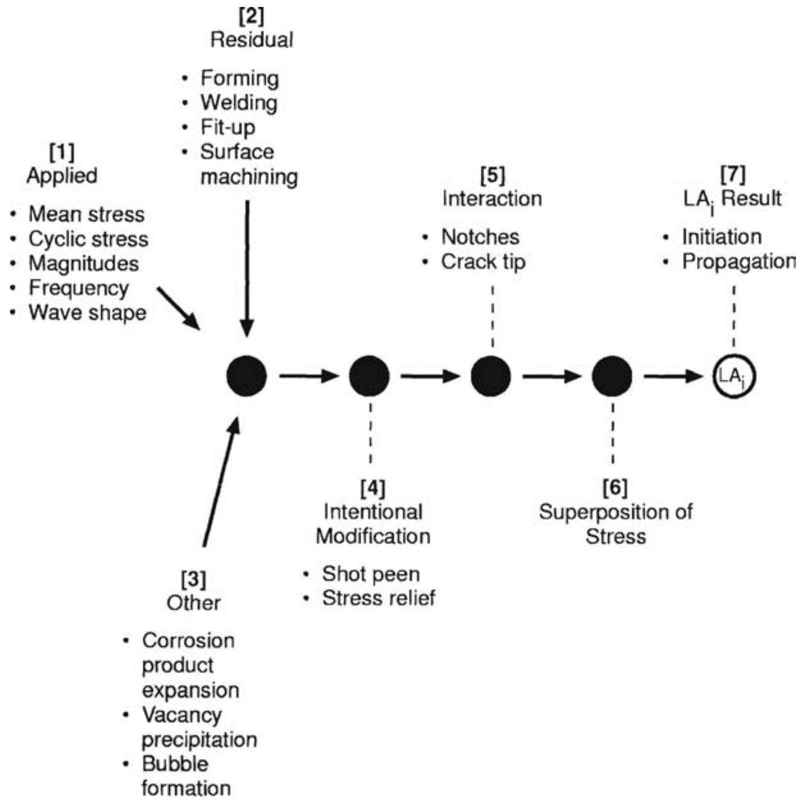

FIGURE 4.13. Analysis sequence for determining stress environment at a location for analysis, LA_i.

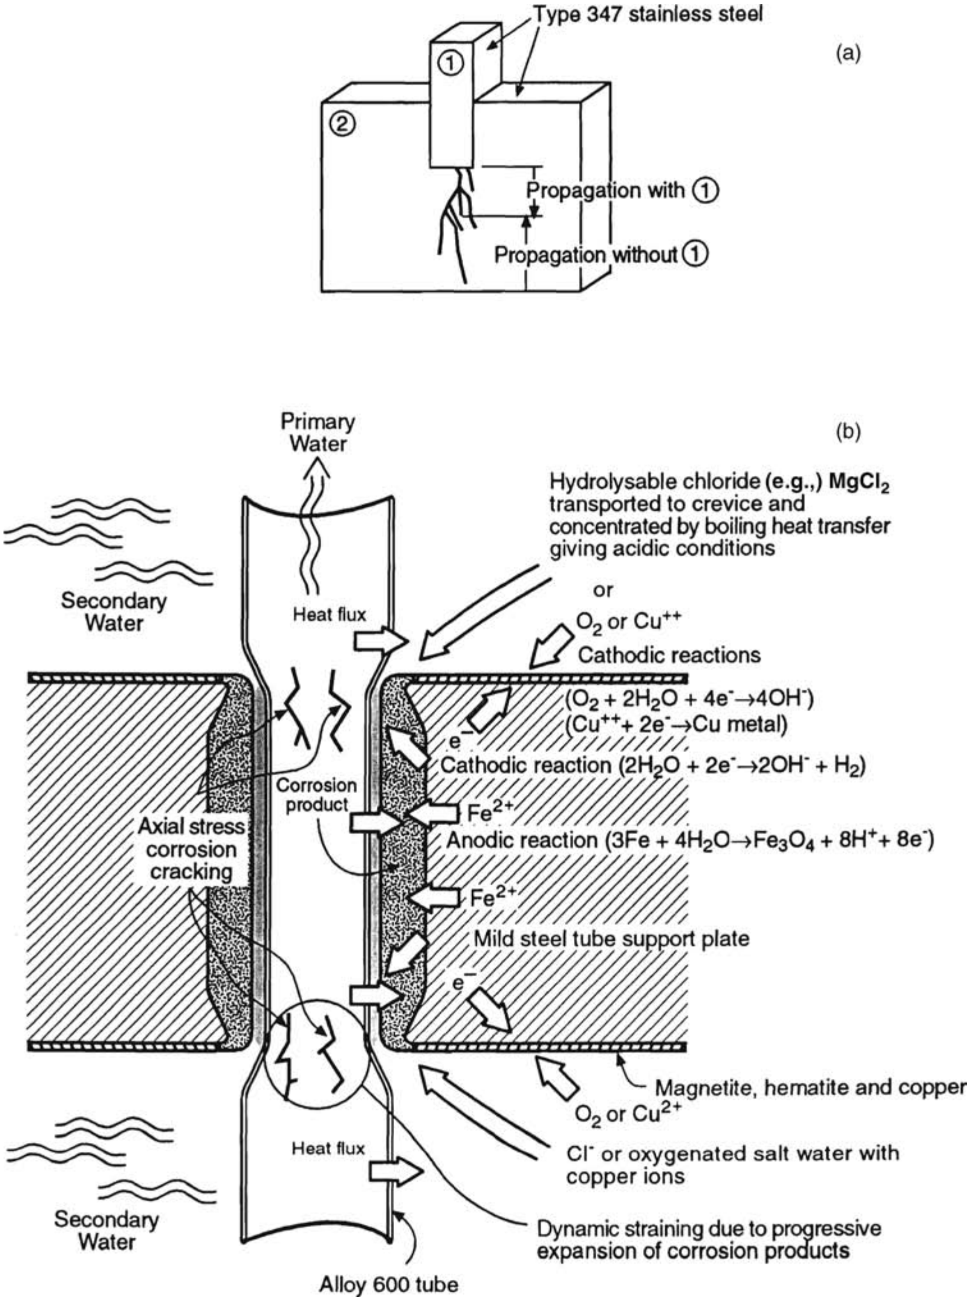

FIGURE 4.14. Schematic views of effects of oxide growth on stresses. (a) Formation of oxides produce stresses between insert and specimen that propagate SCC; when the insert is removed, SCC continues due to stresses from corrosion products inside the cracks. (After Fontana, Beck, and Pickering [23].) (b) Growth of oxides from corroding carbon steel tube support [see Fig. 4.5(a)] constricts the diameter of alloy 600 tube and produces dynamic stressing that causes SCC in the pure water on the inside surface. (Adapted from the Steam Generator Reference Book [21].) This phenomenon is called "denting" since, from the inside of the tube, it appears to be dented at the locations of expanding corrosion products.

of the tubes, these deformations seem to produce dents at the tubesheet locations. Similar stresses from the buildup of corrosion products cause the degradation of reinforced concrete [22].

These other stresses can also be produced by the precipitation of bubbles resulting from the lattice disarray due to neutron bombardment [19], from the formation of helium from the nuclear degradation of B^{10}, which produces an alpha

particle and Li, or from the formation of hydrogen or methane bubbles that embrittle grain boundaries or produce blisters, usually in steel.

Stresses can be modified or minimized, **[4]** in Figure 4.13, by thermal stress relief, shot peening, or surface treatments such as carburizing. Appropriately placed welds can produce intentional contractions in locations where material is prone to SCC as a result of high local tensile stresses.

Stresses interact, **[5]** in Figure 4.13, with geometries and sharp cracks to intensify the local stresses. Such interactions have been studied in great detail as part of fracture mechanics [24]. A principal interest in fracture mechanics is to determine circumstances under which the intensified stresses that result from sharp geometries reach a critical intensity for catastrophic fracture. Catastrophic or fast fracture occurs when the value of a critical stress intensity, $K_{\mathrm{I_c}}$ (I corresponds to the opening mode of the crack), is exceeded. This criterion is given by Eq. (4.4):

$$K_{\mathrm{I}} = \sigma_{\mathrm{m}}\sqrt{C\pi a} \quad (4.4a)$$

$$K_{\mathrm{I_c}} = \sigma_{m}\sqrt{C\pi a} \quad (4.4b)$$

where

σ_{m} = mean stress
a = depth of defect
C = geometric constant
K_{I} = stress intensity for any combination of mean stress and defect depth less than $K_{\mathrm{I_c}}$
$K_{\mathrm{I_c}}$ = critical stress intensity at which catastrophic fracture occurs

Stresses are additive, **[6]** in Figure 4.13, and the total stressing condition needs to be applied to the LA$_i$**[7]** in Figure 4.13. The stress environment needs to be considered together with the chemical environment of Figure 4.11 in assessing the location conditions in the chart of Figure 4.5 (b). At the point where stresses are being calculated in detail and in the presence of discontinuities, careful attention needs to be given to stresses at LA$_i$. This is usually undertaken with finite-element stress analysis together with detailed considerations of geometries of defects.

The interactions between mechanical and corrosion considerations are illustrated in Figure 4.15. In Figure 4.15(a) the continuum of stress intensity [following Eq. (4.4a)] is plotted schematically to emphasize the relative contributions of corrosion and purely mechanical fracture. First, there is a relatively low critical value, usually called $K_{\mathrm{I_{scc}}}$, $K_{\mathrm{I_H}}$, or $K_{\mathrm{I_{CF}}}$ as these symbols relate to SCC, hydrogen effects, or corrosion fatigue. When these lower thresholds are exceeded, cracks start to grow, but slowly. This slow growth may occur at constant stress as for SCC or may be more related to a small increment of crack growth, $\Delta a/\Delta n$, for each cycle of stressing, ΔK, in fatigue. The fatigue crack growth rate may be increased by environmental contributions as noted in Figure 4.15(b). This increase due to environments in Figure 4.15(d) often corresponds to the threshold stress intensity for the onset of SCC (see Fig. 4.15c) although some environments accelerate CF while they do not produce SCC.

For a given material (assuming that the material properties are constant) at a definite temperature, the value of $K_{\mathrm{I_c}}$ is more or less invariant; however, the onset of slow crack growth, especially for SCC, is not. The value of $K_{\mathrm{I_{scc}}}$ for a given alloy depends greatly upon the environment on the surface and may easily vary by factors of 2 or 3. Thus, precision in $K_{\mathrm{I_c}}$ is not nearly so critical to predicting performance as precision in $K_{\mathrm{I_{scc}}}$ (as well as in defining the local environment), which is more difficult to determine owing to its dependence on subtle combinations of environments and materials.

Once a crack starts to grow, reaching $K_{\mathrm{I_c}}$ is inevitable unless there is some intervention to change materials, change the environment, lower the mean stress, or blunt the crack. Thus, $K_{\mathrm{I_{scc}}}$ and similar onset criteria are possibly more critical to long-term performance than $K_{\mathrm{I_c}}$. In addition, it is desirable to know the growth rate, either for SCC or CF, reasonably well so that intervention strategies can be developed: That is, if the crack growth is sufficiently slow and the instantaneous depth produces a K_{I} significantly less than $K_{\mathrm{I_c}}$, a crack may be allowed to grow until it reaches a value below $K_{\mathrm{I_c}}$ that is regarded as a safe upper limit.

This discussion has not considered the region of K_{I} below the thresholds, for example, $K_{\mathrm{I_{scc}}}$. In the subthreshold region, SCC and other forms of localized corrosion produce magnitudes of K that are less than $K_{\mathrm{I_{scc}}}$. These subthreshold modes are usually corrosion related, as noted in Figure 4.15b, unless they relate to defects in the material, design or accidental nicks, and notches. Thus, the first stage of degradation in the subthreshold corrosion may be pitting or SCC. When these reach some critical depth and $K_{\mathrm{I_{scc}}}$ is reached, then the crack growth follows a pattern shown in Figure 4.15(c or d). Thus, there are three sequential stages for the growth of defects:

1. Subthreshold (mainly chemically-related growth): corrosion (localized corrosion as SCC, IGC, or pitting); fatigue (dry and wet). Generally, the chemical environment dominates here.
2. Above chemical growth threshold (slow growth): chemical–mechanical (static and cyclic) interaction. In the absence of necessary environments, the static load cracks stop, and the magnitude of $\Delta a/\Delta n$ decreases.
3. Above $K_{\mathrm{I_c}}$: catastrophic fracture. Totally mechanical.

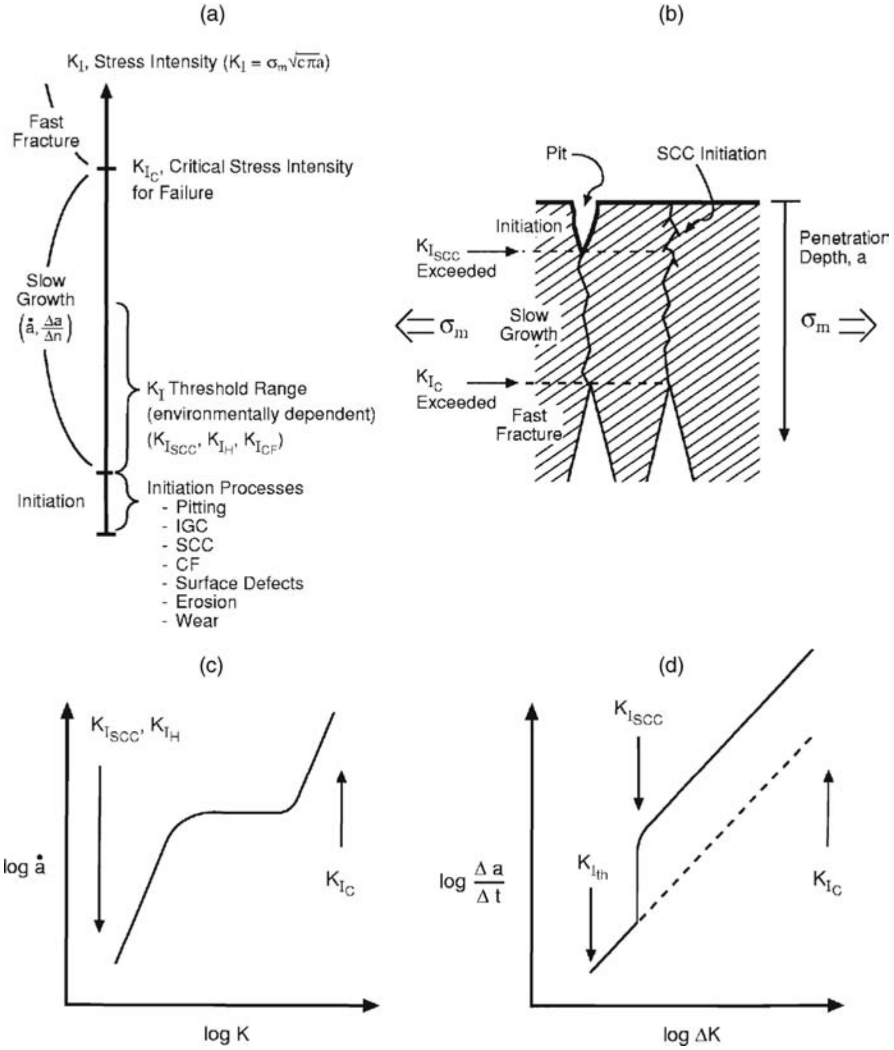

FIGURE 4.15. (a) Schematic view of relative magnitudes of K_I shown with transitions and principal dependencies. The K_I parameter for threshold range is shown to be variable. (b) Morphological regimes. (c) The *da/dt* versus K for SCC and similar environmentally dependent slow growth (e.g., hydrogen), (d) $\Delta a/\Delta n$ versus ΔK for fatigue crack growth showing possible effect of SCC in increasing the slow growth.

In the subthreshold regime, the stress at which SCC initiates depends greatly on the combinations of environments and materials. These interactions are discussed in Section E. The useful stress below which SCC cannot initiate depends on the local situations and is called "situation-dependent strength" [11].

C6. Other Environments

In Section C2, 15 classes of environments are identified, and Figure 4.11 shows how these enter considerations in the LA_i of Figure 4.5(b). All of these environments deserve detailed considerations; however, here, we emphasize the broad and illustrative views of environments; the details of how they are envisioned and incorporated depends on specific applications.

D. CBDA STEP [2]: DEFINING MATERIALS

It would seem that a material such as type 304 stainless steel is well defined and should respond reproducibly when purchased to historically well-established specifications. Unfortunately, this is not always so, and such well-known and extensively used materials sometimes exhibit unexpected behavior—mainly because important details (surface cold work or erroneous heat treatments) of the material are not identified. Sometimes the term "space age material" applied to materials such as titanium is also misleading. Despite the often excellent corrosion resistance of titanium, for example, and partly due to its very high reactivity, it may corrode rapidly and sometimes unexpectedly.

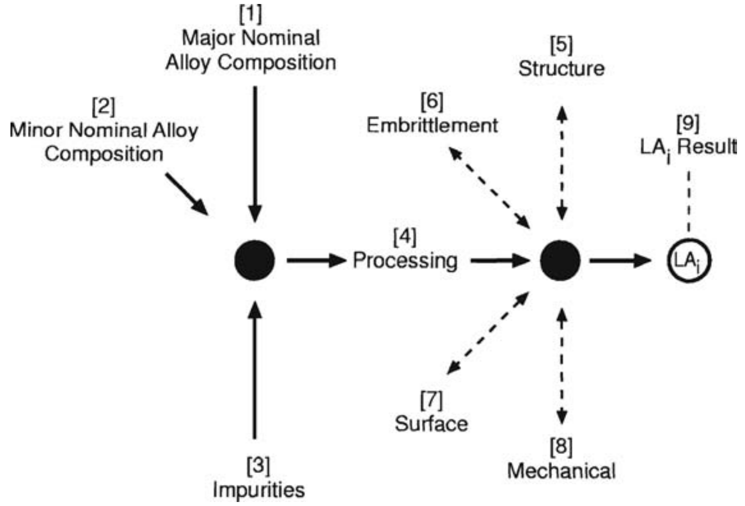

FIGURE 4.16. Analysis sequence for defining materials at a location for analysis, LA_i.

Usually, in environments that can be reasonably well defined, unexpected corrosion results from lack of definition of the material itself. Defining a material by its specification is often, especially for new designs, if not usually, quite inadequate.

As shown in Figure 4.16, defining a material starts with defining its major alloy composition, **[1]**. This step is usually straightforward and is not the reason for unexpected behavior. The next step, **[2]**, involves defining the "minor alloy composition"; this would include carbon, manganese, and sulfur in stainless steel. Such species often increase the intensity of corrosion reactions, especially SCC. Impurities, **[3]**, identify the importance of defining the impurities in the material; some materials, like titanium, are prone to absorbing (e.g., in welding) high concentrations of species such as oxygen, nitrogen, and carbon owing to the high affinity of titanium for these species. Sometimes, the aggregation of even minor elements all on the high side accelerates degradation reactions. Impurities are sometimes absorbed during fabrication operations such as welding and heat treating; this is especially a concern in reactive materials such as titanium.

Probably the most important consideration in defining materials is defining the compositions of their grain boundaries, since many degradation reactions either follow grain boundaries or are initiated at grain boundaries. In addition to corrosion reactions that follow compositionally altered grain boundaries, embrittlement processes often follow the same compositionally altered boundaries, producing, for example, the phenomenon of "temper embrittlement."

Figure 4.17 shows schematically the composition of grain boundaries depending on whether adsorption to grain boundaries occurs as in Figure 4.17(a) or a compound is formed (e.g., a carbide), as in Figure 4.17(b). In the case of

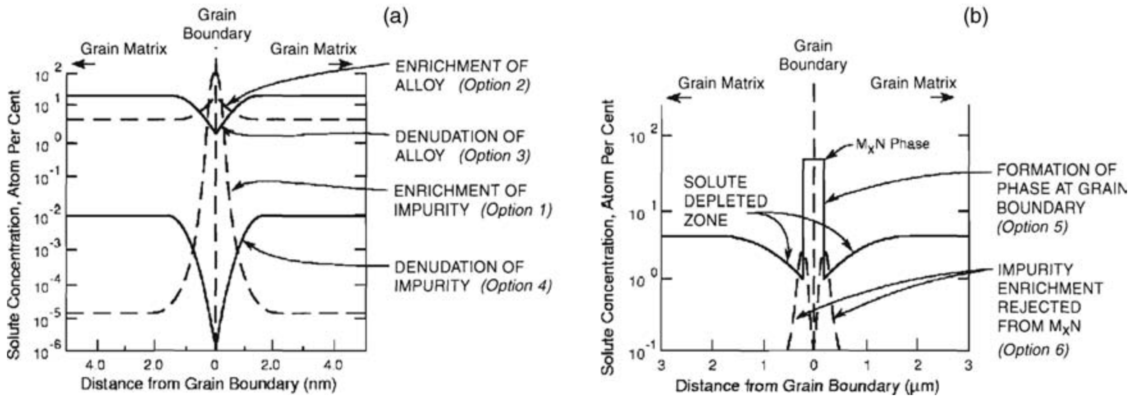

FIGURE 4.17. Schematic view of concentration versus distance from grain boundaries for circumstances where atomic species are adsorbed to the grain boundaries or where precipitates are formed. (a) Four options for concentration versus distance where atoms are adsorbed or rejected at grain boundaries. (b) Principal features of composition versus distance for the case where precipitates are formed at grain boundaries. (After Staehle [11].)

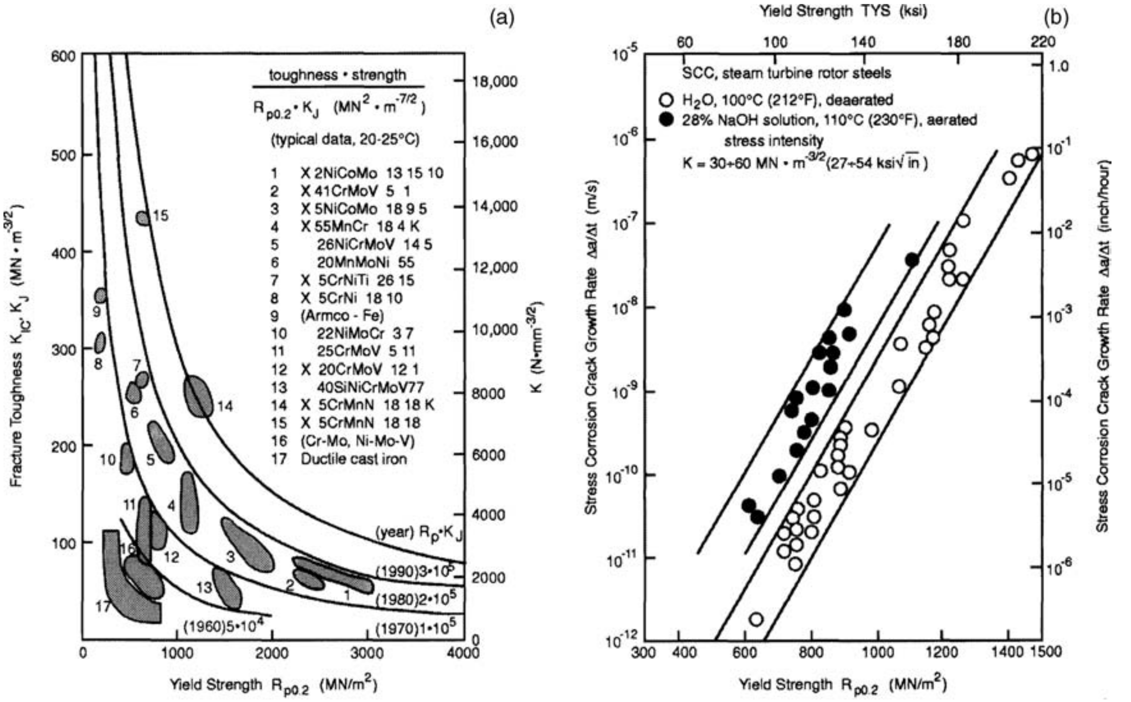

FIGURE 4.18. Effects of strength of iron-based alloys on their toughness (a) and SCC velocity (b). (Adapted from Speidel and Attens [25].)

adsorption, impurities may be concentrated by factors as much as 10^5; alloying species are concentrated less. In the case of compound formation, its composition may be enriched in either a passivating or nonpassivating species. Immediately adjacent to this compound there may be a narrow region of enriched species that are rejected as the compound forms. Finally, there are the "solute-depleted regions" the deficiency of which has supplied the necessary species for forming the compound. A good example of such a region is the depletion of chromium associated with the formation of chromium carbides at grain boundaries in stainless steels when they are exposed to a particular range of temperatures that produces "sensitization" (because the resulting low chromium concentration adjacent to the grain boundaries sustains rapid corrosion in acidic environments).

Degradation reactions are also affected by the presence and distribution of second phases whether at grain boundaries or distributed through the grains. Such second phases are often loci of pitting or, when lined up, may provide preferential paths for chemical degradation. Second phases also produce certain embrittlements such as the formation of sigma phase in Fe–Cr base alloys.

Surface alterations, **[7]** in Figure 4.16, affect corrosion behavior through altered compositions or changed mechanical properties due to surface finishing.

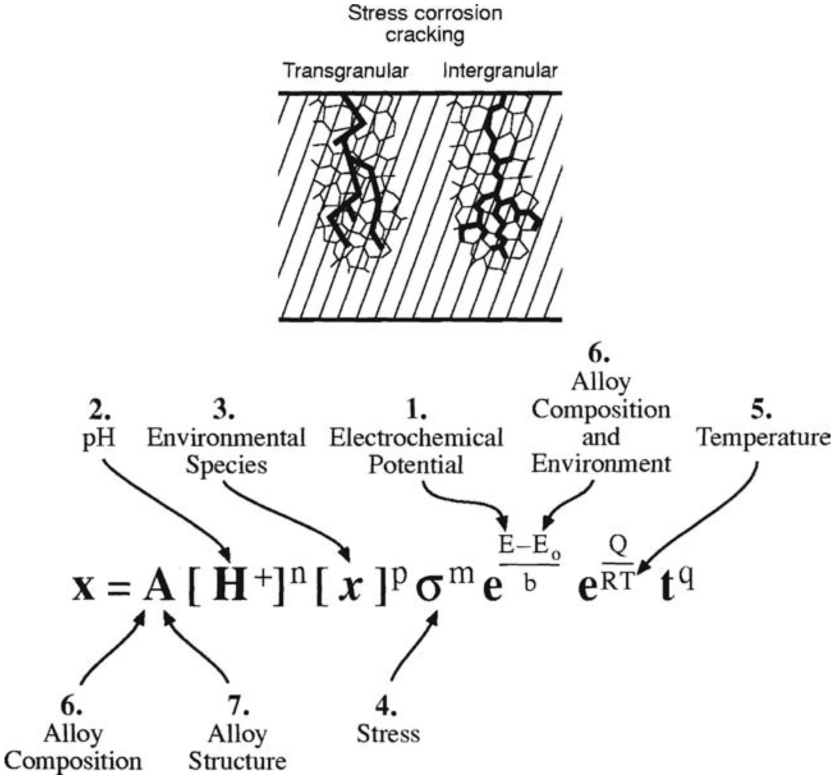
Figure 4.16 shows that **[4]** (processing) affects **[5]** (structure), **[6]** (embrittlement), **[7]** (surface), and **[8]** (mechanical) properties. "Processing" generally includes cycles of temperature, time, and extent of deformation. The fact that unexpected and undesirable behaviors occur involving **[5]**–**[8]** usually results mostly from processing, the important details of which are often obscure. Therefore, it is necessary to determine the aspects of **[5]**–**[8]** by direct measurements (e.g., of grain boundary composition or cold work) as appropriate to their relevance to degradation.

Processing and alloy chemistry also affect the fracture toughness as shown in Figure 4.18. Here, while increasing the strength generally lowers the fracture toughness, improving the purity and the methods of processing can increase the fracture toughness significantly. Other embrittling processes (e.g., temper embrittlement) are similarly affected by alloy composition and processing.

During the design and prototyping processes it is not uncommon for materials to be changed for reasons of performance, compatibility, or cost. When such changes occur, the materials need to be reevaluated according to the steps defined in this section.

E. CBDA STEP [3]: DEFINING MODES (MD_j) AND SUBMODES (SD_j)

Figure 4.3 identifies five modes by which corrosion-related degradation proceeds through solids. These modes occur in every type of engineering solid with some, usually minor, differences that account for the structure and composition of



$$x = A[H^+]^n [x]^p \sigma^m e^{\frac{E-E_o}{b}} e^{\frac{Q}{RT}} t^q$$

FIGURE 4.19. Schematic view of principal variables that control corrosion of metals in aqueous solutions illustrated here for SCC [as in Eq. (4.1)].

the solid. Similarly, the various submodes of these principal modes also follow the same morphologies except that their dependencies upon principal variables are different

Defining modes and submodes means to define (a) the morphologies as shown in Figure 4.3 and (b) the dependencies of the modes and submodes upon principal variables. These modes and submodes are inserted into the chart of Figure 4.5(b).

Not extensively discussed here are the totally mechanical modes of fast fracture, wear, and wear-related processes (e.g., fretting) [26] and dry fatigue. Fast fracture is not discussed as a mode since its morphology, while possibly important to analyzing failure, is of little importance to prediction. The dependence of K_{I_c} on relevant principal variables and the theory of K_{I_c} are not discussed here since this chapter is concerned primarily with environmental effects. Much of wear produces morphologies similar to general corrosion and pitting as depicted in Figure 4.3; however, wear in either its dry or environmental conditions is not considered here, although such a topic in the context of environmental effects as discussed in Section C would be appropriate.

Defining possible modes of degradation is important because they vary so much in their penetration velocity and their extent At a single LA_i it is possible that all modes could occur or only a single one. Such possibilities are illustrated in Figure 4.2.

Defining modes means specifically to define their dependencies upon the "primary variables," as illustrated in Figure 4.19. The primary variables, as defined for metals in aqueous solutions, are potential, pH, species (e.g., chloride as opposed to species that affect potential or pH), temperature, stress, alloy composition, and alloy structure. The dependent variable here would be either penetration or penetration rate depending on which is useful. When a given mode (e.g., SCC) exhibits several submodes (as for alkaline and acidic SCC), they are distinguished by their different dependencies on these principal variables.

The various modes of corrosion (Fig. 4.3) differ greatly in their response to these principal variables depending on whether the initiation or propagation stages are important.

The array of possible modes and submodes can be understood more readily using a diagram such as that in Figure 4.20, which shows submodes of SCC for alloy 600 in aqueous solutions in the range of 300–350°C. These submodes are shown with reference to a potential–pH diagram containing pertinent lines for both iron and nickel (two alloy constituents) in water. The development of this diagram and similar ones is discussed in separate publications [27].

In Figure 4.20, four submodes of SCC are shown for alloy 600. One occurs in the alkaline region, AkSCC, and is bounded at higher and lower potentials to occur in a range

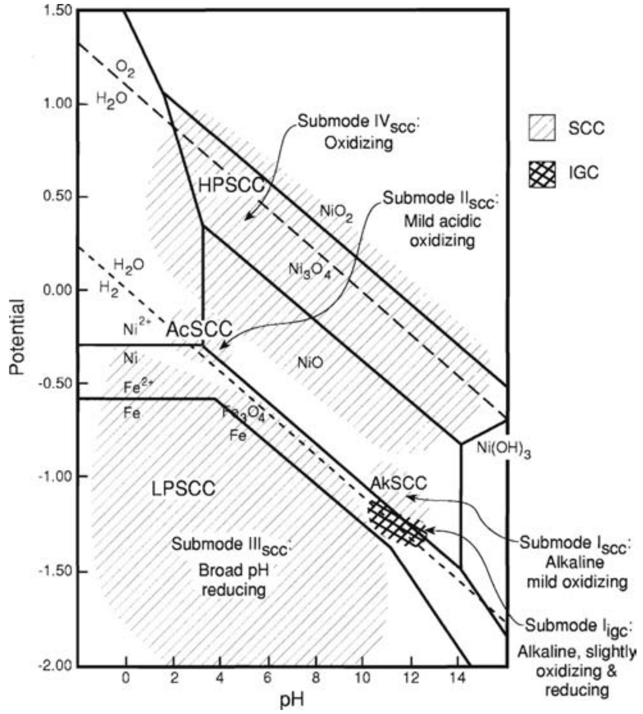


FIGURE 4.20. Occurrence of modes, MD_i, and submodes, SD_i, of SCC and IGC for mill-annealed alloy 600 in the range of 300–350°C in the framework of the electrochemical potential and pH. Selected lines, taken at 300°C, from the Fe–H_2O and Ni–H_2O equilibria shown for reference; also domains of selected species and compounds shown.

of potential of about 300 mV with the onset being about 100 mV above the standard hydrogen equilibrium. This submode is common to many alloys in the Fe–Cr–Ni system, including low-alloy steel. A second submode, AcSCC, occurs in the acidic region and seems to include about the same extent of potential and pH as the alkaline submode; however, the data describing this submode are not so extensive, and the boundaries are not so well defined, although they are better defined for low-alloy steels in the same submode. A third submode occurs generally below a line corresponding to 0.1 atm of hydrogen pressure. This is called low-potential SCC (LPSCC); historically this submode was called "primary water SCC" since it was often observed in the primary side of steam generators in PWR-type nuclear plants [28]. This latter nomenclature is not useful since it would compel this process to occur only in one location and to lack generality. Finally, a fourth submode, high-potential SCC (HPSCC), occurs at higher potentials and generally in a range of about 50–300 mV above the standard hydrogen line. The pH dependence of this submode is not well defined.

Figure 4.20 is called a "mode digagram." A similar mode diagram for various modes of mechanical deformation has been developed by Ashby and Tomkins [29].

Additional modes and submodes of SCC occur for alloy 600 and could also be shown on the same coordinates in Figure 4.20; however, the information becomes less clear, and using separate mode diagrams is more convenient. A separate mode diagram for minor environmental species (e.g., Cu, Pb, S, Si, Al) is not shown here.

The mode diagram of Figure 4.20 is useful for identifying the general conditions for the occurrence of modes and submodes of corrosion. This presentation is useful also for comparing with prevailing environmental chemistries, as discussed in Section F on the subject of superposition. Figure 4.20 does not give the detailed dependencies of penetration or rate of corrosion as a function of principal variables; rather, this figure provides perspectives for the occurrence of the modes and submodes.

It appears that diagrams such as Figure 4.20 relate primarily to conditions of surface chemistry that relate to the initiation of SCC. As SCC progresses, it is progressively more controlled by conditions at the tip of the advancing SCC and less controlled by conditions at the surface. It is likely that the propagation phase of each of the submodes in Figure 4.20 is controlled by the same crack tip chemistry [30], whereas the initiation phase is controlled by the electrochemistry defined in Figure 4.20. Evidence for the pH independence of crack propagation in the same chemical system is shown in Figure 4.21. Thus, while the AkSCC and AcSCC submodes are well defined and are limited, respectively, by a lower and higher pH, the propagation of SCC as shown in Figure 4.21 shows no such dependence. Whether the propagation of SCC can be properly considered as a

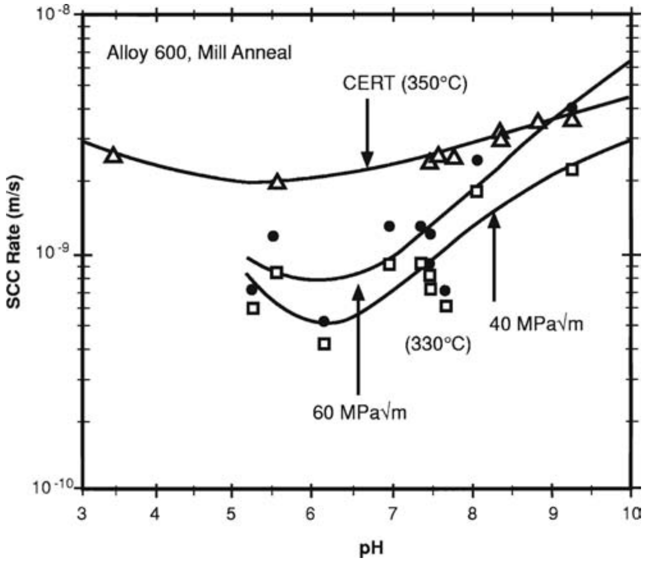

FIGURE 4.21. Effect of pH on the velocity of SCC for alloy 600. Constant Extension Rate Test (CERT) results obtained at 350°C and constant-load test results obtained at 330°C, (After Szklarska-Smialowska et al. [31].)

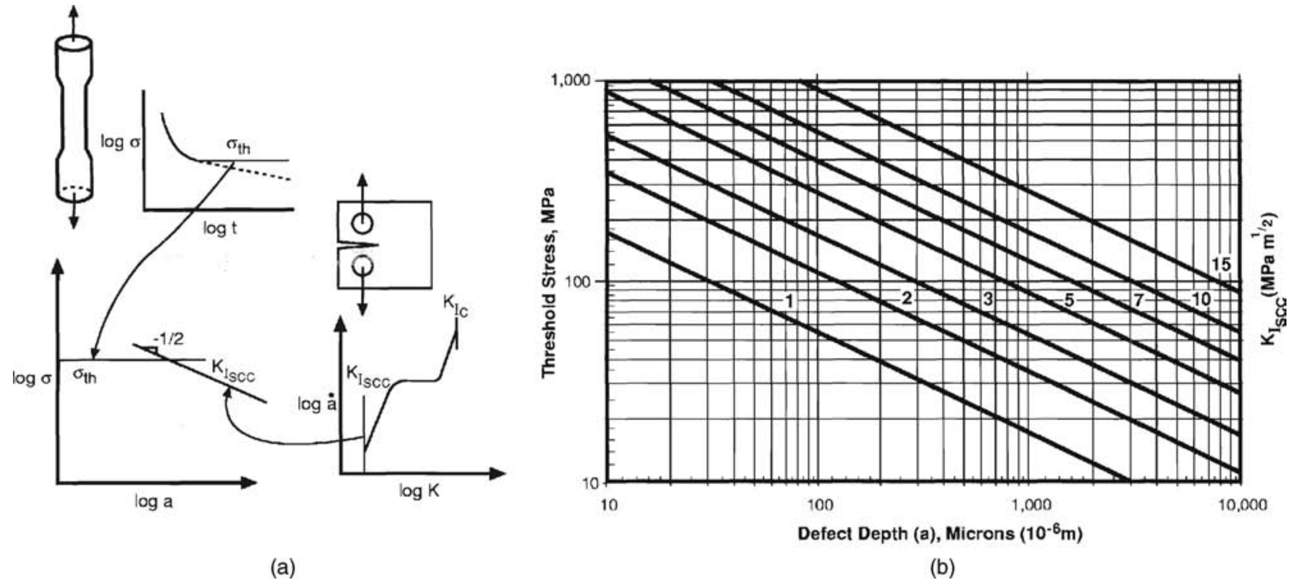

FIGURE 4.22. Procedure for distinguishing between initiation and propagation. (a) Schematic view of log stress versus log of defect depth for the cases of initiation stress as determined from smooth surface and SCC growth as determined from a precracked specimen. (After Staehle [1].) (b) Log–log plot of parametric values of threshold stress (horizontal lines) and $K_{I_{scc}}$ ($-\frac{1}{2}$ slope).

single chemical process independent of the surface environment is not clear.

In developing the dependencies of SCC in the initiation and propagation stages, it is useful to understand the depth of the transition between initiation and propagation. Figure 4.22 provides such bases. Figure 4.22(a) shows a schematic plot of log stress, σ, on the ordinate and log defect depth, a. The horizontal line, σ_{th}, corresponds to a threshold stress for SCC based on testing smooth specimens; a line with a slope of $-\frac{1}{2}$ [cf. with Eq. 4.4(a)] is shown in Figure 4.22(a) corresponding to $K_{I_{scc}}$ (see Fig. 4.15) obtained from SCC testing with precracked specimens. The intersection between the horizontal and sloping lines defines the transition between initiation and propagation.

A parametric plot is shown in Figure 4.22(b) where specific values of horizontal and $-\frac{1}{2}$ sloping lines are plotted. Suppose, for example, using the plot in Figure 4.22(b), that the threshold stress for SCC is 100 MPa and the $K_{I_{scc}}$ is 5 MPam$^{1/2}$; these lines intersect at a defect depth a of 800 μm or 32 mils, which is most of the wall thickness of the tubes shown in Figures 4.2 and 4.5(a). This depth is the nominal transition between initiation and propagation for a specific material in a specific environment; the numbers of this example are typical for AkSCC of alloy 600 at 300°C.

In addition to there being multiple submodes of SCC as shown in Figure 4.20, multiple submodes often occur for general corrosion, pitting, and intergranular corrosion as these submodes depend differently on principal variables. Other submodes than for SCC are noted in the chart of Figure 4.5(b).

These different modes of corrosion and degradation, in the past, have been described as "forms" of corrosion. However, in the formulation of the historic so-called forms of corrosion, differences between the intrinsic response of materials and the prevailing geometric conditions were never distinguished. For example, in addition to the forms of corrosion being identified as general corrosion, pitting, intergranular corrosion, SCC, and corrosion fatigue (as in Fig. 4.3), such geometry-dependent forms of corrosion were identified as "crevice corrosion" and "galvanic corrosion." The latter are not intrinsic to the materials but are rather consequences of how local geometries affect chemical environments on local surfaces. For example, intergranular corrosion can initiate from a free surface or within a crevice or in a galvanic cell. Similarly, all modes of corrosion can initiate within a microbiological enclave.

This chapter defines modes of corrosion in Figure 4.3 as the intrinsic response of materials regardless of the geometry and environment. Geometric effects as they affect local chemistries are discussed in Sections C2–C6.

F. CBDA STEP [4]: SUPERPOSITION

At the CBDA step of superposition the domains of modes and submodes are compared with the domains of the environments as they are known at this point in the analysis. These domains can be compared as shown in the simple schematic illustration of Figure 4.23. Figure 4.23 compares a schematic view of an environment in potential–pH space with a mode of

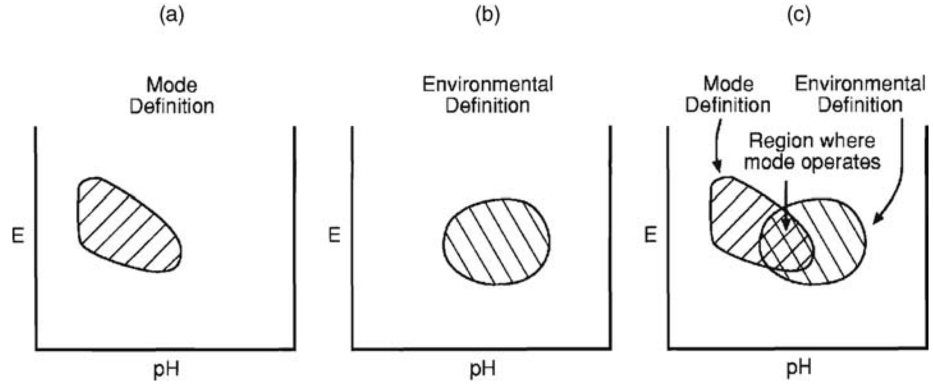

FIGURE 4.23. Schematic views of a corrosion mode diagram (a) (see Fig. 4.20), an environmental definition diagram (b), and their superposition (c). Shaded regions define boundaries of existence of a specific mode and a relevant environment. (After Staehle [27].)

corrosion plotted in the same coordinates. Where the shaded regions overlap is where significant degradation can be expected. In this region of overlap, it is desirable to determine how rapidly degradation can advance within whatever design life is expected. This depends on evaluating the principal variables that describe both the mode and the environmental conditions that apply to a specific LA_i.

If the overlap determined at this step of superposition involves significant corrosion, then changes may be required Such changes might involve changing alloys, revising the environment, changing the temperature, lowering stresses, or changing the design. Inhibitive environmental species can be identified at this point.

The step of superposition is, generally, the first where the need for changes is identified. The need for changes also becomes apparent during accelerated testing (Section I), prediction (Section J), and operation (Section K). There is, naturally, an obvious incentive to make necessary changes early.

G. CBDA STEP [5]: DEFINE FAILURE AND ACTION LEVELS

Failure needs to be defined because it provides the objective for analyses and ultimately for prediction. For example, in the food or architecture industries, a barely visible rusting may be a failure since it is unsightly. In much industrial equipment, a corrosion rate of 0.001 in./year for steel is quite acceptable, whereas such amounts of rust from the point of view of the food industry would be unacceptable. Each of these applications would be analyzed differently.

It is not uncommon for growing cracks to be considered acceptable (see Fig 4.15) so long as they are substantially less than a critical crack size [Eq. (4.4b) and Fig. 4.15(a)] and can be repaired at the next outage or shutdown. Until an inspection identifies a rate of crack growth or general corrosion that would produce penetration before the next outage (with some safety factor), remedial actions are usually not taken.

In the development of sites for storing radioactive waste, failure is taken as a minimum amount of radioactivity appearing in the groundwater after some time in the range of 10,000–10^6 years. Thus, the overall concept of failure here may have nothing to do with the integrity of the storage container but everything to do with the transport of radioactive species in the surroundings. This particular problem is challenging since it is not so easy to monitor the performance of containers of the radioactive waste owing to the long times and their relative inaccessibility associated with radioactivity.

Defining failure also involves statistical implications. Failure may not relate to failure at the mean lifetime (i.e., 50% failure) but to the occurrence of failure of 1%, 0.01%, or 0.001% of the tubes, welds, area, or units. Thus, failure might be defined for an entire heat exchanger, for example, as perforation of the first 10% of tubes; failure might be defined for other applications as failure of 0.1 or 0.01% loss of the elements. If the analysis and testing has not considered such a statistical objective, which occurs at times substantially less than the mean time to failure, the analysis is deficient, The application of statistical methods is discussed in Section H.

In designing components, it is common to define a "design life" [design life objective (DLO)] within which a component is expected to perform reliably. Sometimes a conservative additional life ["design life conservative objective" (DLCO)] is required so that there is no question about reliable performance within the desired design life. This design life or the conservative version becomes the target for prediction, and failure is defined when perforation occurs earlier than either DLO or the DLCO.

In addition to the initial DLO and DLCO concepts, certain equipment is built initially or modified later for life extension. Such an objective carries with it the need for even longer life. Thus, a life extension objective (LEO) and a life extension conservative objective (LECO) can be defined. At each

increment in these objectives longer life is needed from the components.

In addition to defining failure, it is necessary to define the extent of response in the event that failures occur. Such responses take the form of "action levels." Presumably, following the steps in the CBDA would minimize or even prevent the occurrence of failures. However, when failures occur and, almost by definition, are unexpected despite the attention given during a responsible CBDA, a clear idea of response is necessary. Such responses can be calibrated in terms of the DLO, DLCO, LEO, and LECO objectives. Thus, when failure occurs at a time less than that DLO, a substantial response is required. Such a response would be defined as "action level number one" (AL-1). Action levels are discussed in connection with Figure 4.36 in Section J. Thus, five action levels can be defined in terms of life objectives (where t_f is time to failure).

Action Level	Corresponding Time to Failure
AL-1	t_f < DLO
AL-2	t_f < DLCO
AL-3	t_f < LEO
AL-4	t_f < LECO
AL-5	t_f > LECO

The implementation of these action levels is discussed in Section J on prediction. Such targets as DLO, DLCO, LEO, and LECO provide objectives for the durations over which no failures should occur. Choosing which of these is a reasonable objective for design is a management problem.

In defining failure there are certain implications that need to be considered as follows:

[**1**] *Small Cumulative Fractions.* Most experimental work and resulting correlation equations are based on obtaining mean values, although such a condition is rarely stated (i.e., failure of 50% of the population). Often, the time required to fail 50% of anything is significantly beyond a practically acceptable fraction failed. More likely, failure occurs when a small fraction of elements, welds, or areas fail; and such small fractions failed may be taken as 0.001, 0.01, or 0.1%. Such smaller fractions of failure often occur several orders of magnitude earlier in time than the mean failure time depending greatly on the slope of the statistical dispersion curve. This situation is discussed in connection with Figures 4.27 and 4.33 in Section J.

Thus, if a small fraction failed is, in fact, an operating definition of failure, then serious considerations need to be given to how such a failure is actually predicted since there is no prevailing theory for the physical bases of dispersion, and there are few data available that describe dispersion (dispersion relates to the distribution of data and is discussed in Section J) as applied to corrosion data. This subject is considered in Section J, where step **[6]** of the CBDA, establish statistical framework, is discussed.

[**2**] *Location of Initial Perforation Relative to a Catastrophic Path.* If perforation were to occur in che middle of a relatively tough material, its significance might be relatively minor except for the leak that might ensue. On the other hand, if the same perforation occurs in the path of a low-toughness element (e.g., a weld), the perforation is more important, especially since one perforation rarely occurs by itself. Owing to a possibly much lower K_{I_c} or lower $K_{I_{scc}}$ in the weld region compared with the surroundings, an initially minor penetration could become critical at a relatively small size. Such possibilities are illustrated in Figure 4.24. Figure 4.24(a) shows a circumferential weld, Figure 4.24(b) shows a longitudinal weld, and in Figure 4.24(c) a multiple welded vessel is shown. In Figure 4.24, a relatively small defect is magnified in its influence by the extensive low-toughness paths available for propagation.

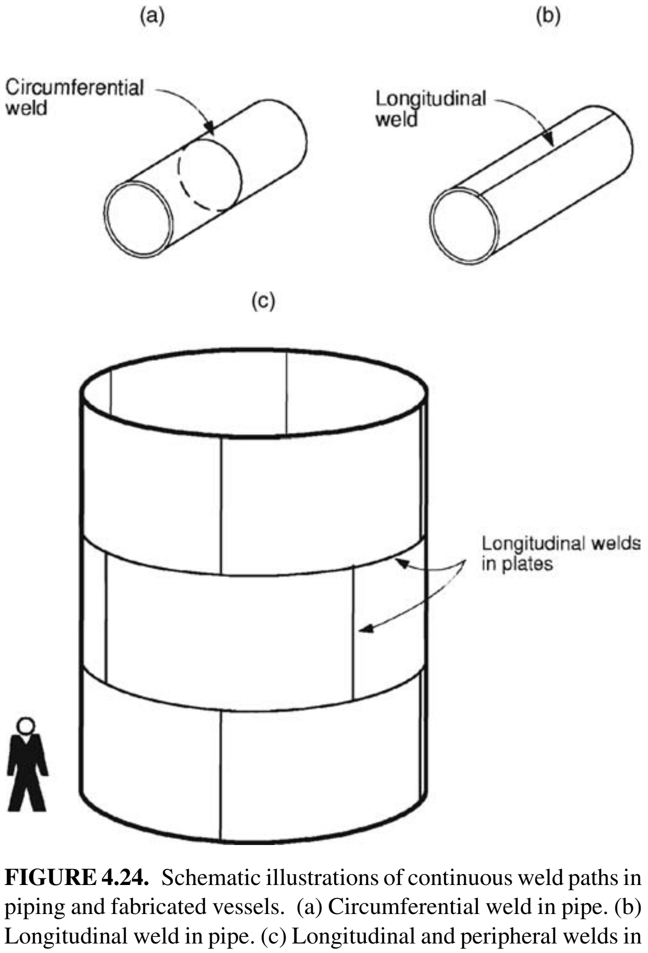

FIGURE 4.24. Schematic illustrations of continuous weld paths in piping and fabricated vessels. (a) Circumferential weld in pipe. (b) Longitudinal weld in pipe. (c) Longitudinal and peripheral welds in a weld-fabricated vessel.

[**3**] *Simultaneous Penetration Due to Multiple Similar Conditions.* In the case of a cylindrically welded pipe, there are three factors that act to promote simultaneous penetration around the periphery: (a) similar weld heating conditions that might, for example, produce a corrosion-prone microstructure such as sensitization; (b) similar stresses owing especially to automatic welding; and (c) a uniform crevice, for example, from a peripheral thermal shield (similarly uniform crevices are often produced in heat transfer crevices and in sludge piles). These are illustrated in Figure 4.25. Figure 4.25 shows three cases of uniform conditions around a circular geometry where combinations of uniform environment, uniform metallurgy, and/or uniform stresses can be simultaneously present ("congruent" condition). Figure 4.25(a) shows the case of a tube in a tubesheet [similar to Figs. 4.2 and 4.5(a)]; Figure 4.25 (b) shows the case for a circumferential weld of a pipe; Figure 4.25(c) shows the case for a thermal sleeve in a nozzle attached to a pressure vessel. The occurrence of a failure related to the uniform conditions illustrated in Figure 4.25(c) is shown in Figure 4.26, where the SCC penetration extended 270° of the periphery and the penetration was approximately uniform. All of the penetration noted in this figure occurred before leaking was detected.

While Figure 4.25 suggests that all three factors of metallurgical structure, stress, and crevice chemistry can produce extensive penetration before leaking is observed; such relatively uniform penetration can occur when only one of these factors exists. Such a circumstance is favored in some cases where the velocity of cracks is independent of stress intensity in the "plateau region" in the plot of crack velocity versus stress intensity shown in Figure 4.15(c). The main factor that affects uniform penetration is uniformity in any or several of the three main influences.

[**4**] *Direction of Defect Relative to "Double-Ended Rupture*." When a corrosion defect occurs and is parallel to the axis of a tube or pipe (an axial defect), its perforation produces a leak. However, when a similar defect occurs and is circumferential, then the leak may lead to the rupture of the total cross section of the pipe. Thus, the direction of perforation relative to

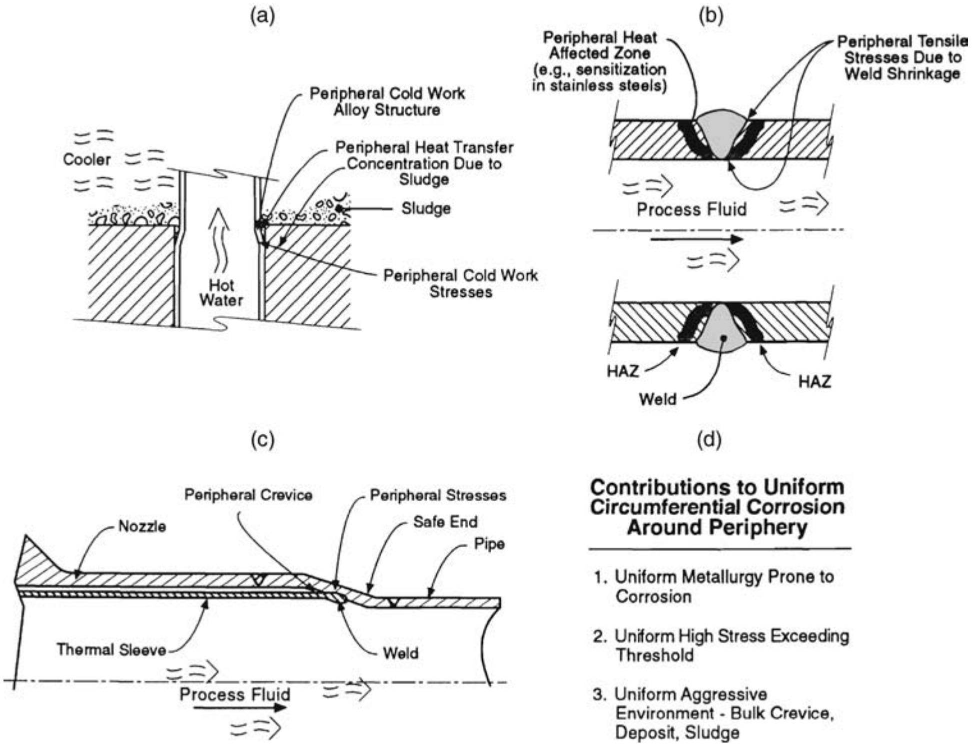

FIGURE 4.25. Schematic views of circumstances where relatively uniform conditions occur around periphery of components with circular cross sections. The major uniform peripheral conditions, when they occur, are usually, metallurgy, stress, and aggressive environments. (a) Sludge pile adjacent to cold-expanded tube in tubesheet at the bottom of a heat exchanger. (b) Weld around pipe with process fluid inside, uniform metallurgy, and uniform stresses. (c) Thermal sleeve in nozzle of pressure vessel with uniform crevice, uniform weld metallurgy, and uniform weld stresses. (d) Summary of uniform conditions leading to uniform SCC or other corrosion.

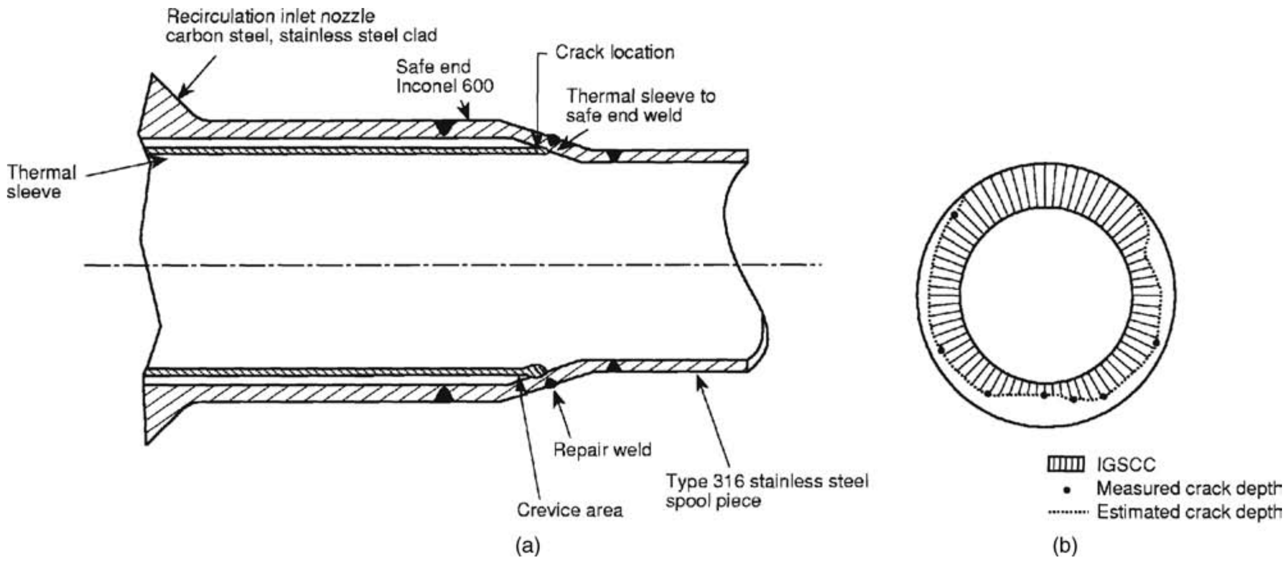

FIGURE 4.26. Crosssection of a recirculation inlet nozzle safe end from the Duane Arnold boiling water nuclear reactor. (a) Crosssection of safe end. (Pressure vessel to the left.) (b) Plan view of crack depth and peripheral distribution looking in the direction of the axis of the pipe. (After [32] modified by Staehle [1].)

the axis of a tube determines whether the tube will sustain only leaks or a rupture of the total cross section. The latter is called a double-ended rupture.

[**5**] *Redundant and Nonredundant Elements*. An example of redundant and nonredundant elements is found in bridge suspensions. The failure of the Silver Bridge in Ohio involved the complete collapse of a suspension bridge [33]. The suspension was provided by a series of bars connected by dowel joints. Failure occurred when a SCC defect propagated, eventually exceeded K_{I_c}, and catastrophic fracture occurred.

The type of nonredundant suspension used in the Silver Bridge is no longer used. Instead multiple cables are used which, in turn, have multiple wires; such cables are also substantially overdesigned. If a wire breaks, it is a minor problem, and its failure can usually be detected.

The cable-type suspension is a redundant structure whereas the Silver Bridge was a nonredundant structure. In a nonredundant structure, more attention has to be given to corrosion protection and to fracture toughness (a high K_{I_c}) as well as to more frequent and more careful inspections.

[**6**] *Sequential Failures*. Figure 4.15 identifies the sequence of events that lead to exceeding K_{I_c}. The earliest step may involve simply a penetration due to localized corrosion. When this defect exceeds either a SCC or CF threshold (e.g., $K_{I_{scc}}$), slow growth is initiated. After an SCC crack grows to a critical depth for an existing mean stress, K_{I_c} is exceeded, and fast fracture occurs.

Figure 4.15 suggests that when localized corrosion is observed, the eventual occurrence of catastrophic failure can be foreseen. This predictable sequence of events suggests that the occurrence of the initial defects should be prevented and that, should they occur, they or their cause should be removed.

[**7**] *LBB and BBL*. It is common to assume that corrosion-related failures will produce detectable leaks before any serious failure occurs. Such a condition is called "leak before break" (LBB). Such an assumption is supported by the fact that many industrial alloys have relatively high fracture toughnesses so thai any penetration by corrosion would be less extensive than could be reasonably expected before K_{I_c} would be exceeded. Thus, a leak due to corrosion would occur before K_{I_c} is exceeded. However, the considerations associated with the discussion of Figures 4.25 and 4.26 indicate that the LBB criterion for design may not be justified in some cases and especially where the simultaneous conditions described in Figure 4.25d obtain.

Had a serious mechanical transient occurred before the leak associated with Figure 4.26, a "break before leak" (BBL) would have occurred. Assuming that the BBL will not occur is not justified, in general, although such an occurrence is much less frequent than LBB.

[**8**] *Fraction Penetrated as Determined by Nondestuctive Examination (NDE)*. A common means of defining failure or of defining when an element should be removed or repaired is related to a fraction of the crosssection penetrated by corrosion. These penetrations arc usually determined by some NDE method. However, these NDE methods are often quite inaccurate unless they have been carefully calibrated and are

applied by experienced personnel. Even under the best of circumstances, results from NDE measurements are inaccurate. Thus, if 50% penetration (relative to an NDE method) is defined as the criterion for removal or for some kind of repair action, it needs to be recognized that the NDE measurement can be substantially inaccurate; thus, a measured penetration (by NDE) of less than some target extent could exceed the criterion for failure.

H. CBDA STEP [6]: ESTABLISH A STATISTICAL FRAMEWORK

Statistical methods are widely used for characterizing properties of environments, materials, and modes of failure. Generally, statistical methods are used to characterize both central tendencies and the dispersions about these central tendencies. There are numerous statistical methods used for such applications, and these are described in numerous textbooks [34, 35]. Distributions such as the normal, lognormal, Weibull, and extreme value are often used in characterizing failure phenomena. In this discussion only the Weibull distribution is discussed since it usually provides the best and most flexible characterization for corrosion and failure data.

Corrosion phenomena are particularly suited to statistical characterization owing to the inherently variable behavior of environments, materials, and modes even under the best of circumstances. While statistical methods have potentially great utility for characterizing and interpreting corrosion phenomena, such methods have not been used extensively. A useful overview of applying statistical methods specifically to corrosion has been prepared by Shibata [36]. Also, statistical methods have been applied to characterizing SCC by Akashi and Nakayama [37], where they have characterized several sequential steps with different statistical expressions and then combined the results in a single mathematical expression.

In addition to using statistical methods for characterizing the central tendencies and the dispersions of data, these methods can be used for predicting and analyzing the very early stages of failure where relatively small fractions of a system have failed (e.g., failure of a few tubes from thousands in a heat exchanger). The application of statistical methods is essential for predicting both central tendencies and the very early stages of failure; some of the important approaches are discussed here.

In many applications, it is necessary to predict when a small fraction or a single element of a system (e.g., one of many welds) would fail; that is, when does the first tube in a heat exchanger or the first weld of many in a long pipe fail? When does the first canister of radioactive waste fail? Unfortunately, achieving such predictions is not often an objective of experimental work. Most experimental work is organized to determine when the mean failure occurs, and no methods or data are produced to predict the first failure or even to predict the functionality of the dispersion of data which would be required to predict trends relevant to the occurrence of the first failure.

This section concerning step **[6]** of the CBDA considers the statistical framework for predicting failure in the context of the mode–location chart of Figure 4.5(b). Thus, each of the mode–location cases, or a given *j–i* combination, if it is relevant and needs to be evaluated, should be characterized by some kind of statistical construction. Such constructions can be estimated, can be based upon prior engineering performance, or can be based upon laboratory data.

For the purpose of this discussion, we are not concerned with the more gross cases of the failure of automobiles, jet engines, or other complex machinery where failures can occur and can be modeled by statistical procedures but where the details of failure may be related to multiple mechanical and human, but not necessarily degradation, factors.

There are numerous texts that describe the application of statistical methods to problems such as the mode–locations of concern here. Such texts from Abernethy [38] and Nelson [39, 40] should be reviewed.

There are three main sources of variability in considering the statistical predictions necessary for evaluating the *j–i* cells of the mode–location matrix in Figure 4.5(b). The first source is the mode or submode itself. While sentiment has been expressed for the "deterministic" prediction of modes and submodes of corrosion (or any degradation), the occurrence of these modes under the best of circumstances is inherently variable. For example, the location of initiation sites is inherently variable. Local stresses vary by a factor of about 3, and propagation of stress-related modes depends generally on a power law function. Any intergranular path contains variable chemistries. As the mode propagates, the region in which propagation has occurred is filled with reaction products of nondefined porosity and chemistry. Thus, the initiation and propagation of any mode is inherently and intrinsically variable.

The second source of variability arises from the heat-to-heat, weld-to-weld, or fabrication and processing variability. These sources are extrinsic to the inherent variability. The third source of variability arises from the environments (Section C2)], which are both variable and often difficult to specify.

The most widely used statistical correlation for characterizing failures is the Weibull distribution. Its probability density function is given by Eq. (4.5) and its cumulative distribution (probability of failure) is given by Eq. (4.6):

$$f(t) = \left[\frac{b}{\theta - t_0}\left(\frac{t - t_0}{\theta - t_0}\right)^{b-1}\right]\left\{\exp\left[-\left(\frac{t - t_0}{\theta - t_0}\right)^{b}\right]\right\} \tag{4.5}$$

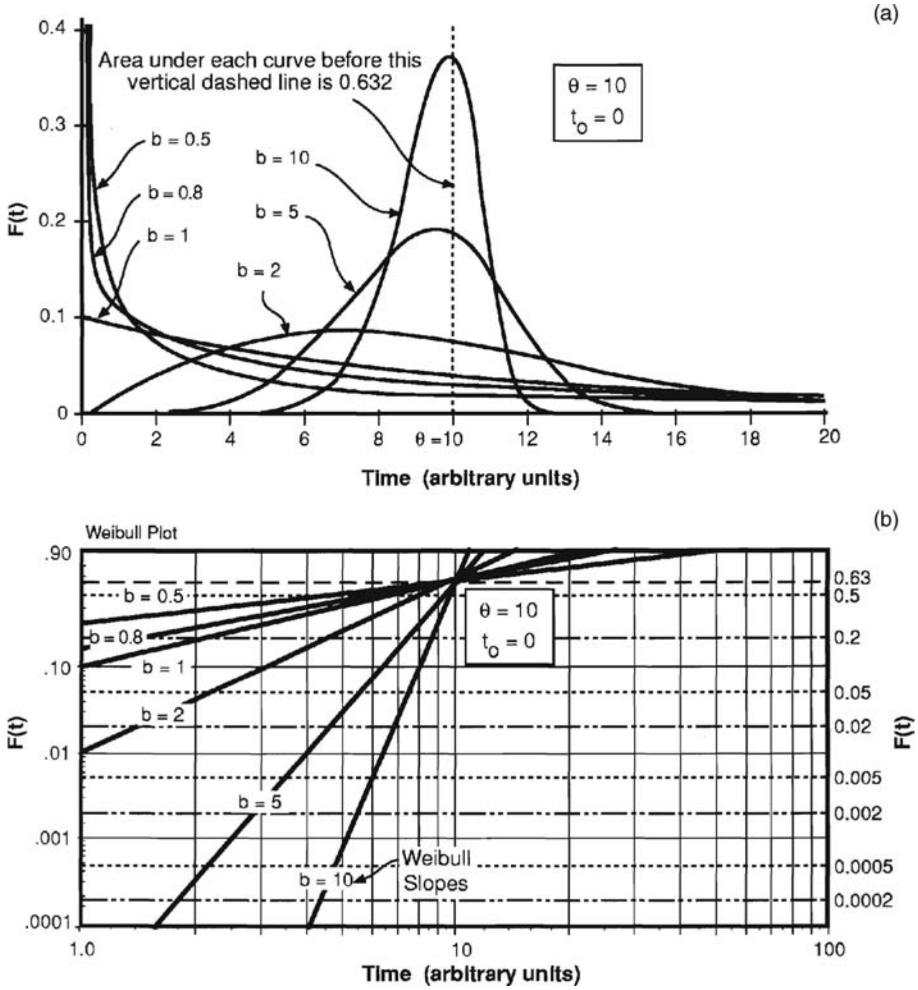

FIGURE 4.27. Weibull plots for constant characteristic, $\theta = 10$, and various slopes, $b = 0.5$, 0.8, 1.0, 2, 5, 10. The parameter t_0 is taken as zero. Time in arbitrary units. (a) Probability density function, f(t), versus time. (b) Cumulative fraction failed, F(t), versus time. (After Staehle et al. [42].)

$$F(t) = 1 - \exp\left[-\left(\frac{t - t_0}{\theta - t_0}\right)^b\right] \tag{4.6}$$

where

$t =$ time
$f(t) =$ probability density function
$F(t) =$ cumulative distribution [integral of $f(t)$]
$\theta =$ Weibull characteristic value
$t_0 =$ initiation time (a statistical constant)
$b =$ Weibull slope (higher values indicate less dispersion)

Figure 4.27 shows examples of the probability density function and cumulative distribution for a constant value of the Weibull characteristic, $\theta = 10$, and the $t_0 = 0$. Of particular interest in prediction is Figure 4.27(b), which shows $F(t)$ versus time; typical slopes for materials-related failures vary from $b = 0.5$ to $b = 10$, although some failure processes occur outside this range. Taking, for example, the lower slopes of $b = 1$ or 2, the time of occurrence of failure at 0.01 or 0.001 (1 or 0.1%) in Figure 4.27(b) is seen to be substantially less than the Weibull characteristic θ (close to the mean), which is taken as 10 in this schematic plot. Thus, having determined the mean behavior is useless for predicting early failures without a knowledge of the dispersion or slope of the probability plot of Figure 4.27(b).

Some clear quantification of the Weibull slope b (dispersion) is desirable for predicting performance, although, in practice, such information is not often available. In fact, the slope of the dispersion, the Weibull b, is often developed initially by plotting the fractions failed versus time for early field failures; such fractions would be in the range of 0.001–0.1% for large numbers of elements (e.g., tubes in a heat exchanger). Such fractions are shown on the ordinate of

Figure 4.27(b). The procedure for developing cumulative distributions from early failure data is particularly well described by Abernethy [38].

An example of data from the SCC failure of welds in stainless steel piping plotted in Weibull coordinates is shown in Figure 4.28 from the work of Eason and Shusto [41]. The data here are taken over a large population of welds in stainless steel pipes in numerous boiling water reactor (BWR)–type nuclear plants. In the case of leaking at a weld, as noted in Figure 4.24, even a single leak in a pipe requires that the plant be shut down for repairs. Furthermore, if leaking of radioactive water is involved, such a failure is even more serious. The data in Figure 4.28 emphasize that important failures can occur at times much shorter than the mean value, that is, 0.50 of cumulative fraction. From Figure 4.28, it is evident that predicting the mean value of failure is not adequate; a method for predicting the dispersion, the Weibull slope, is required for predicting the very earliest failures. While the failures noted in Figure 4.28 have occurred over times as long as ~ 20 years, the Weibull characteristic time θ (0.632 fraction failed) occurs at 144 and 1675 years for the large and small pipes, respectively. This large difference between the Weibull characteristic and the times observed in Figure 4.28 results from the large dispersions of data that are characterized by low values of the Weibull slope b, which are 1.2 and 1.4 [for comparison,

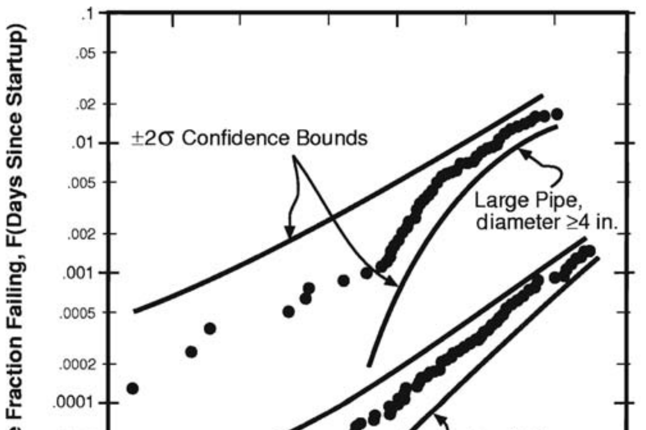

FIGURE 4.28. Cumulative fraction of welds failed in terms of repair rates in stainless steel pipes designated as "large diameter, ≥4 in." or "small pipe diameter, <4 in." from BWR-type nuclear plants. The larger diameter pipes include only IGSCC, and the smaller pipes include all failure modes. The Weibull characteristic θ and the Weibull slope b for the larger diameter data are approximately 144 years and 1.2 and for the smaller diameter are approximately 1675 years and 1.4, respectively. (After Eason and Shusto [41].)

the effects of slopes are shown in Fig. 4.27(b)] for the large and small pipes, respectively.

From the discussion concerning the mode–location cases in Figure 4.5(b), it is clear that whatever statistical formulation is developed needs to incorporate dependencies on the principal variables, as shown in Figure 4.19 and Eqs. (4.1)–(4.3). Furthermore, these dependencies need to be developed in such a framework that predictions from accelerated tests can be integrated into the statistical expressions. If a general correlation of data, starting with Eqs. (4.1)–(4.3) has the form of Eq. (4.7), for example, for SCC, involving simple dependencies on hydrogen ion concentration, stress, and temperature, then the Weibull parameters of Eqs. (4.5) and (4.6) would be expected to have the forms shown in Eqs. (4.8)–(4.10) [42]:

$$x = D[\mathrm{H}^+]^n \sigma^m e^{-Q/RT} t^q \tag{4.7}$$

$$\theta = \theta_0 [\mathrm{H}^+]^{n_\theta} \sigma^{-m_\theta} e^{Q_\theta/RT} \tag{4.8}$$

$$\frac{1}{b} = \frac{1}{b_0} [\mathrm{H}^+]^{-n_b} \sigma^{-m_b} e^{Q_b/RT} \tag{4.9}$$

$$t_0 = t_{0,0} [\mathrm{H}^+]^{-n_{t_0}} \sigma^{-m_{t_0}} \mathrm{e}^{Q_{t_0}/RT} \tag{4.10}$$

where the equations have the same meanings as for Eqs. (4.1)–(4.3), (4.5), and (4.6). The constants would be particularized to the Weibull parameters. Note that Eq. (4.8) is given as $1/b$; in this sense an increasing value corresponds with increasing dispersion. In Eqs. (4.7)–(4.10), some terms have been omitted for simplicity; more extensive expressions are given in Eqs. (4.1)–(4.3).

An example of relating Weibull parameters to a physical variable has been investigated by Shimada and Nagai [43] where they determined the effect of stress as shown in Figure 4.29; here, they determined the cumulative distributions for the SCC failure of Zircaloy-2 in iodine gas and from these data obtained correlations for the Weibull parameters. The correlation equations for the Weibull parameters were calculated by Fang and Staehle [44].

If data for use in Figure 4.5(b) are obtained from statistical methods, it is likely that the information to be entered into the *i–j* cells would be failure times for some cumulative failure fraction. For example, time to failure of 0.1% might be taken as the appropriate data. For comparison, it might also be useful to enter the mean time to failure (i.e., time for 50% failure). The relationship between statistically defined data and *j–i* cells of Figure 4.5(b) is shown schematically in Figure 4.30.

As a final note, despite the great importance of the dispersion as well as the initiation time to predicting early failures, there is no theory or physical foundation for their character. Most physical theory in corrosion is relevant only

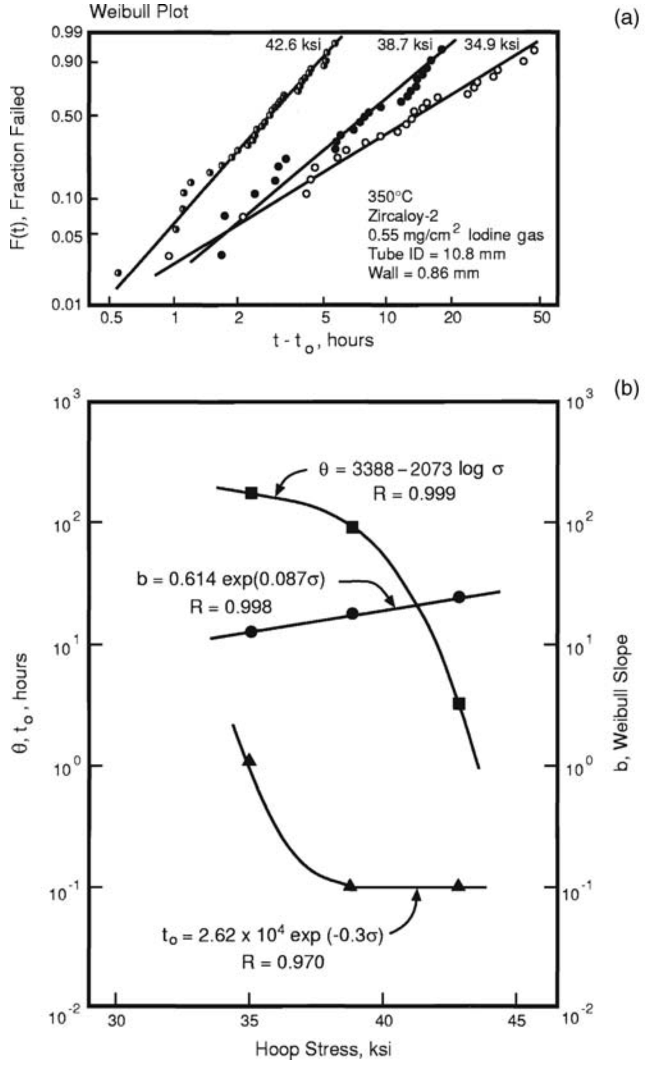

FIGURE 4.29. Effect of stress on the cumulative failure rate of Zircaloy-2 (1.5 Sn–0.15 Fe–0.10 Cr–0.05 Ni) in iodine gas. (a) Cumulative distributions for three stresses. (b) Effect of stress on Weibull characteristic θ, Weibull slope b, and Weibull initiation time t_0. (Adapted from Shimada and Nagai [43].) Correlation equations in (b) calculated by Fang and Staehle [44]. The coefficient of correlation for these curves with the data are given as *R*.

to the mean value or the Weibull characteristic, and even such theories require adjustable parameters.

I. CBDA STEP [7]: ACCELERATED TESTING

The purpose of accelerated testing is to confirm or improve the credibility of predictions that support achieving an objective such as design life (DLO). Accelerated testing is usually carried out by conducting experiments at more intense conditions using specifically intensified variables, "stressors," and, then, extrapolating the results to the conditions of interest. Such stressors might include temperature, stress, pH, increased concentrations of species, number of fatigue cycles per unit time, and similarly more intense conditions. For example, the "salt spray test" is often used to qualify materials and components for use on salted highways or for ocean and seaside use. In this case, the stressor involves more salt and more frequent applications together with continued high humidity relative to conditions expected for automobiles on winter highways. Incidentally, this test does not always provide reliable results.

The most important consideration in accelerated testing is that the mode of failure in the accelerated test must be the same as the mode of failure expected in the operating equipment. A well-known problem of erroneous accelerated testing involves corrosion fatigue. In much of the fatigue testing over the years, it has been found that the effects of stress cycling expected of a component over time can be assessed by conducting experiments where the number of expected stress cycles is accelerated by using higher cyclic frequencies in order to obtain data in a relatively short time.

However, when fatigue is affected by environments, the incremental propagation of fatigue cracks has been shown to depend on cyclic frequency with increasing propagation per fatigue cycle occurring at lower cyclic frequencies in the range of 1 Hz and lower with little effect of environments observed above 10 Hz. Thus, to have conducted experiments in excess of 1 Hz, when assessing the effects of environments on fatigue, would give a nonconservative result [45]. Premature failures, especially of ship propellers, have occurred because of such errors.

Figure 4.31 illustrates three stressors (temperature, stress, and pH) that could be used relative to an application involving relatively less intense conditions (i.e., target performance conditions). Along the coordinates for each stressor is noted the amount of acceleration based on a key parameter such as the activation energy (temperature), the stress exponent (stress), and the hydrogen ion exponent (concentration of hydrogen ions). In practice, these accelerations have to be determined.

Following the suggestion from Figure 4.29 [43], Figure 4.32 suggests that the effect of temperature could be studied at more intense conditions within a statistical framework and then extrapolated to lower temperatures. This plot suggests that both the mean value and the distributions can be extrapolated.

Statistical interpretations of data provide insights into apparent inconsistencies that result from accelerated testing. Figure 4.33 shows two hypothetical lines on a cumulative distribution plot similar to Figure 4.27(b). Line N-l corresponds, schematically, to a typical result for the mean and dispersion for the nominal condition. It is similar to the low Weibull slopes of Figure 4.28. The schematic line A-l corresponds to a cumulative distribution for a hypothetical accelerated test, and *b* is taken as 5.0, which is typical of such

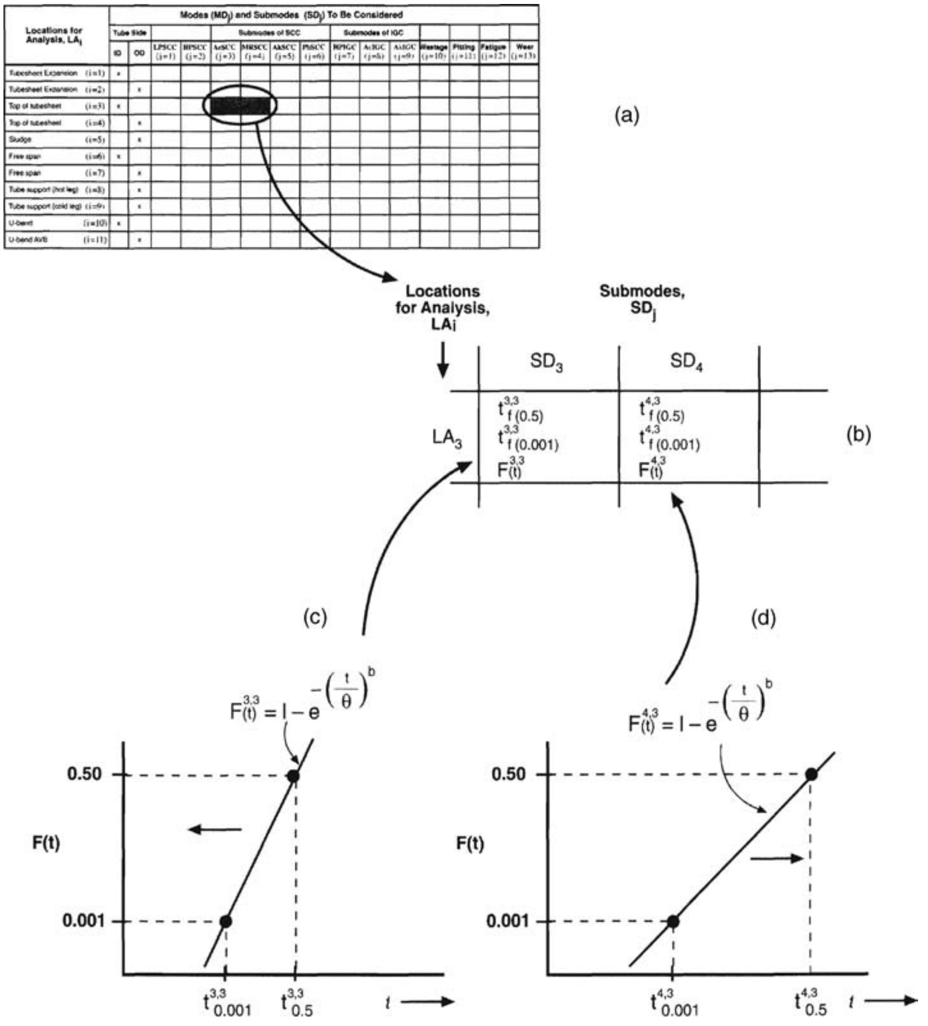

FIGURE 4.30. Including statistically calculated results in *j–i* cells of the mode–location matrix of Figure 4.5(b). From the mode–location chart of (a), sample cells are shown in (b), where values from two schematic data plots are shown in (c) and (d). Included in the cells are the times to failure for cumulative fractions failed of 0.001 and 0.50 (mean) together with the expressions for $F(t)$ from (c) and (d).

accelerated tests. Line N-l represents a real result from field performance after the equipment was designed, built, and operated. For the accelerated test, which might have been conducted ahead of time, the mean value of line A-l is determined to be 0.4 year. Thus, for the accelerated test the mean value occurs at 0.4 year, which is 100-fold less than the expected mean based on extrapolating early failure points on line A-l. A 100-fold acceleration is a common objective for accelerated tests, although such a factor of acceleration is often considered to be at the edge of credibility.

Comparing the hypothetical field result, N-l, with the hypothetical accelerated tests, A-l, shows that the ratio of the mean of the field results to the mean of the accelerated test is 100; however, comparing these results at a cumulative fraction failed of 0.01 gives a ratio of 3.4 rather than 100 between the two. At a cumulative fraction failed of 0.001, the ratio is <1 and is ~ 0.7. This ratio means that the failure of the field elements would occur earlier than the failure of the accelerated test at a cumulative fraction failed of 0.001. The ratio would be even less at 0.0001, which is in the early range of the field data of Figure 4.28.

The implication of the comparison in Figure 4.33 is that the mean values from accelerated tests are not generally good predictors for failure. Thus, a mean value from an accelerated test, following the pattern of stressors in Figure 4.31, would be both inadequate and misleading. This dilemma can be rationalized by referring to Eqs. (4.7)–(4.10). The comparison of mean values essentially follows Eq. (4.8). However, the dispersion follows Eq. (4.9); the dispersions provide the primary differences in lines N-l and A-l at the lower cumulative fractions.

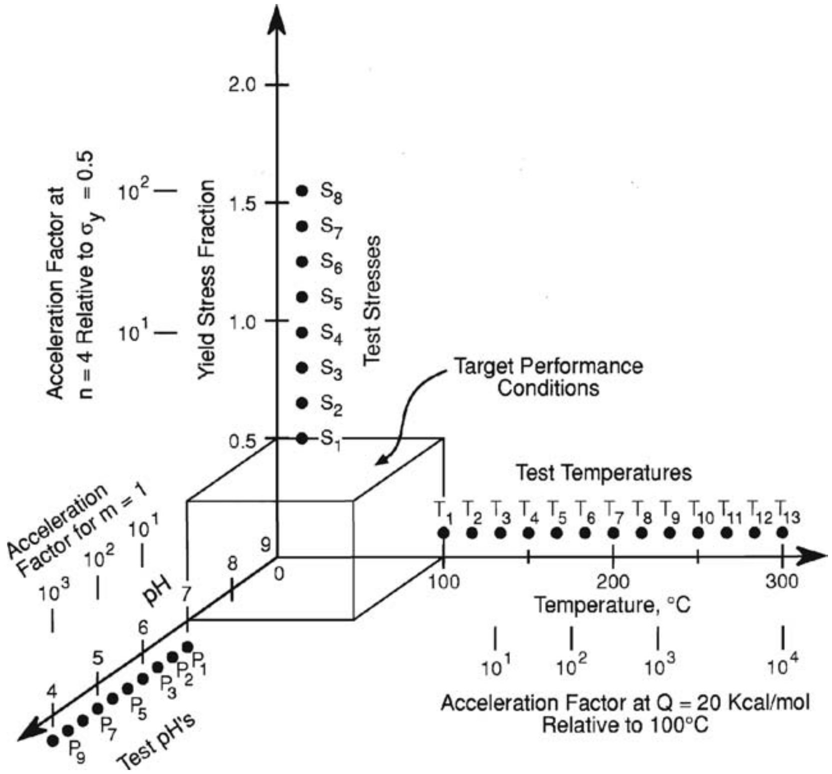

FIGURE 4.31. Stressors of temperature, stress, and pH relative to target performance conditions. Possible test conditions shown along each stressor with the magnitude of acceleration shown for selected values of stressor constants. (After Staehle [1].)

Equation (4.9) suggests that increased values of the stressors decrease the dispersion. While this is assumed in the formulation of Eq. (4.9), the pattern is well known. Thus, the steeper slope of A-l in Figure 4.33 compared with N-l results from the more narrow dispersion (greater slope of the Weibull *b*) produced by the accelerating stressors.

Line A-2 in Figure 4.33 shows how a predicted failure rate would appear if the Weibull slope did not change from the accelerated test in A-1 for a 40-year life. However, even with such a prediction the cumulative failure would be $\sim$10 years for the 0.001 fraction. This does not provide the 40-year life if the 0.001 cumulative fraction is taken as the 40-year objective. In fact, if the Weibull slope remains 5.0, then a cumulative rate of the type in A-3 would be required with a mean time of $\sim$ 170 years. Line N-2 shows the characteristic failure rate that would be required if the criterion for failure is a cumulative failure fraction of 0.001 and the Weibull slope is 1.0.

Comparing Figure 4.33 with Figure 4.32 suggests an inconsistency. However, had several cumulative distributions been determined as suggested in Figure 4.32, the result of Figure 4.33 could have been predicted by extrapolation.

Validating accelerated tests is a continuing concern. On the other hand, were it not for accelerated tests, performance of equipment would have to be guessed, or substantial delays would be required until credible data could be accumulated. To develop useful accelerated tests, it is necessary to quantify and predict both the mean and the dispersion.

J. CBDA STEP [8]: PREDICTION

Predicting failure (as defined in step 5 of the CBDA, Section G) and assuring performance are the goals of steps **[1]**–**[7]**. Step **[8]**, prediction, then involves synthesizing the results of steps **[1]**–**[7]** of the CBDA. The format for organizing the necessary data to support predictions is that in Figure 4.5(b), and the steps are identified in Section B3. Possible approaches for responding to each of the *j*–*i* cells are shown in Figure 4.6(a), and the application of statistical analyses to answering the questions of each cell is illustrated in Figure 4.30.

At this point, it is necessary to decide what specific information should be placed in each of the *j*–*i* cells and how the information in all the cells for a given subcomponent should be aggregated. [Actually, such a step would have been resolved in connection with CBDA steps **[5]** and **[6]**—define failure and action levels and establish a statistical framework

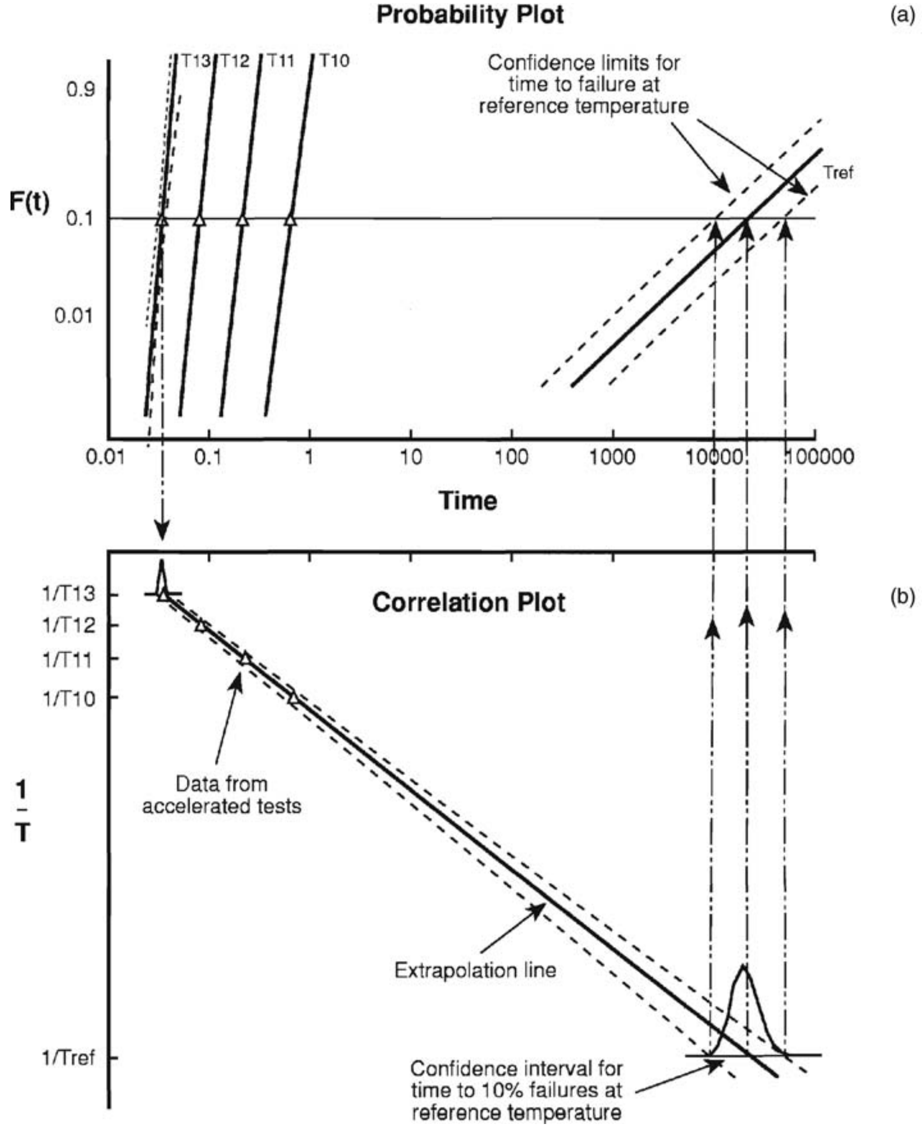

FIGURE 4.32. (a) Schematic cumulative failure plots showing curves for high temperatures associated with acceleration tests and for a reference temperature associated with the expected application. Confidence limits are also noted. (b) Plot of $1/T$ versus time showing probability density functions corresponding to cumulative probability plots. (After Staehle et al. [42].)

(Sections G and H)]. A simple approach could involve determining the time for (e.g., 0.1%) failure in each of the cells assuming that something is known about the relationship between accelerated testing and field performance as described in Section I. Such an approach is illustrated in Figure 4.30. If the necessary statistical distributions are available, then this or any percent failure as a criterion can be calculated and used in the *j–i* cells. Other approaches can be developed, especially when the statistical distributions can be developed from either laboratory data or field experience.

A specific approach to evaluating the contribution of multiple mode–location cases is illustrated in Figure 4.34 for the case of a steam generator considered in Figures 4.2 and 4.5 [46], The mode–location cases of Figure 4.34 include many of those that are illustrated in Figure 4.2. The data for cumulative failures (dots) shown in Figure 4.34 are based on information taken by NDE methods when examining tubes during outages.

At each outage, the total probability of failure is calculated by the relationship in Eq. (4.11). Equation (4.11) is based on the relationship that the total probability of success is $1 - F_T(t)$, that is, 1 minus the total probability of failure, $F_T(t)$. The total probability of success is then the product of the individual probabilities of success, that is, $1 - F_{j-i}(t)$, where $F_{j-i}(t)$ is the cumulative probability of failure of each

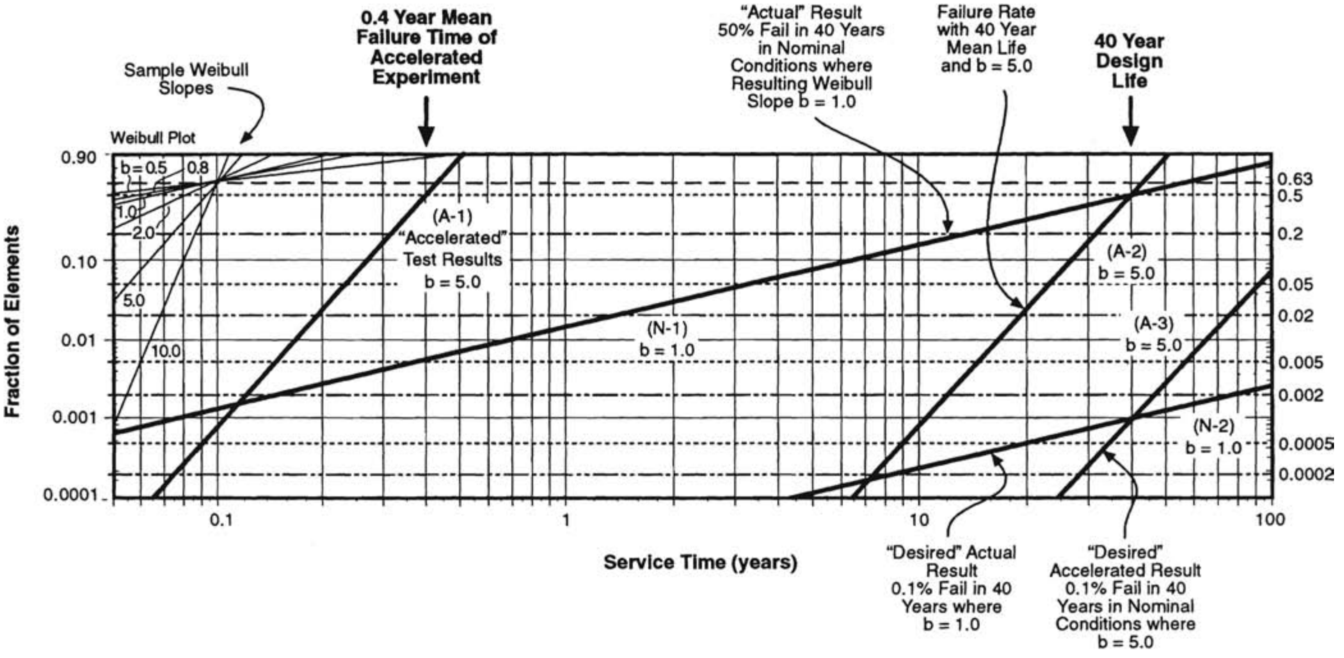

FIGURE 4.33. Schematic comparison of hypothetical actual field results with hypothetical accelerated testing using cumulative distributions versus time. The line N-1 corresponds to the nominal field failure rate with $b = 1$. Line A-I with $b = 5.0$ corresponds to an accelerated test. Line N-2 is the desired field failure rate that does not exceed 0.001 cumulative failures in 40 years. Line A-2 has the same slope as A-l for a mean life of 40 years; line A-3 has the same slope but with 0.001 failure in 40 years.

mode–location case. For simplicity, the $F_{j\text{–}i}$ (mode–location cases) are given as $F_1, F_2, \ldots, F_n$:

$$F_T(t) = 1 - [1 - F_1(t)][1 - F_2(t)] \cdots [1 - F_n(t)] \quad (4.11)$$

After the last measurements shown in Figure 4.34, given by the last dot on the respective plots of $F_{j\text{–}i}$, the curves are extrapolated using expected functionalities. The individual cumulative probabilities can then be summed as in Eq. (4.11) to give the overall aggregate of all mechanisms. In the case of steam generators failure occurs at some point where the number of tubes that have been "plugged" (i.e., taken out of service by plugging to prevent access of the primary to secondary side because perforation failures were identified by NDE) exceeds a designated fraction of the total number of tubes that corresponds to excessive loss of power. This point of overall failure might be, for example, 10% of all tubes or a 0.10 cumulative fraction failed of "the aggregate of all mechanisms." A prediction such as that in Figure 4.34 results from an orderly aggregation of all failures as identified in Figure 4.5(b).

Once specific versions of Figure 4.5(b) are organized for various subcomponents, then it is possible to predict overall performance. Another layer of analysis may be required to deal with the collected functionalities of the data in Figure 4.5(b). Such an approach is followed in applying Eq. (4.11) for the separate mode–location cases in Figure 4.34. However, the most appropriate approaches for aggregating data from the set of mode–location cases depend on both the forms of the results in the cells of Figure 4.5(b) for the various components and the criteria for failure of the engineering project.

The process of engaging in the CBDA and developing predictions is dynamic. As the *j–i* cells are evaluated, the design is changed to minimize the intensity of degradation in any cell. The overall performance will then be based upon a set of modified and rejected *j–i* cells. Once the conditions of individual cells are stabilized and agreed upon, it is possible to predict the overall performance, recognizing, of course, that certain cells have been assumed to be irrelevant or that certain approximations to their functional character can be developed. However, even such decisions would be (could be) a matter of record for later review and possible modification.

Once the *j–i* matrices are completed for various subcomponents, they can be aggregated as shown in the first step of Figure 4.35 for components. The results from the various components can then be aggregated as shown in the successive steps of Figure 4.35.

The predicted times to failure or similar results, as summarized in the appropriate versions of Figure 4.5(b), need to be compared with objectives for DLO, DLCO, LEO, and LECO as described in Section G, where step **[5]** of the CBDA is described. Providing that the predicted times to failure exceed the goals for DLO, DLCO, LEO, or LECO as required

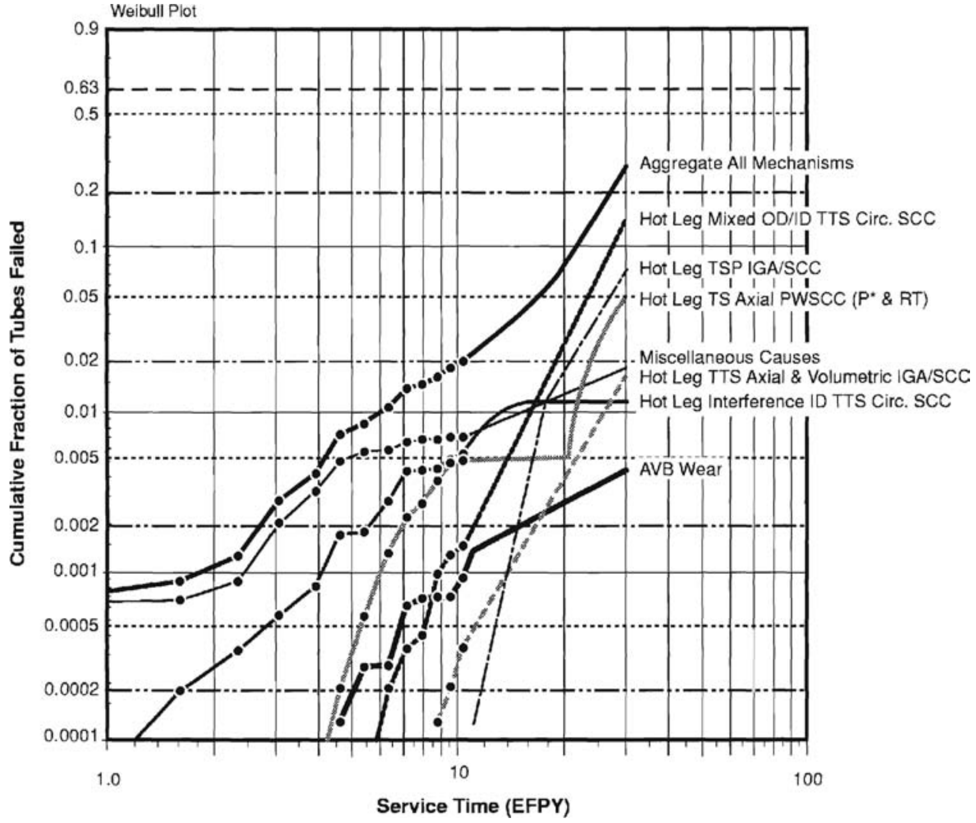

FIGURE 4.34. Cumulative fraction of tubes failed versus service time in equivalent full power years (EFPY) for seven mode–location cases from the set of steam generators in the Ringhals 4 pressurized water nuclear plant: TTS refers to "top of tube sheet," TS to "tubesheet," Circ. SCC to "circumferential SCC," P* to a special location where SCC may not be serious, RT to SCC at the "roll transition" location, and the AVB to "antivibration bars" (at top of steam generator to stabilize the tops of the U–bends), (Unpublished data provided by L. Bjornkvist of Vattenfall and J. Gorman of Dominion Engineering.)

by the application, no further work of prediction is required. Such conclusions assume that the *j–i* cells, which have been judged irrelevant or where correlations have been assumed based on marginal data, do not pose excessive risks.

One of the major benefits of the CBDA approach implicit in Figure 4.5(b) is the necessity for explicit action on every cell. Presumably, the design group would require that every cell be accounted for by some formal procedure. Whether the cell is evaluated (as in Figs. 4.6 and 4.30) by laboratory data, prior history, engineering judgment, assumption of irrelevance, or assumption of no problem, these actions would become part of the written record of the design.

The times specified for DLO, DLCO, LEO, and LECO then become action levels for operators; if failures occur in times less than these objectives, then certain actions are required. Figure 4.36 indicates hypothetically possible responses if failures in the field occur earlier than predicted. For example, if action level 1 (AL 1) is taken as failures occurring at times less than DLO, then numerous and serious actions might be required. These are illustrated by the black dots in Figure 4.35. If failures occur at longer times, the action levels require less extensive responses; progressively lower priority actions are noted by shaded and then nonshaded dots.

Figure 4.35 becomes the agenda for a major design review with respect to the CBDA. By the time it is possible to prepare a complete version of Figure 4.35, sufficient information should be available for a comprehensive assessment of the design. Often, owing to the necessities of schedules and costs, it is sometimes thought necessary to move ahead on construction before all the detailed designs are completed. The CBDA, through the chart of Figure 4.5(b), provides a continuing framework for assessing what decisions are necessary as detailed designs are completed.

In some designs, there are circumstances where inspection and design are not possible, although such circumstances should be avoided. For example, in the storage of radioactive waste where times of possibly 1 million years of nonfailure (i.e., nonrelease of more than a minimum amount

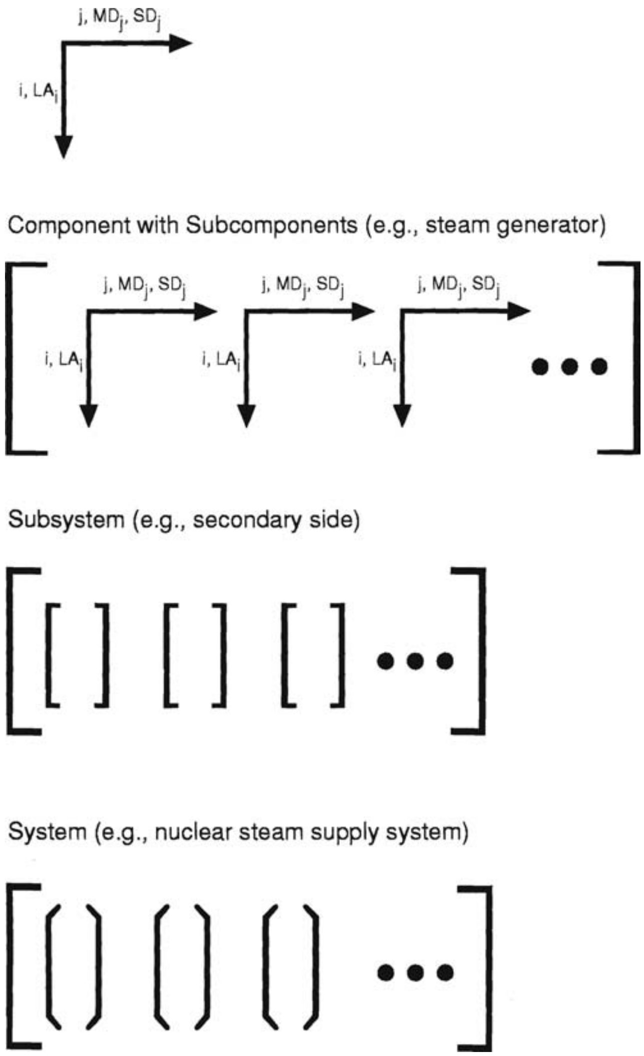

FIGURE 4.35. Mode–location, MD_j/SD_j–LA_i, charts aggregated for successively higher levels of system hierarchy.

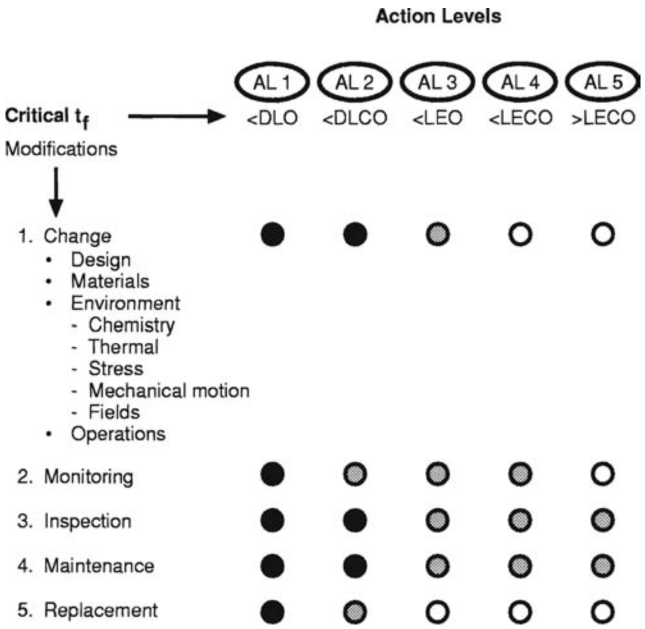

FIGURE 4.36. Schematic view of relationships among hypothetical times to failure, targets for design life (DLO, DLCO, LEO, and LECO), action levels (AL 1, AL 2, AL 3, AL 4, and AL 5), and responses appropriate for each action level. Black dots indicate high-priority actions; shaded dots indicate lower priority actions; open circles indicate no action.

of radioactivity) may be desired, a greater emphasis needs to be placed upon reliability than cases where much shorter design lives are specified. Other cases where explosions, release of radioactivity, or failure of implantable medical devices could occur, higher levels of assurance are required and need to be acknowledged in preparing Figure 4.5(b). Finally, in some relatively ordinary lifetimes certain subcomponents are not inspectable or cannot be monitored. Here, again, higher priorities need to be given to assuring performance in preparing Figure 4.5(b).

K. CBDA STEP [9]: MONITORING, INSPECTION, AND FEEDBACK

Monitoring and inspection provide feedback to designers and operators for comparing with predictions and for defining action levels. These responses vary greatly with applications and industries.

A discussion of monitoring, inspection, and feedback is a large subject and is not elaborated upon here. However, the choice of methods for monitoring and inspection should be based upon cues provided by the CBDA steps **[1]–[5]** (Sections C to G). Furthermore, the frequency of monitoring and inspection should consider the statistical character, step **[6]** (Section H), of the mode–location combinations.

Certain components and subcomponents are not readily inspectable, which implies that certain features of failure must be assumed, and higher levels of certainty of reliable performance should be required for such applications.

L. CBDA STEP [10]: MODIFICATION

As failures occur, certain inadequacies in the assumptions of high-priority mode–location cases and in what *i–j* cells can be neglected become apparent The occurrence of premature failures guides appropriate modifications and reconsideration of these assumptions. Once indications of performance and failures are available, then designers and operators can act to modify the design and/or operation.

As modifications are implemented, steps in the CBDA need to be repeated since modifications change the system and its response to various stressors.

ACKNOWLEDGMENTS

I am greatly indebted to many of my friends and colleagues for their insights, suggestions, and interest in the subject of this chapter. I have discussed various aspects of this subject over many years with: Bob Abernmethy of Weibull Risk and Uncertainty Analysis, Masatsune Akashi of Ishikawajima Harima, Peter Andresen of General Electric, Mick Apted of QuantiSci, Hans Arup formerly of the Danish Corrosion Center, Allen Baum of Westinghouse Bettis, Richard Begley of Westinghouse, Philippe Berge formerly of EDF, Lars Bjornkvist of Vattenfall, Walter Boyd formerly of Battelle, Ron Brown formerly of Shell, Spencer Bush formerly of Pacific Northwest Laboratories, Dwayne Chesnut of Lawrence Livermore National Laboratory, Kim Clark of Aptech Engineering, Richard Claassen formerly of Sandia, the late Norman Cole of MPR Associates, John Congleton of the University of Newcastle-upon-Tyne, Robert Cowan of General Electric, Gustavo Cragnolino of Southwest Research, David Curtis of Naval Sea Systems Command, Jacques Daret of CEA, Tom DeWitz of Shell, the late Abe Dukler of the University of Houston, David Duquette of Rensselaer Polytechnic Institute, Ernie Eason of Modeling and Computing Services, Geof Egan of Aptech Engineering, Jan Engstrom of Vattenfall, Zhi Fang of the University of Minnesota, the late Mars Fontana of The Ohio State University, Peter Ford of General Electric, Rick Gangloff of the University of Virginia, Frank Garner of Pacific Northwest Laboratories, Dick Garnsey of NNC Limited, Tracy Gendron of Atomic Energy Canada Limited, Bill Gerberich of the University of Minnesota, Gerry Gordon formerly of General Electric, Jeff Gorman of Dominion Engineering, Mac Hall of Westinghouse Bettis, Carolyn Hansson of the University of Waterloo, Bob Hermer of Westinghouse Bettis, Dick Horvath of Shell, Keizo Hosoya of JGC, the late Bob Jaffee of the Electric Power Research Institute, Lee James formerly of Westinghouse Bettis, Randy John of Shell, Joung Soo Kim of Korea Atomic Energy Research Institute, Uh Chul Kim of Korea Atomic Energy Research Institute, Yong Soo Kim of Yonsei University, Tatsuo Kondo formerly of Japan Atomic Energy Research Institute, Jerry Kruger formerly of Johns Hopkins University, Il Hiun Kuk of Korea Atomic Energy Research Institute, Jiro Kuniya of Hitachi, Ron Latanision of the Massachusetts Institute of Technology, Phil Lindsay of Aptech Engineering, Bill Lindsay formerly of Westinghouse, Brenda Little of the Stennis Space Center, Jesse Lumsden of Rockwell International, Digby Macdonald of Stanford Research Institute, Dan McCright of Lawrence Livermore National Laboratory, Art McEvily of the University of Connecticut, Al McIlree of the Electric Power Research Institute, Harry Mandil formerly of Naval Sea Systems Commands, Tom Marciniak of Engineering Systems, Bruce Miglin of Shell, Peter Millett of the Electric Power Research Institute, Anders Molander of Studsvik Energy, Charles Morin of Engineering Systems, Tomomi Murata of Nippon Steel, Joe Muscara of the Nuclear Regulatory Commission, Hiroo Nagano formerly of Sumitomo, Paul Nelson of Shell, Roger Newman of the University of Manchester, Suat Odar of Siemens, Hideya Okada formerly of Nippon Steel, Takatsugu Okada of Toshiba, Bob O'Shea of Engineering Systems, Redvers Parkins of the University of Newcastle-upon-Tyne, Tom Passell of the Electric Power Research Institute, Joe Payer of Case Western Reserve University, Tom Pigford of U.C. Berkeley, Fred Pocock formerly of Babcock and Wilcox, the late Marcel Pourbaix of CEBELCOR, Mike Pryor formerly of Olin, Robert Rapp of The Ohio State University, Peter Rhodes formerly of Shell, Ted Rockwell formerly of Naval Sea Systems Command, Dan van Rooyen formerly of the Brookhaven National Laboratory, Bo Rosborg of Studsvik Energy, Norio Sato of Hokkaido University, Bill Schneider of Babcock and Wilcox, Peter Scott of Framatome, Toshio Shibata of the University of Osaka, Tetsuo Shoji of Tohoku University, Doug Sinclair of Lucent Technologies, Susan Smialowska of The Ohio State University, Bill Smyrl of the University of Minnesota, Heinz Spähn formerly of BASF, Markus Speidel of ETH, Narasi Sridhar of Southwest Research, Robert Steele formerly of Naval Sea Systems Command, Bernhard Stellwag of Siemens, Michael Streicher formerly of Dupont, Shunichi Suzuki of Tokyo Electric Power, Hiroshi Takamatsu of Kansai Electric Power, Bob Tapping of Atomic Energy Canada Limited, George Theus of Engineering Systems, Shigeo Tsujikawa of the University of Tokyo, Art Turner of Dominion Engineering, Hisao Wakamatsu of Ishikawajima Harima, Jay Warren of Cardiac Pacemakers, Bob Wei of Lehigh University, Bill Wilson formerly of Naval Sea Systems Command, Graham Wood of the University of Manchester, Brian Woodman of Aptech Engineering, Katsumi Yamamoto of JGC, Toshio Yonezawa of Mitsubishi, Edwin Zebroski formerly of the Electric Power Research Institute, Zhang Sen Ru of the Nuclear Power Design Research Institute of China, Zhang Weiguo of the Chinese Institute for Atomic Energy, Zhu Xu Hui of the China National Nuclear Corporation.

I am also indebted to several who supplied figures including Peter Andresen of General Electric, Lars Bjornkvist of Vattenfall, Ken Burrill of Atomic Energy Canada Limited, and Jeff Gorman of Dominion Engineering.

Appreciation is also expressed to my office and support staff for their enthusiastic help and professionalism: Nancy Clasen, Julie Daugherty, John Ilg, Mary Ilg, Barbara Lea, and Tim Springfield.

Finally, I am indebted to Winston Revie, who invited me to prepare this chapter and who encouraged me in its preparation.

A. INTRODUCTION

Metal loss corrosion is one of the major causes of pipeline failures. For example, failure statistics collected by the U.S. Department of Transportation indicate that 17% of reportable gas pipeline failures and 27% of reportable liquid pipeline failures are caused by corrosion [1]. In Alberta, where there is a large percentage of gathering pipelines and consequently more significant internal corrosion problems [2], corrosion accounts for approximately 40% of all pipeline failures.

As the pipeline network ages, it is important to understand the risk of failure due to corrosion and take appropriate measures to keep it at tolerable levels. Risk is defined in the Concise Oxford Dictionary as "the chance of loss," which captures the two main components of risk, namely an uncertain event (chance) that can cause adverse consequences (loss). In the context of pipeline corrosion, risk R can be defined as the probability of a corrosion-caused failure P multiplied by a measure of the failure consequences C (i.e., $R = PC$).

There is a significant body of literature dealing with pipeline failure risks due to corrosion [3–10]. Existing approaches can be classified as either qualitative or quantitative methods. Qualitative methods provide approximate rankings of pipeline segments with respect to the risk of failure. These rankings are based on combining subjective scores assigned to each attribute that affects the risk of corrosion (e.g., age, operating temperature, cathodic protection, and soil corrosivity). Quantitative risk assessment methods on the other hand attempt to provide actual estimates of the probability and consequences of failure based on historical data and analytical models. As such, they require a more significant effort to implement; however, they have the potential to provide more objective and reliable results.

The objective of this chapter is to describe an approach for estimating the risk of pipeline failure due to corrosion and for making efficient maintenance decisions to control corrosion-related problems. Although the focus is on pipeline corrosion, the overall framework and many of the concepts are applicable to other systems such as downhole casing, boilers, and pressure vessels.

B. CHARACTERIZING PIPELINE CORROSION

Figure 5.1 shows a sketch of a typical external corrosion defect, which usually consists of a number of individual pits

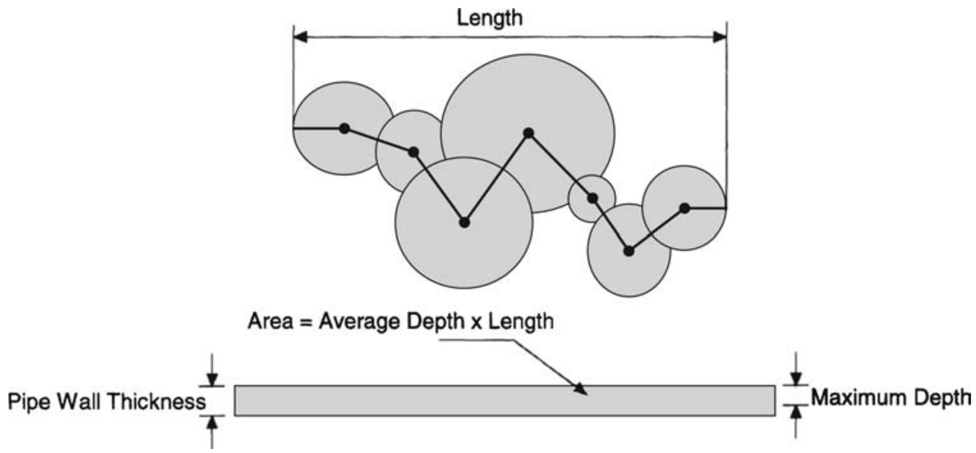

FIGURE 5.1. Geometry of a corrosion defect.

that grow until they join together into a single feature. The parameters used to characterize a corrosion feature are shown on the figure. They may include defect length (defined as the maximum length of the corrosion feature along the pipe axis) and defect depth (which can be characterized by either the maximum depth or the average depth along the deepest route through the feature).

There are several inspection technologies that can be used to provide direct or indirect information on pipeline corrosion defects. These include the following:

Coating damage survey methods such as Pearson surveys, current attenuation surveys, close interval potential surveys (CIPSs), and the direct-current (dc) voltage gradient (DCVG) survey technique. These methods detect coating damage and provide an indication of the severity (or size) of damage. Differences between these methods relate to the physical principles used and the type of information and interpretation required. Some survey methods produce additional information (beyond coating damage indications) that is relevant to corrosion. The CIPSs, for example, determine the effectiveness of cathodic protection, whereas DCVG surveys provide an indication of whether or not corrosion is active at a given location. Harvey [11] gives a summary of the capabilities and limitations of different coating damage survey methods.

Low-resolution or high-resolution in-line inspection tools. Low-resolution tools generally provide the location of metal loss corrosion defects and a coarse estimate of the maximum defect depth (e.g., $< 30\%$, 30–50%, and $> 50\%$ of the pipe wall thickness). High-resolution inspection tools provide information on the number, location, and geometry of defects (including estimates of defect length, width, and average or maximum defect depth). Some inspection vendors offer an incremental approach in which low-resolution data are provided, with the option of an information upgrade that provides high-resolution inspection data.

Regardless of how sophisticated a certain inspection method is, there are always accuracy limitations associated with the information provided.

C. PRESSURE RESISTANCE OF CORRODED PIPELINES

The degree of reduction in the pressure capacity of a pipeline at a corrosion defect depends on the defect size (specifically depth and length). The pipe resistance R can be calculated as a function of defect geometry, pipe geometry, and material yield strength using the following relationship [12]:

$$R(\tau) = \frac{2.3T}{D} S \left[\frac{1 - H(\tau)/T}{1 - H(\tau)/M(\tau)T} \right] + C \qquad (5.1a)$$

$$M(\tau) = \sqrt{1 + 0.6275 \frac{[L(\tau)]^2}{DT} - 0.003375 \frac{[L(\tau)]^4}{D^2T^2}} \qquad (5.1b)$$

where T is the wall thickness, D is the pipe diameter, S is the yield strength, $M(\tau)$ is a geometric factor (called the Folias factor) that accounts for bulging of the pipe before failure, L is the defect length, C is a model uncertainty factor (see below), and τ is time. It is noted that the resistance is a function of time since both defect depth and length are treated as functions of time to account for defect growth:

$$H(\tau) = H(0) + \tau G_h \qquad (5.2a)$$

$$L(\tau) = L(0) + \tau G_l \qquad (5.2b)$$

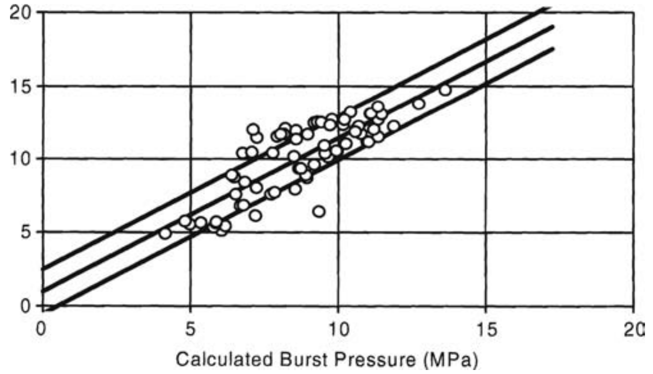

FIGURE 5.2. Burst test versus corrosion model results.

where $H(0)$ and $L(0)$ represent the defect depth and length at present, and G_h and G_l are the defect depth and length growth rates.

Equation (5.1) is based on a semiempirical relationship that was developed in the early 1970s [13, 14]. Figure 5.2 shows the results of this model plotted against the results of burst tests carried out on corroded pipe taken out of service [15]. This figure indicates that there is some uncertainty associated with the results of the model—hence the model uncertainty factor C in Eq. (5.1). Regression analysis of the data in Figure 5.2 shows that C has an average value of 1.38 MPa.

Example 5.1. Consider a 914-mm outside diameter (OD) X60 pipeline with a wall thickness of 8.74 mm and an operating pressure of 5.7 MPa. Assume that the line has a corrosion feature with a length of 75 mm and an average depth of 1.5 mm. Also assume that defect depth and length have growth rates of 0.35 and 1.0 mm/year, respectively. Figure 5.3 shows the resistance of this corrosion defect as a function of time as calculated from Eqs. (5.1) and (5.3). Figure 5.3 shows that, if not repaired, this feature will fail after 17 years.

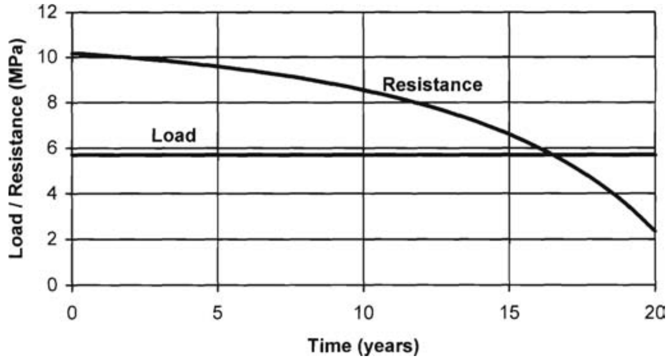

FIGURE 5.3. Resistance at a single corrosion defect as a function of time (Example 5.1).

D. PROBABILITY OF FAILURE DUE TO CORROSION

As demonstrated in Section C, a corrosion failure occurs when the pressure resistance at the defect drops below the maximum operating pressure (see Figure. 5.3). Because of the uncertainties associated with defect sizes, growth rates, pipe material yield strength, and model error, there is some uncertainty regarding the calculated value of the time to failure for a specific corrosion defect. The time to failure is therefore best characterized in probabilistic terms. The probability of failure on or before time τ, $p_f(\tau)$, is equal to the probability that the resistance, $R(\tau)$, will drop below the applied pressure, A. This can be expressed as follows:

$$p_f(\tau) = p[R(\tau) < A] = p[R(\tau) - A < 0] \tag{5.3}$$

Substituting the value of $R(\tau)$ from Eqs. (5.1a) and (5.2a) gives the probability of failure as the probability of occurrence of a particular combination of pipeline and defect attributes (viz. diameter wall thickness, yield strength, defect dimensions, and growth rates) that lead to a lower resistance than the applied pressure. There are a number of standard methods that can be used to calculate this probability from the probability distributions of the basic pipeline and defect attributes [16, 17].

It is also possible to calculate the probability of failure during a given time interval (τ_1 to τ_2) given that the pipeline survives to the beginning of this interval from Eg. (5.5) [17, p. 287]:

$$p(\tau_1 < \tau < \tau_2) = \frac{p(\tau < \tau_2) - p(\tau < \tau_1)}{1 - p(\tau < \tau_1)} \tag{5.4}$$

If the time interval is taken as one year, Eq. (5.4) gives the annual probability of failure as a function of time.

Finally, if it is assumed that failures at individual corrosion features are independent events, the probability of failure per kilometer of pipe can be calculated by multiplying the probability of failure per defect by the number of defects per kilometer.

Example 5.2. Assume that the pipeline in Example 5.1 has an average of 2.5 corrosion defects per kilometer and that the pipeline and defect attributes used in Eqs. (5.1) and (5.2) are as given in Table 5.1. Figure 5.4 gives the annual probability of failure as a function of time [as calculated from Eqs. (5.3) and (5.4)] for this pipeline.

E. IMPACT OF MAINTENANCE ON RELIABILITY

E1. Characterization of Inspection Accuracy

E1.1. Detection Power. An inspection method is not guaranteed to detect all defects and therefore there is a

TABLE 5.1. Probability Distributions of Input Parameters (Example 5.2)

Length growth rate	5 mm/year	0	Fixed	Assumed

Note: COV = coefficient of variation.

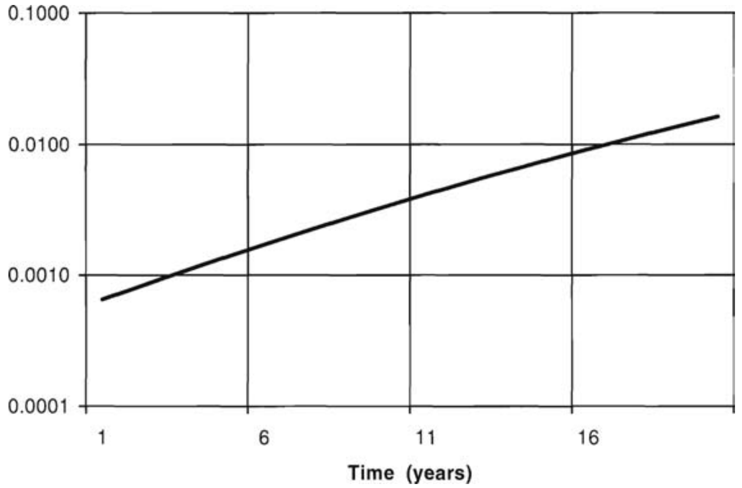

FIGURE 5.4. Probability of failure as a function of time for pipeline in Example 5.2.

chance that an existing defect will be missed. The probability of detecting a specific defect can be characterized as a function of defect size; the larger the defect, the higher the probability that it will be detected. Rodriguez and Provan [19] suggested the following characterization of the probability of detection:

$$p_{d/h} = 1 - e^{-qh} \tag{5.5}$$

where $p_{d/h}$ is the probability of detection for a defect with size h, and q is a constant that determines the overall power of the detection method.

E1.2. Sizing Accuracy. There is also a random measurement error E associated with defect sizes estimated from in-line inspection. Measurement errors are usually modeled by a normal distribution. The mean value of E is equal to the systematic bias of the measurement (or zero if there is no bias) and the standard deviation represents the random error component. These parameters can be obtained from vendor specifications or from verification excavation data [20].

E2. Effect of Inspection and Repair on Defect Size

The process of inspection and repair improves the pipeline condition by modifying the probability distributions of defect size and defect frequency. The degree of modification depends on the accuracy of the inspection method and the threshold used for repair.

Figure 5.5 illustrates the steps involved in characterizing the remaining defects after inspection. Initially, the inspection divides the population of original defects into *detected* and *undetected* defects. Since larger defects are more likely to be detected (see Section E1), detected defects are likely to be larger on average than the original defects. Similarly, undetected defects will be smaller on average than the original defects. This is illustrated in Figure 5.6 [21], which shows that the size distribution is shifted to the right for detected defects and to the left for undetected defects. The inspection tool used in developing the plots in Figure 5.6 is assumed to have a detection constant $q = 0.4$ [see Eq. (5.5)].

The inspection tool will provide a *measured* size of detected defects, which will be somewhat different from the *actual* size because of tool accuracy limitations. A repair

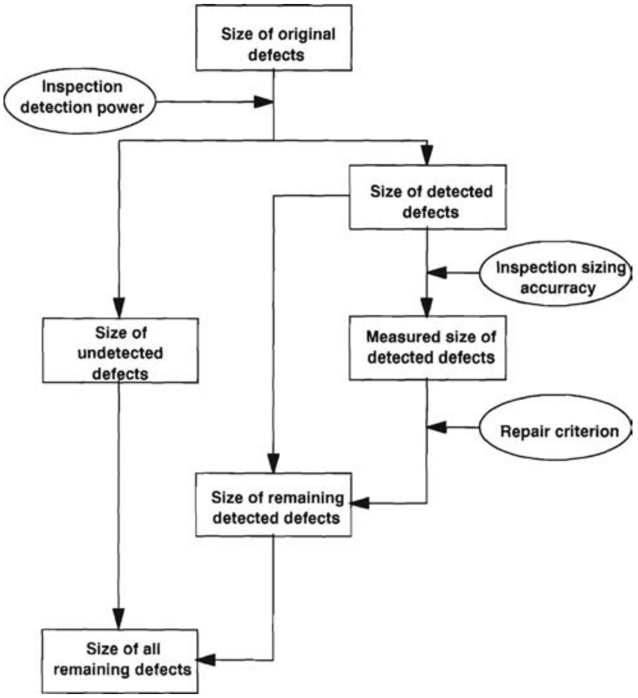

FIGURE 5.5. Modeling the impact of inspection and repair on corrosion defect population.

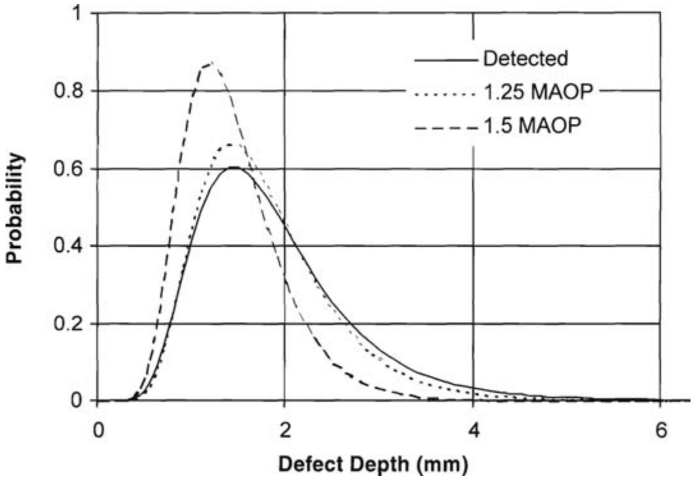

FIGURE 5.7. Probability distributions of defect size before and after repair.

criterion will typically be applied to each detected defect to identify ones that require repair. The repair criterion may be based on the measured defect depth or the calculated failure pressure (from the measured defect depth and length) at the defect location. The population of *remaining* defects will then consist of defects that did not meet the repair criterion. Because the repair decision is based on the measured (rather than the actual) defect size, some critical defects may have been undersized by the inspection tool and will therefore be left not repaired.

The population of *remaining defects* can be obtained by combining undetected defects with defects that were detected but not repaired. Figure 5.7 shows a comparison between the size distributions of an original defect population and the corresponding population of defects remaining after inspection and repair of all defects with a failure pressure $<$ 1.25 and 1.5 of the maximum allowable operating pressure (MAOP). The measurement error parameters for the inspection tool used are assumed to be as shown in Table 5.2. The figure shows that the inspection and repair shifts the defect size to the left (lower values). The average number of defects per kilometer remaining after repair can be obtained by subtracting the number of defects that are detected and repaired from the original average number of defects per kilometer.

Details of the calculations used to produce the results in this section are given by Nessim and Pandey [21].

F. APPLICATION TO MAINTENANCE PLANNING

F1. Problem Definition

Consider the gas pipeline used in Examples 5.1 and 5.2 (914-mm OD X60 with a wall thickness of 8.74 mm and an operating pressure of 5.7 MPa) with the corrosion defect population given in Table 5.1. Assume that the pipeline is being considered for a high-resolution in-line inspection with the tool characterized in Table 5.2. A maintenance plan in this case involves answering the following questions:

1. What is the optimal time interval to first inspection of the pipeline?
2. Once the first inspection is performed, what are the optimal repair criterion and interval to next inspection?

F2. Time to First Inspection

The annual failure probability for this pipeline in its initial state is plotted in Figure 5.4. The time to first inspection can be estimated from this figure by defining a maximum allowable probability of failure and finding the time at which this probability will be exceeded. Figure 5.4 shows that if the maximum allowable probability were 10^{-3}/km·year, the inspection would be required after 3 years.

It is also possible to base the decision on a cost optimization analysis. The expected total annual cost c_t for each choice can be calculated from

$$c_t = p_f c_f + (c_i + n_r c_r)\left[\frac{u}{1-(1+u)^{-\tau_i}}\right] \tag{5.6}$$

in which the first term is the expected annual failure cost calculated as the annual probability of failure, p_f, multiplied by the cost of failure, c_f, in present-day currency, and the second term is the total maintenance cost per kilometer amortized over the time to next inspection. The total maintenance cost is calculated as the sum of the inspection cost per kilometer, c_i, and the average number of repairs per kilometer, n_r, multiplied by the cost per repair, c_r. This cost is amortized over the interval to next inspection, τ_i, based on a real interest rate of u.

If we assume that the cost of failure is \$1 million, the inspection cost is \$4000/km, the cost of repair is \$5000 per defect, and the real interest rate is 5%, the total expected cost will be as shown in Figure 5.8. This figure plots the results for the status quo and for an inspection followed by repair of all defects with a failure pressure less than 1.25 MAOP. The minimum cost associated with the inspection option is \$1.8 million, corresponding to an inspection interval of ~7 years. The cost associated with the status quo is less than \$1.8 million for the first 9 years. This means that the optimal solution is to carry out the inspection after 9 years.

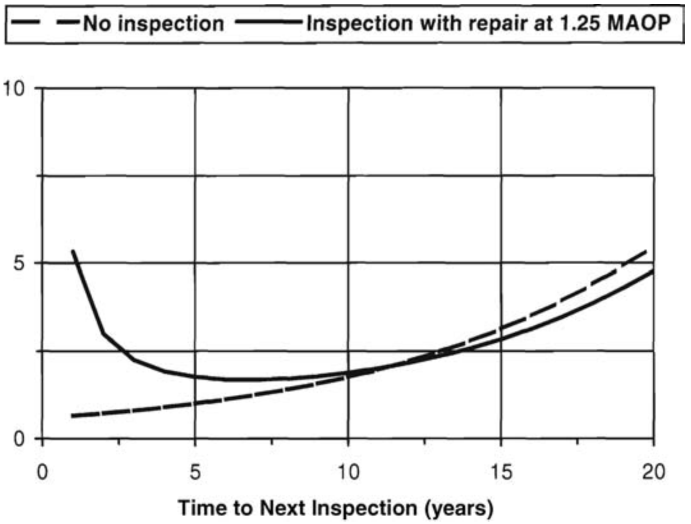

FIGURE 5.8. Total annual costs for the inspection and no-inspection options.

F3. Inspection Interval and Repair Criterion

It is now assumed that the inspection has been carried out after 9 years and that an average number of 1.3 defects per kilometer is found, with the depth and length distributions given in Table 5.3. The maintenance planner wishes to choose a repair criterion and an interval to next inspection. Figure 5.9 can be used to make this decision on the basis of the maximum allowable failure probability. It shows that a repair criterion of 1.25 MAOP is inadequate to meet a target annual failure probability of 10^{-3}. A repair criterion of 1.5 MAOP would lead to an acceptable probability of failure for the next 15 years. Based on this, a repair criterion of 1.5 MAOP should be used and the next inspection should be carried out after 15 years.

The cost optimization calculations lead to the results in Figure 5.10. The lowest cost is associated with a repair criterion of 1.5 MAOP and an interval to next inspection of 14 years.

TABLE 5.3. Corrosion Parameters Obtained from an Inspection

Parameter	Average	COV (%)	Distribution Type
Defect depth	2.5 mm	60	Lognormal
Defect length	120 mm	50	Lognormal
Number of detected flaws	1.3 per km	0	Fixed

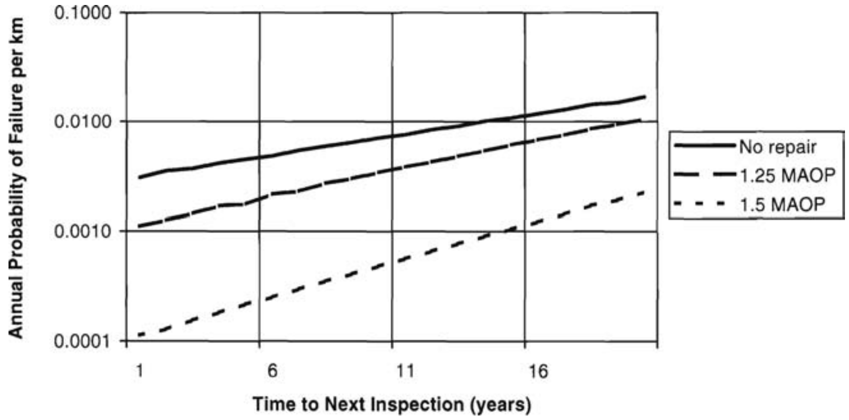

FIGURE 5.9. Annual probability of failure for three different repair criteria.

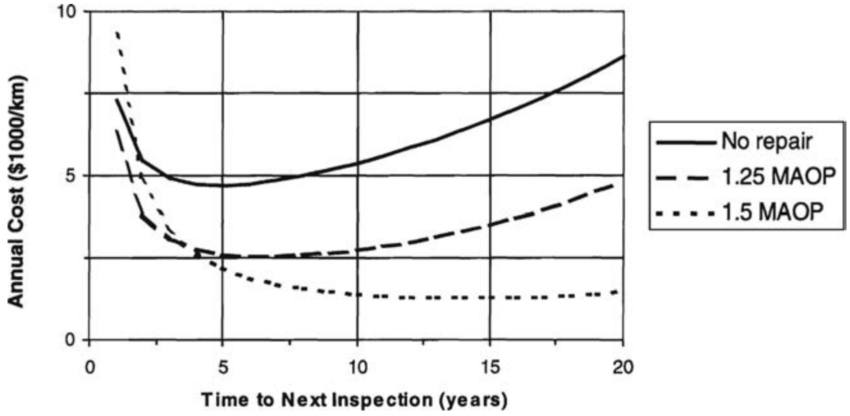

FIGURE 5.10. Total annual cost for three different repair criteria.

G. SUMMARY

This chapter described a framework for risk-based assessment of pipeline corrosion risk and demonstrated maintenance planning with a risk-based approach. The examples developed serve to demonstrate the benefits associated with risk-based planning:

1. *Consistent Safety Levels.* Minimum safety targets can be set and actions taken to ensure that they are met across a whole system.
2. *Optimal Balance between Maintenance Costs and Failure Risks.* Maintenance plans that achieve safety goals at a minimum possible cost can be defined. This can result in significant savings in overall operating costs.
3. *Documentation of Rationale Behind Decisions.* The analysis process provides the reasoning and documentation needed to communicate prudent risk management

A. INTRODUCTION

The choice (and detailed specification) of a material known to be chemically resistant to a given environment is one step in the selection process. Another step, of equal importance, is the choice of proper design configurations and principles to permit the material to perform in the desired manner. Listed below are a number of design-related causes of corrosion in metallic systems:

1. Dissimilar metals
2. Improper drainage
3. Joints between metals and nonmetals
4. Crevices
5. Stray currents
6. Complex cells
7. Relative motion between two interacting parts or between a part and its environment
8. Selective loss of one or more ingredients of the alloy
9. Inability to clean the surface properly

There is a third step in assuring good performance, which unfortunately is often given inadequate attention. That is careful inspection and verification that design specifications and recommendations actually are carried out in the installation.

The detailed methods by which corrosion may be mitigated by design are listed below and are illustrated in the accompanying figures:

1. Where dissimilar metals are involved, select materials that have a minimum difference in electrode potential under the conditions of temperature and electrolyte composition encountered.
2. Where feasible, design structures so that butt joints rather than lap joints are employed, use drip skirts to avoid moisture collecting under structures.
3. Support tanks on stanchions rather than pads if possible. If pads are required for tanks, provide sufficient "crown" on the pads to assure drainage and to avoid "oil can" effects. For large field-erected tanks use domed, compacted, oiled sand where appropriate as a support for tank bottoms.
4. Employ resilient sealants to exclude moisture from potential crevices.
5. Employ cathodic protection where appropriate. This includes the use of galvanized steel or alclad aluminum products or sprayed metals to provide cathodic protection in crevices.

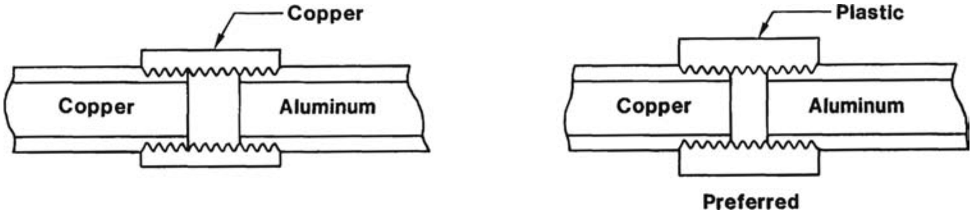

FIGURE 6.1. Insulating material between dissimilar metals, such as copper and aluminum, prevents galvanic corrosion.

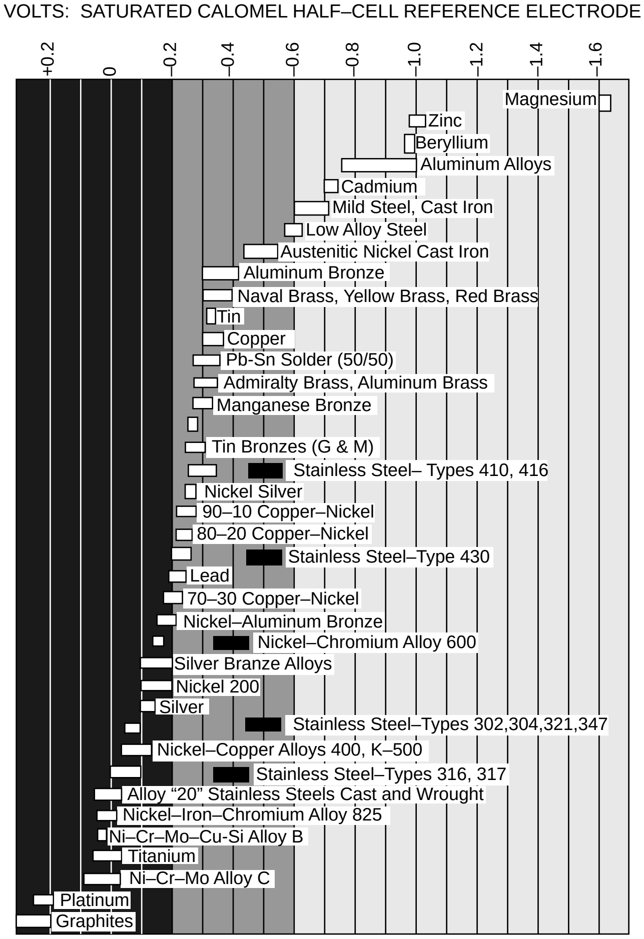
6. Equalize the electrode potential between electrically interfering structures that are exposed in the same electrolyte (e.g., underground or in large tanks). Cross-bonding, use of cathodic protection, and careful grounding are important methods for accomplishing this.
7. Use special care to avoid turbulence. This involves study of flow patterns, avoidance of constrictions, or sharp changes in direction and attention to the relationship between pressure and amplitude of motion between parts.
8. Select materials known to be compatible with the environment and with each other. For important structures this implies pretesting.
9. Provide redundant systems for critical applications. This includes spare heat exchanger bundles, replaceable spools in pipe systems, or scavengers for removal of dissolved heavy metals.
10. Use nonmetallic materials when required.

B. DESIGN-RELATED CAUSES OF CORROSION

B1. Dissimilar Metals

The electromotive force (emf) series can be of qualitative guidance in predicting which material is likely to be sacrificed in a dissimilar metal couple. Unfortunately, the emf series (which lists pure metals in solutions of their own ions of unit activity) bears little relationship to actual applications. Consequently, the predictions of the emf series are likely to be reliable only for those circumstances where there is a very large difference in electrode potential. An example might be aluminum versus copper (Fig. 6.1). In most circumstances, aluminum would sacrifice itself to protect copper in a conductive electrolyte. The actual electrode potential of a given metal will be strongly influenced by the composition of the electrolyte and the temperature. In practical cases, pure metals seldom are used as materials of construction. More commonly alloys are employed. The addition of alloy ingredients changes the electrode potential from that of the predominant pure metal ingredient. Thus it is important to know the electrochemical relationships between dissimilar metal alloys under the real conditions of exposure in order to assess the likelihood of dissimilar metal action. Figure 6.2 shows a galvanic series for alloys exposed in seawater.

The intensity of dissimilar metal action will be strongly influenced by the relative areas of the dissimilar metals exposed in the electrolyte that is common to them both. Of



Alloys are listed in the order of the potential they exhibit in flowing sea water. Certain alloys indicated by the symbol: ■ in low–velocity or poorly aerated water, and at shielded areas, may become active and exhibit a potential near –0.5 volts.

FIGURE 6.2. The galvanic series in seawater.

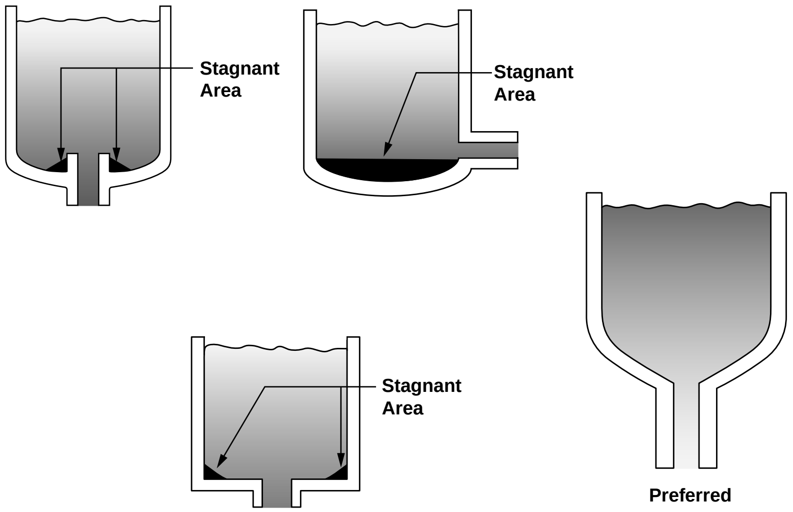


FIGURE 6.3. Design for drainage.

particular interest is the anode current density. In most metal systems exposed to aqueous environments, the corrosion process is under "cathodic control." This means that the size of the cathode will control the anode current density. The larger the area of the cathode as compared to the anode area, the greater will be the anode current density. Thus the design should maximize the anode area and minimize the cathode area where possible. It is good practice to avoid using rivets that are anodic to metal parts being joined since such a practice would lead to failure of the joint by corrosion of the rivets.

B2. Drainage

Drains should always be located at the lowest point in a tank. The joint between the tank and the drain pipe should be designed to permit free drainage (Fig. 6.3). Usually, this will mean the avoidance of weld beads projecting into the tank that could trap residues or moisture. The use of sumps in large tanks is a useful procedure to mitigate problems related to drainage; however, special care must be made in the design of sumps to be sure that they are also free draining or can be inspected and cleaned easily. Inspection flanges are convenient for such purposes. Large flat-bottom tanks present a particular problem from the standpoint of drainage because of the difficulty of assembling such tank bottoms in a manner that will avoid areas that are difficult to drain. The design should incorporate some positive means of providing drainage, perhaps by sloping the bottom. Rain water or other moisture on the exterior of tanks can be drawn under flat-bottom tanks by capillary action. Use of "drip skirts" around the edges of such tanks will direct moisture to the ground rather than allowing it to cling to the tanks and be drawn under the tanks and will reduce danger of trapping moisture (Fig. 6.4).

Particularly for pipes and small- to moderate-size tanks, it is good practice to support them on stanchions rather than on pads. This provides free access of air around the bottoms of the tanks and facilitates periodic inspection, Metal cradles welded to the tanks for support above grade provide another option (Fig. 6.5).

Flat cement pads should be avoided as a supporting means for flat-bottom tanks. Instead, the pads should have a crown from center to edge of $\sim$1 mm/12 mm radius (1 in./foot of radius). It is difficult to manufacture a flat-bottom tank with a tank bottom that is actually flat. Consequently, when the tank is empty, the tendency is for the tank bottom to stand away from the base irregularly. When the tank is filled, the tank settles onto the pad. However, each time the contents of the tank are emptied, there is a tendency for portions of the bottom to rise away from the pad. Thus the bottom can snap

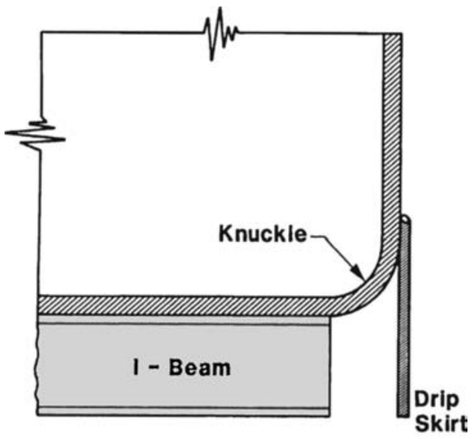

FIGURE 6.4. A drip skirt reduces moisture collection under flat-bottom tanks.

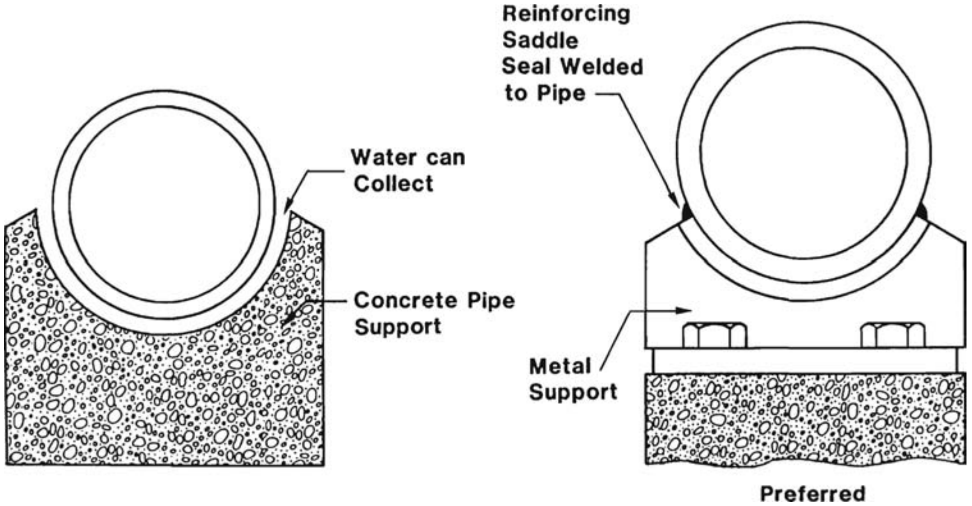

FIGURE 6.5. Sealing and a metal cradle avoid accumulation of water under a pipe in outdoor construction.

back and forth much in the manner of the bottom of an oil can and in so doing "pump" moisture under the tank. The use of a crowned pad will prevent this pumping action. The diameter of the supporting pad should be *smaller* than the tank being supported. The use of smaller size pads in conjuction with drip skirts is effective in reducing the amount of moisture that collects under a tank. For very large tanks set on the ground (e.g., large field storage tanks for oil), it is customary to use a cement ring to support the edge of the tank and support the bottom on compacted, crowned, oiled sand. The use of oiled sand serves to provide corrosion protection for the underside of the tank bottom.

The use of butt welds rather than lap welds in piping systems tends to reduce the danger of entrained solids collecting in the bottoms of pipes. It may be desirable in critical applications to employ special procedures (e.g., grinding) to reduce the tendency for weld beads to trap solids.

B3. Sealants

For lap joints and other "designed" crevices, special attention is warranted to avoid the introduction of moisture (Fig. 6.6). In the presence of moisture, such crevices represent a serious likelihood of crevice corrosion. Such action usually is initiated by differential aeration cells. In such cells, the "oxygen-starved" regions (within the crevices) normally are anodic with respect to the "oxygen-rich" areas outside the crevice and tend to corrode preferentially. Sealants (Fig. 6.7) used must be selected with care. Ideally, a sealant will remain resilient during its expected life. Special attention should be given to avoid sealants that harden or change dimensions with time under the conditions of exposure. Where sealants cannot be employed the use of galvanized steel mating parts or the use of alclad aluminum mating parts (e.g., in a riveted structure) can provide cathodic protection within the crevice, thereby mitigating the corrosion problem.

B4. Cathodic Protection

The use of cathodic protection either by use of galvanic anodes or by driven electrodes can be effective in preserving the integrity of a designed structure. Attention must be given to adjacent structures that may inadvertently either provide cathodic protection to the structure under consideration or receive cathodic protection from the structure. Examples are buried pipelines that may be in close proximity. It is not uncommon under these circumstances for current to flow from one structure to the other. When this occurs, special corrosion is observed where current flows from the structure into the electrolyte and protection occurs where the current flows from the electrolyte into the structure. A common design procedure is to connect the neighboring structures

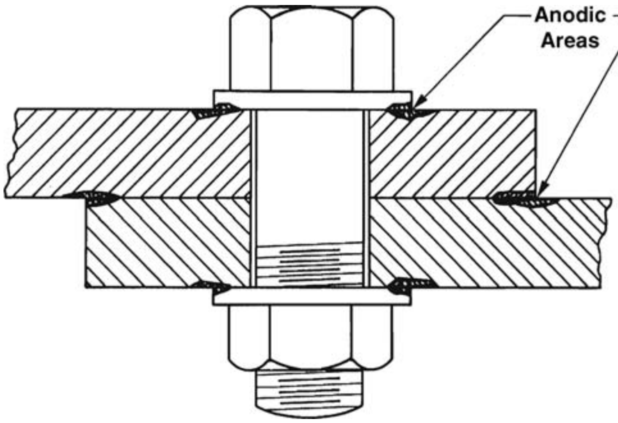

FIGURE 6.6. Crevices lead to concentration cell corrosion.

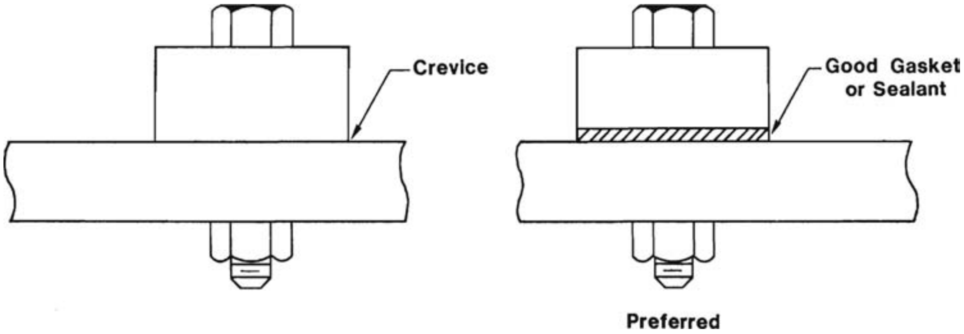

FIGURE 6.7. Gasket or sealant to avoid crevices.

electrically with a suitable bond so that their potentials will become the same. Often such cross-bonding procedures are incorporated with installation of cathodic protection.

B5. Grounding

Leakage currents have been discovered on a number of metallic structures because of inadequate grounding. Particularly in environments where there is a considerable fluctuation in the water table, buried structures have suffered serious deterioration from leakage currents. The grounding of electrical services to buried water lines is a common practice. Such structures should then be connected to ground rods that are deep enough to be in permanent soil moisture. If the water table falls below the level of the grounding system, there is increased danger that leakage currents will result in wastage of the water piping.

B6. Flowing Systems

In flowing systems, the relative motion between the environment and the parts operating in the environment can lead to erosion corrosion, cavitation, or abrasive wear. All of these types of damage are related exponentially to the flow rate (relative motion). Thus it is good practice to reduce the flow rate if feasible and to avoid localized constrictions or sharp changes in direction in flowing systems. The entrance end of heat exchanger tubes is an example of a location where special damage may occur. One way to mitigate inlet end corrosion (or erosion) of heat exchanger tubes is by the use of metallic or nonmetallic ferrules inserted in the ends of the tubes. Damage ultimately requires the replacement of such ferrules; however, the integrity of the system is maintained. Where ferrules are cemented in place, special care must be exercised to avoid extruding sealant beyond the ends of the ferrules since "stalactites" or collections of sealant can serve as local sources of turbulence in the flowing system. Entrained trash, sand, or marine organisms such as crustaceans may collect in flowing systems setting up not only local turbulence but also the possibility of crevice corrosion from differential aeration cells. Structures should be designed so that they may be cleaned periodically by use of "pipe pigs," brushes, or sponge balls that can be pumped through the system. Such procedures can result in dislodging of collected debris and can restore heat transfer in heat exchangers. At sharp (unavoidable) changes in direction, localized impingement damage can be mitigated by incorporation of wear-resistant devices (Fig. 6.8).

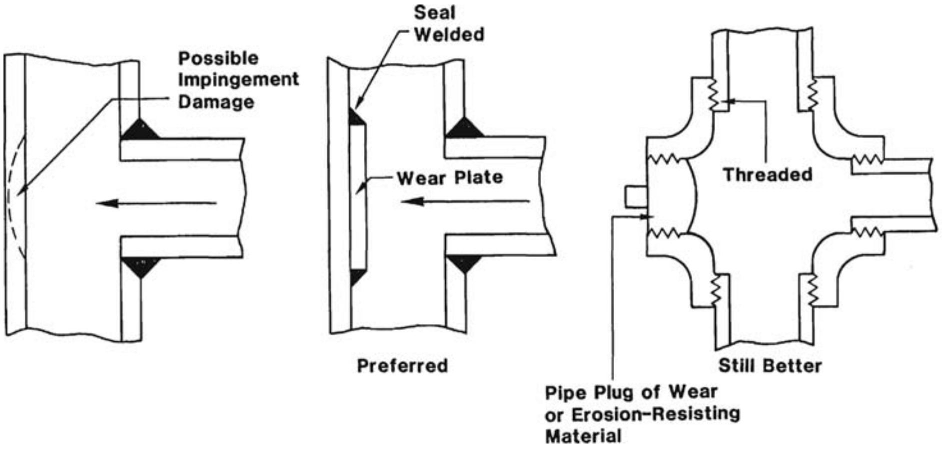

FIGURE 6.8. Wear-resisting designs to minimize corrosive wear.

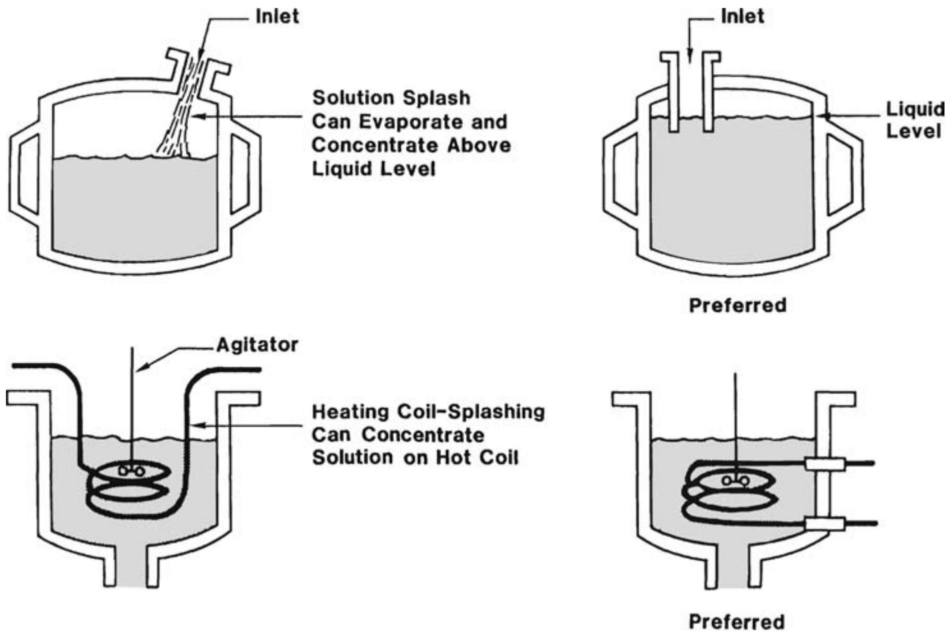

FIGURE 6.9. Designs to minimize evaporation and concentration of solutions.

B7. Liquid–Vapor Systems

Conditions that permit evaporation of splashed liquids or localized condensation of vapors, which then can evaporate and become more concentrated, often can lead to special corrosion. Splashing can be avoided by designs such as those shown in Fig. 6.9. Localized condensation usually can be avoided by thermal insulation or by preheating liquids so that surfaces of piping or equipment are above the ambient temperature (and dew point).

B8. Redundant Systems

In critical process applications, such as heat exchangers, it is common practice to design the system so that several extra heat exchanger bundles are installed on a manifold to permit periodic inspection and/or repair or replacement of systems without shutting down the entire plant operation. In piping systems, it also is common practice to install heavy wall "spool" sections to bear the brunt of special corrosion problems. An example is a piping system involving steel and aluminum alloy pipes (Fig. 6.10). To mitigate the effects of this potential dissimilar metal cell, a short length of heavy wall (Schedule 80, e.g.) alclad aluminum pipe may be inserted between the steel pipe and the aluminum pipe. The alclad coating will provide cathodic protection to both the adjacent steel and aluminum pipes and also will scavenge dissolved copper ions that may be present in the flowing aqueous system, thereby sparing the aluminum

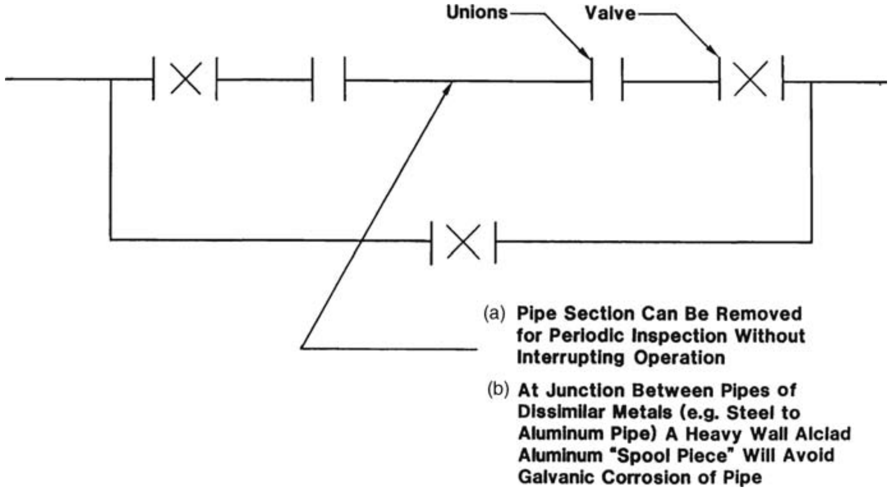

FIGURE 6.10. Design that allows inspection to be carried out without interrupting operation.

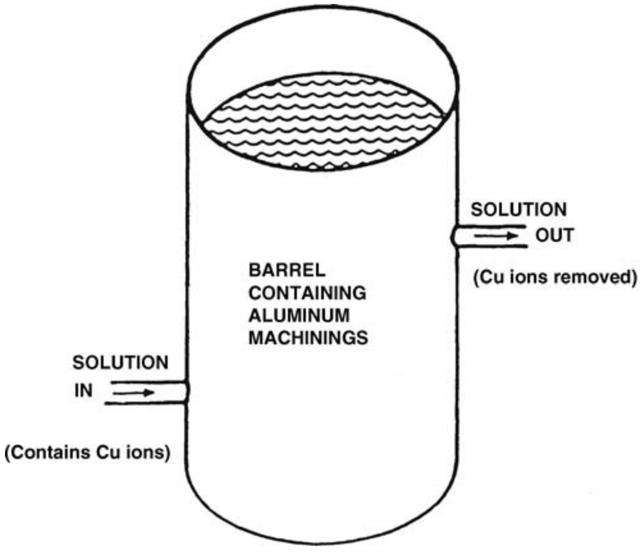

FIGURE 6.11. Heavy metals trap to remove heavy metals from a process stream.

pipe downstream from dissimilar metal action. Periodically, the system is shut off and the spool is examined and/or replaced if necessary. It is possible to put in two such spool sections in parallel with suitable valving so that the system need not be taken out of service during inspection and/or replacement.

Some flowing systems are significantly contaminated by heavy metal ions such as copper, lead, and so on. These ions tend to be plated out on steel or aluminum piping downstream and can result in corrosion of the downstream piping. This can be avoided readily by the inclusion of a "heavy metals trap" upstream from the steel or aluminum piping (Fig. 6.11). A typical trap might be a tank or drum filled with aluminum machinings. Periodically, it would be necessary to dispose of exhausted machinings by replenishing with new machinings.

B9. Welded Joints

In design of equipment involving use of carbon steel to stainless steel welded joints, there is the possibility of alloy dilution in the welded joints. This presents the potential problem of reduced corrosion resistance at welded joints. This problem may be mitigated by designs such as that shown in Figure 6.12. Joints in piping systems provide opportunities for the inadvertent incorporation of crevices. Vigilance to avoid such crevices is urged (see Fig. 6.13). When attaching dished heads to the sidewall of pressure vessels it may be necessary to machine the surface of the dished head to

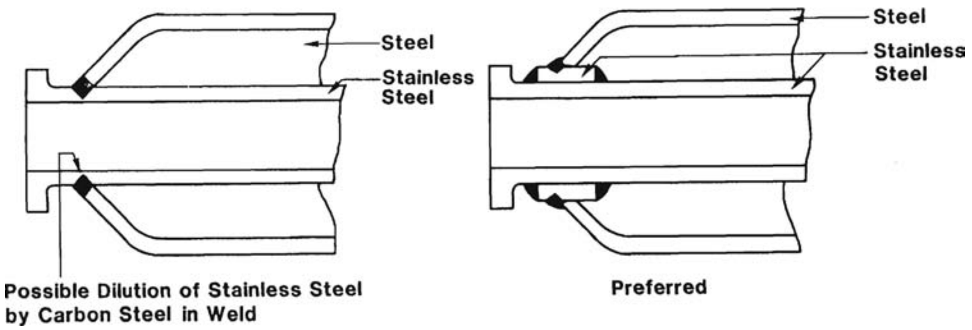

FIGURE 6.12. Design to prevent base metal dilution.

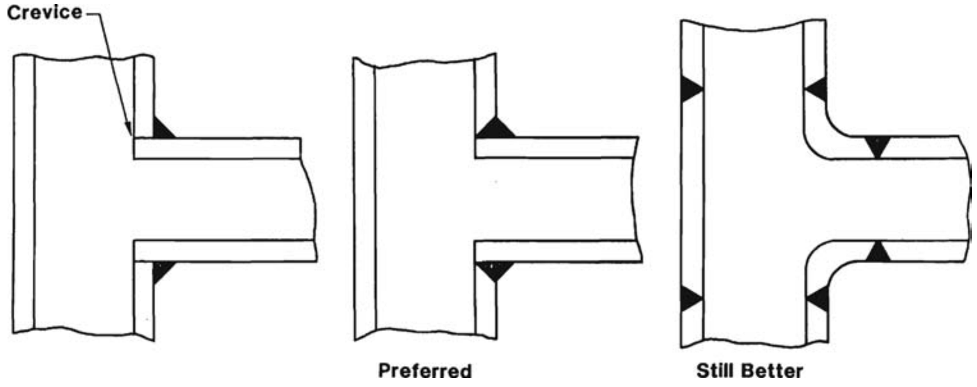

FIGURE 6.13. Designs to avoid crevices caused by incomplete weld penetration.

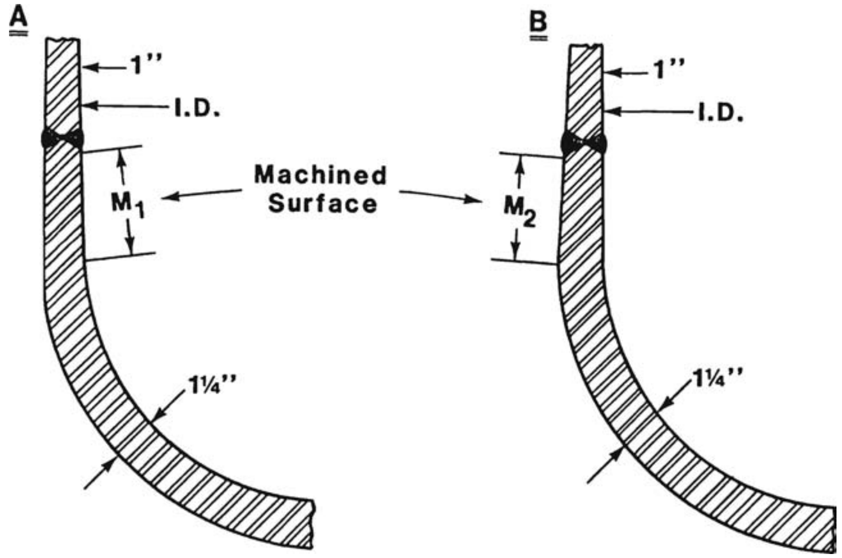

FIGURE 6.14. Design of attachments to the sidewall of pressure vessels so that the final machining operation is carried out on the exterior of the vessel.

accommodate the thickness transition. It is recommended that the dished heads be sized such that this final machining operation be performed on the *exterior* of the vessel (Fig. 6.14).

B10. Nonmetallics

Nonmetallic materials can be exceedingly valuable in providing corrosion resistance or ease of maintenance under circumstances where metallic systems are inadequate. The use of nonmetallic materials such as fiber-reinforced plastics requires special design attention to avoid premature failure. In the case of the fiber-reinforced products, special attention must be given to avoid wicking of moisture up the fibers. This normally means that a finish coat is required, which will prevent exposure of the environment directly to the "raw ends" of the reinforcing material. Attention also must be given to the effect of temperature on the mechanical properties of plastic materials. Plastics are considerably more susceptible to fatigue failure than

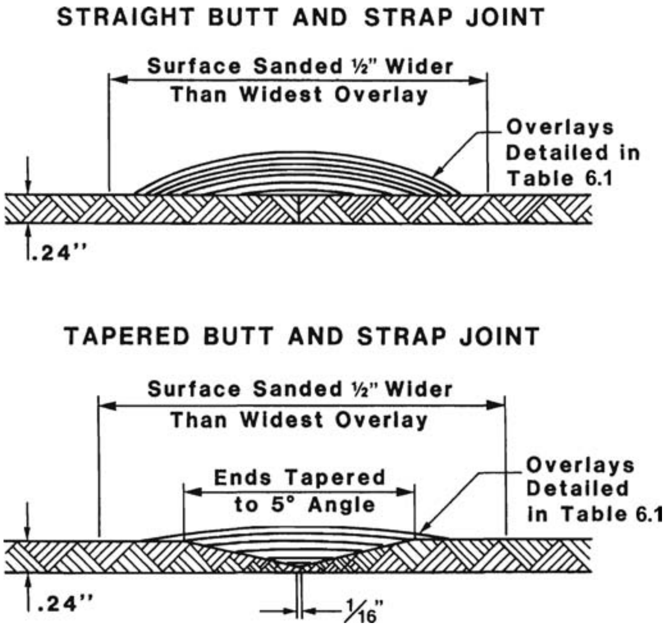

FIGURE 6.15. Joint designs.

TABLE 6.1. Major Types of Failures in Reinforced Plastics and Their Causes

System	Type of Failure	Cause
Piping	Cemented joint	Failure to follow recommended practice
	Chemical attack	Poor resin selection or change in environmental conditions
	Impact damage	Various (generally handling damage)
Tanks and process vessels	Chemical attack	Poor resin selection or environmental data wrong
	Internal pressure	Operational errors and poor process design
	External pressure (vacuum)	Poor equipment design
	Secondary bond failure	Faulty fabrication
	Impact	Handling damage
Scrubbers and absorbers	Chemical attack	Service conditions wrong and change in process specs
	Vacuum damage	Poor equipment design
	Impact	Handling damage
	Fire	Lack of maintenance, lack of adequate safeguards, lack of interlocks, possible lack of employee training, or no scrubbing liquid
Ducts, fans, and stacks	Joint failures	Generally—glue line
	Chemical attack	Poor resin selection, wrong or changed service conditions
	Fire	80% of fires originate from an internal or process source, while 20% of fires originate externally. Lack of sprinkler protection is by far the largest single reason for large losses occurring.

are metals. They must also be protected from degradation by ultraviolet light. Thermal expansion of plastic materials is considerably greater than metals, a particularly important consideration when considering piping systems or composite structures such as plastic-lined pipe. Special attention must also be given to the possibility of fire damage. A number of suggested joint details are given (Fig. 6.15). Table 6.1 lists a number of types of failures that have occurred in plastic systems. Many of these could have been avoided by careful design, fabrication, and installation.

There are numerous applications of ceramic or glass materials in the chemical and pharmaceutical industries. Successful use of this class of materials requires that they be protected from impact loadings or flexure.

A. Introduction
B. Thermodynamic background
C. Construction of diagrams
D. Applications of Pourbaix diagrams
References

A. INTRODUCTION

For the behavior of metals in aqueous solutions, one of the most important contributions to the corrosion literature has been the work of Pourbaix [1, 2] and his associates in the development of thermodynamic equilibrium diagrams (E vs. pH), called Pourbaix diagrams. A vast amount of data may be presented simply and concisely in Pourbaix diagrams. When the advantages and limitations of such diagrams are understood, valuable inferences may be made regarding corrosion phenomena. The selection of conditions for cathodic and anodic protection is simplified. Candidates for consideration as inhibitor species may be selected with greater efficiency. Critical corrosion experiments may be designed with equal efficiency.

Corrosion processes involve both chemical and electrochemical phenomena. In 1923, Evans [3] observed that, if two samples of iron connected by a galvanometer are immersed in two solutions of potassium chloride separated by a porous membrane and if a stream of air is bubbled through one of these solutions, an electric current circulates between the aerated sample, which becomes the cathode, and the nonaerated sample, which becomes the anode and corrodes. On the other hand, if a sample of iron and a sample of another metal (copper, zinc, or magnesium) are connected as above, a passage of electric current is also observed. Under these circumstances, iron becomes the anode and corrodes when connected to copper, whereas zinc or magnesium become the anode and corrode providing protection to iron. Thus, it is necessary to consider not only chemical thermodynamics but also electrochemical thermodynamics when considering corrosion reactions.

Chemical equilibria are defined as those that do not involve oxidation–reduction processes but do involve the law of mass action and the law of solubility product (involving partial pressures or fugacities and concentrations or activities). By contrast, electrochemical reactions are defined as those in which free electric charges, or electrons, participate.

B. THERMODYNAMIC BACKGROUND

The procedure for calculating Pourbaix diagrams is straightforward and is amenable to computer calculation. On the other hand, certain assumptions are made that must be borne in mind when applying the information available from Pourbaix diagrams in "real" situations. First is the assumption of equilibrium. Since Pourbaix diagrams are equilibrium diagrams, they give no information on the kinetics of the reactions considered. Kinetic information may be obtained experimentally by methods described elsewhere [4]. It also is assumed that the reaction products are known and that the

free energy of formation of each solid and ionic species is known for the conditions of temperature and pressure of interest. The pH of the solution is assumed to be known and constant in the bulk as well as at the metal or reaction product surface. Temperature and pressure are considered to be constant and are usually assumed to be 298 K (25°C) and 1 atm, respectively. Pourbaix diagrams may be calculated for other temperatures if thermodynamic data are available or may be estimated [5]. Generally, the features of Pourbaix diagrams are not significantly altered by increased pressures since thermodynamic properties are relatively insensitive to pressure (as compared with temperature).

The simple graphical methods described herein greatly facilitate the practical consideration of the various equilibrium reactions involved. For chemical reactions, it is convenient to make use of the Van't Hoff equation, which involves the equilibrium constant:

$$\Delta G^\circ = -RT \ln K = -2.303 \times 1.987 \times 298 \log K$$

for electrochemical reactions, the procedures involve manipulation of the Nernst equation, which can be written as

$$\phi = \phi^\circ + \frac{0.0591}{n} \log \frac{(a_\mathrm{P})^p (a_{\mathrm{H}^+})^h}{(a_\mathrm{R})^r (a_{\mathrm{H_2O}})^w} \tag{7.1}$$

where

ϕ = reduction potential
$\phi^\circ = \Delta G^\circ / n\mathcal{F}$
ΔG° = standard free energy change
$\mathcal{F}$ = Faraday's constant
n = number of free electrons

for the general reaction,

$$r\mathrm{R} + w\mathrm{H_2O} \rightarrow p\mathrm{P} + h\mathrm{H}^+ + n\mathrm{e}^-$$

Note that electrochemical reactions are written as oxidation reactions; that is, electrons are on the right.

Taking

$$a_{\mathrm{H_2O}} = 1$$

and

$$\mathrm{pH} = -\log a_{\mathrm{H}^+}$$

then

$$\phi = \frac{\Delta G^\circ}{n\mathcal{F}} + \frac{0.0591}{n} \log \frac{(a_\mathrm{P})^p}{(a_\mathrm{R})^r} + \frac{[-0.0591h]}{n}\,\mathrm{pH} \tag{7.2}$$

The standard free-energy change, ΔG°, for the reaction can be obtained readily from tabulated thermodynamic data. Therefore, the first term to the right of the equality sign in Eq. (7.2) is a constant. The second term also becomes a constant when values of a_P and a_R are chosen in the normal manner. In constructing Pourbaix diagrams, the concentration of the ionic species at the boundary between a solid substance and a dissolved substance is usually taken as a very low value, such as $10^{-6}M$. The sum of the first two terms in Eq. (7.2) gives a constant equal to the value of the potential, ϕ, at pH 0. The resulting expression is the equation of a straight line of slope equal to the coefficient of the pH term, $-0.0591h/n$, and intercept equal to ϕ at pH 0.

Pourbaix diagrams are constructed from the three, and only three, types of straight-line relationships, which result from the analysis of the possible chemical and electrochemical equilibria in the system under consideration. Depending on the reactants and products of the assumed reactions, these straight lines will be either horizontal, vertical, or sloping:

1. A reaction involving a solid substance, a dissolved substance, and hydrogen ion in water without free electrons gives a vertical straight line, that is, independent of potential (when $n = 0$, the slope of the line equals ∞).
2. A reaction involving a solid substance and a dissolved substance in water plus free electrons but without hydrogen ion gives a horizontal straight line, that is, independent of pH (when $h = 0$, the slope = 0).
3. A reaction involving a solid substance, a dissolved substance, free electrons, and hydrogen ion will give a straight line with a slope equal to $-0.0591h/n$.

After plotting the straight lines on potential versus pH coordinates, the domain of the thermodynamic stability for each individual species is determined by requiring that all equations involving that species be satisfied simultaneously.

Example 7.1. One solid substance, one dissolved substance, and hydrogen ion in water without free elections:

$$2\mathrm{Fe}^{3+} + 3\mathrm{H_2O} = \mathrm{Fe_2O_3} + 6\mathrm{H}^+ \tag{7.3}$$

Assuming the activities of H_2O and Fe_2O_3 to be unity, the equilibrium constant may be expressed as

$$K = \frac{(a_{\mathrm{H}^+})^6}{(a_{\mathrm{Fe}^{3+}})^2} \tag{7.4}$$

$$\begin{aligned} \log K &= 6 \log(a_{\mathrm{H}^+}) - 2 \log(a_{\mathrm{Fe}^{3+}}) \\ &= -6\,\mathrm{pH} - 2 \log(a_{\mathrm{Fe}^{3+}}) \end{aligned} \tag{7.5}$$

Referring to tabulated thermodynamic data and substituting in the Van't Hoff equation, log K may be calculated:

$$\Delta G^\circ = -RT \ln K = -2.303 \times 1.987 \times 298 \log K$$

$$\log K = \frac{-\Delta G^\circ}{2.303 \times 1.987 \times 298} \tag{7.6}$$

$$= \frac{-(-1970)}{1373} \tag{7.7}$$
$$= 1.43$$

Substituting in Eq. (7.5) and rearranging, we obtain a generalized Pourbaix equation,

$$\log(a_{Fe^{3+}}) = -0.72 - 3\text{pH} \tag{7.8}$$

In the case where

$$(a_{Fe^{3+}}) = 10^{-6}$$

then pH = 1.76.

This gives a vertical line on the Pourbaix diagram.

Example 7.2. One solid substance, one dissolved substance, and electrons, but without H^+ as a reactant or product:

$$Fe \rightarrow Fe^{2+} + 2e^- \tag{7.9}$$

$$K = a_{Fe^{2+}} \tag{7.10}$$

$$\log K = \log (a_{Fe^{2+}}) \tag{7.11}$$

Using tabulated thermodynamic data, substitution in Eq. (7.2) gives

$$\phi = \frac{-20,300}{2 \times 23,060} + \frac{0.0591}{2} \log(a_{Fe^{2+}}) \tag{7.12}$$

$$\phi = -0.440 + 0.0295 \log(a_{Fe^{2+}})$$

which is a generalized Pourbaix equation.

In the case where

$$a_{Fe^{2+}} = 10^{-6}$$

then

$$\phi = -0.617\text{ V}$$

This gives a horizontal line on the Pourbaix diagram.

Example 7.3. One solid substance, one dissolved substance in water, plus free electrons, and hydrogen ion:

$$2Fe^{2+} + 3H_2O = Fe_2O_3 + 6H^+ + 2e^- \tag{7.13}$$

The equilibrium constant for this reaction may be expressed as

$$K = \frac{(a_{H^+})^6}{(a_{Fe^{2+}})^2} \tag{7.14}$$

and

$$\begin{aligned} \log K &= 6 \log(a_{H^+}) - 2 \log(a_{Fe^{2+}}) \\ &= -6\text{ pH} - 2 \log(a_{Fe^{2+}}) \end{aligned} \tag{7.15}$$

Substitution into Eq. (7.2) gives

$$\phi = \frac{33,570}{2 \times 23,060} + \frac{0.0591}{2}[-6\text{ pH} - 2\log(a_{Fe^{2+}})]$$
$$= 0.728 - 0.1773\text{ pH} - 0.0591 \log(a_{Fe^{2+}}) \tag{7.16}$$

a generalized Pourbaix equation.

In the case where

$$a_{Fe^{2+}} = 10^{-6}$$

then

$$\phi = 1.0826 - 0.1773\text{ pH}$$

This gives a sloping line on the Pourbaix diagram.

C. CONSTRUCTION OF DIAGRAMS

Table 7.1 lists the data for the iron–water diagram together with the various reactions and equilibrium formulas [1]. Figure 7.1 shows a resulting Pourbaix diagram considering that the only solid species are iron, Fe_3O_4, and Fe_2O_3. Naturally, a number of other assumptions could have been made. However, this serves to illustrate the construction of a diagram. Lines ⓐ and ⓑ designate the limits of thermodynamic stability of water at 298 K and 1 atm pressure. Above line ⓑ, water is unstable with regard to the evolution of oxygen, and below line ⓐ, water is unstable with respect to the evolution of hydrogen. The other dashed lines on the diagram comprise an "ionic species diagram." For ionic species (dashed lines), the coexistence lines represent the condition wherein the thermodynamic activity of the species on each side of that line is the same. For example, on line 6′, the activities of Fe^{2+} and $Fe(OH)_2{}^+$ are equal. The triple point involving lines 1′, 6′, and 7′ is an invariant point at which the activities of Fe^{2+}, $Fe(OH)_2{}^+$, and $HFeO_2{}^-$ are the same.

A line on the diagram represents a univariant system, whereas a family of lines, each of which is related to a value of a parameter, represents a divariant or trivariant system depending on whether the parameter contains one component (concentration) or two components (a term containing two concentrations). Heavy solid lines are used to separate solid species, whereas lighter weight solid lines are used to delineate the boundaries between a solid species and an ionic species.

TABLE 7.1. Information, Reactions, and Equilibrium Formulas for the Iron–Water System at 298 K (25°C) and 1 atm

A. Substances Considered and Substances not Considered

	Oxidation Number (Z)	Considered	Not Considered	μ°(cal)	Name, Color Crystalline System
Solid substances	0	Fe	—	0	α-Iron, light gray, face-centered-cubic (fcc)
	+2	FeO hydr.	—	– 58,880	Ferrous hydroxide $Fe(OH)_2$, white, rhomb.
	+2	—	FeO anh.	—	Ferrous oxide, black, cubic
	+2.67	Fe_3O_4 anh.	—	– 242,400	Magnetite, black, cubic
	+2.67	—	$Fe_3O_4 \cdot xH_2O$	—	Hydrated magnetite, green-black
	+3	Fe_2O_3 anh.	—	(a) – 177,100	Haematite, red-brown, rhomb. or cubic
	+3	Fe_2O_3 hydr.	—	(b) – 161,930	Ferric hydroxide $Fe(OH)_3$, red-brown, fcc
Dissolved substances	+2	Fe^{2+}	—	– 20,300	Ferrous ion, green

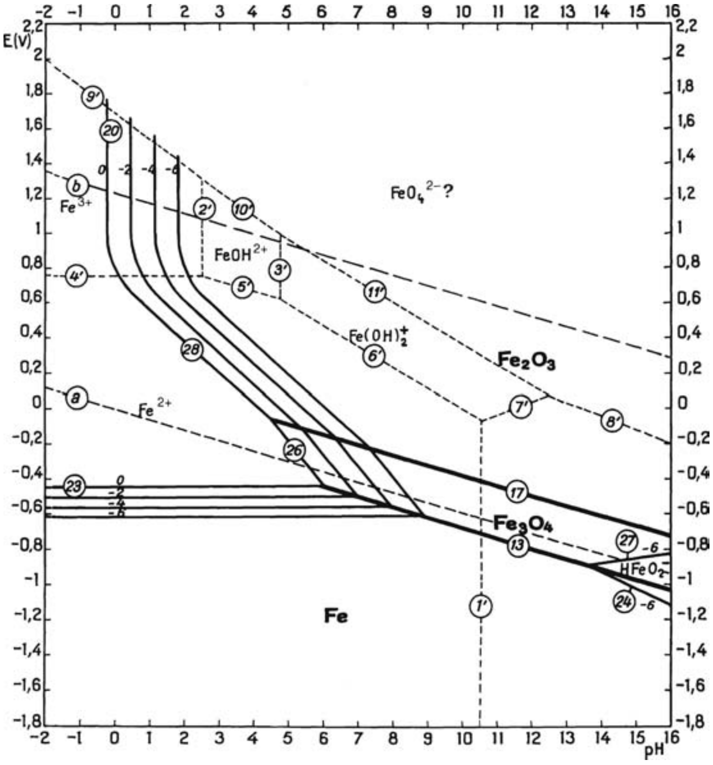

FIGURE 7.1. Potential–pH equilibrium diagram for the system iron–water at 25°C (considering as solid substances only Fe, Fe_3O_4. and Fe_2O_3) [1], Reproduced with permission from [1]. Copyright © Marcel Pourbaix.

Example Problem. It is suggested that the reader construct the Pourbaix diagram for the Fe–H_2O system (considering the solid species Fe, Fe_3O_4, and Fe_2O_3) at 298 K and 1 atm pressure. Plot the diagram on graph paper using pH ranging from -2 to $+16$ and the electrode potential from -1.8 to $+2.2$ V_{SHE}. The equations for each coexistence already have been calculated and are listed in Table 7.1. It will be necessary to define what ionic activity will be considered to represent "significant corrosion." The establishment of what is considered to be "corrosion" evolves into a determination as to the amount of metal dissolution which is permissible "for all practical purposes." It often has been found convenient to consider the solubility of 10^{-6} g atoms of soluble ion per liter as representing "no corrosion for all practical purposes." On Figure 7.1, this assumption is represented by the lines marked -6 (the logarithm of the activity).

The domain of the metal is found at the bottom of the diagram. For simplicity, it is suggested that the equilibrium involving the metal and its least highly oxidized ionic form is an easy equilibrium to start with. In this case, we are considering Eq. (7.23) in Table 7.1 involving iron and ferrous ion. In as much as no hydrogen ion is involved, it is apparent that this equilibrium coexistence involves a family of horizontal lines on potential versus pH coordinates the position of which depends on the assumed value of thermodynamic activity chosen for the ferrous ion. If you choose 10^{-6} for the ionic activity, you will obtain only one line. The question arises as to whether the domain of iron is above or below the line. Referring to the electrochemical equation,

$$Fe \rightarrow Fe^{2+} + 2e^-$$

a "thought experiment" is helpful in answering this question. If electrons were added, the reaction would be driven in the direction of iron; thus, the addition of electrons (and hence more negative potentials) favors iron rather than Fe^{2+}. Therefore, Fe is below the line and Fe^{2+} above the line.

The next question is "How far along the pH axis does the horizontal Fe/Fe^{2+} equilibrium coexistence extend?" To the left, the boundary is usually chosen arbitrarily by selecting the range of pH of interest. The limit for this line in the direction of higher pH depends on the activities of the ionic species and the restrictions imposed by other equilibria, for example, line 13 in Fig. 7.1, which is the coexistence between iron and Fe_3O_4.

$$3Fe + 4H_2O \rightarrow Fe_3O_4 + 8H^+ + 8e^-$$

This is a logical choice for next consideration, since Fe_3O_4 is the solid species that involves oxide with the lowest level of oxidation of iron. Reaction 13 in Table 7.1 involves both

electrons and hydrogen ion and will be a sloping line on the diagram. Another thought experiment will reveal on which side of line 13 iron is stable and on which side Fe_3O_4 is stable. Since this is a sloping line, there are two ways in which this decision can be made. Adding electrons will favor Fe; hence, Fe will be on the more negative side of the line (i.e., below the line). Addition of hydrogen ion (lower pH) also stabilizes the species iron. Thus, iron should be to the left of (or below) the line and Fe_3O_4 to the right (or above). Simultaneous solution of the equations for lines 23 and 13 will reveal the point of intersection and consequently the termination of dominance of the Fe/Fe^{2+} coexistence.

A similar calculation for reaction 26 in Table 7.1 between Fe^{2+} and Fe_3O_4 yields another line with a slope different from reaction 13:

$$3Fe^{2+} + 4H_2O \rightarrow Fe_3O_4 + 8H^+ + 2e^-$$

Adding either H^+ or electrons to the right side pushes the reaction to the left to restore equilibrium. This favors the species on the left (Fe^{2+}). By using the same procedures, it is observed that lines 23, 26, and 13 in Figure 7.1 intersect at an invariant point for a given activity of ferrous ion.

Line 20, the equilibrium between Fe^{3+} and Fe_2O_3, represents a reaction in which there is no electron transfer. Thus, by inspection of the equation, this coexistence will appear as a vertical line on the Pourbaix diagram. The decision of which species is on which side of the line can easily be made by assessing the effect of adding hydrogen ions and observing that this addition favors Fe^{3+}. Thus, Fe^{3+} is on the low-pH side of the line.

It is suggested that the equilibrium coexistences be taken one at a time progressing from the elemental state through the various oxidized states to establish the limits of each of the lines. It usually becomes complicated to draw all the lines and to remove those lines and portions of lines that are redundant or improper.

When the diagram is complete, it is possible to test the predictions of the Pourbaix diagram you have just drawn. Table 7.2 reports a number of experiments conducted by

TABLE 7.2. Corrosion and Noncorrosion of Iron at 298 K[a,b]

[a]Experimental conditions used to test the predictions of the Pourbaix diagram for the iron–water system.
[b]Excerpted from M. Pourbaix. Lectures on Electrochemical Corrosion, NACE, Houston, 1995 p. 18.
[c]Abbreviations: Y = corrosion; N = no corrosion.

Pourbaix in which iron electrodes were immersed in various solutions. The pH and the electrode potential were measured in each case, and the specimens were allowed to stand in beakers containing each of the indicated chemical environments. Now plot on the diagram the data from the experiments numbered 1–25 in Table 7.2. For convenience, the sample numbers should be written beside each data point. This will make it possible to compare the experimental results of Pourbaix with the predictions based on the Pourbaix diagram. Remember, the term "immunity" is reserved for noncorrosion and represents the case in which corrosion cannot occur for thermodynamic reasons. The term "corrosion" is reserved for areas of the diagram where an ionic species is the stable species thermodynamically. "Passivation" describes the portion of the diagram where a solid reaction product is formed. Presumably, if the solid reaction product is protective, corrosion will stop. Thus, the term "passivation" might be said to apply to a region in the diagram where (thermodynamically) corrosion is possible, but it does not occur, because of the formation of a barrier coating. The diagram is not sufficient to decide whether a solid reaction product is also protective. This information can only be gained by performing an experiment, Comparison between the data points on your diagram with the information contained in Table 7.2 should reveal that in each case shown the Pourbaix diagram would have predicted correctly whether or not corrosion would occur merely by knowing the electrode potential and the pH of the solution.

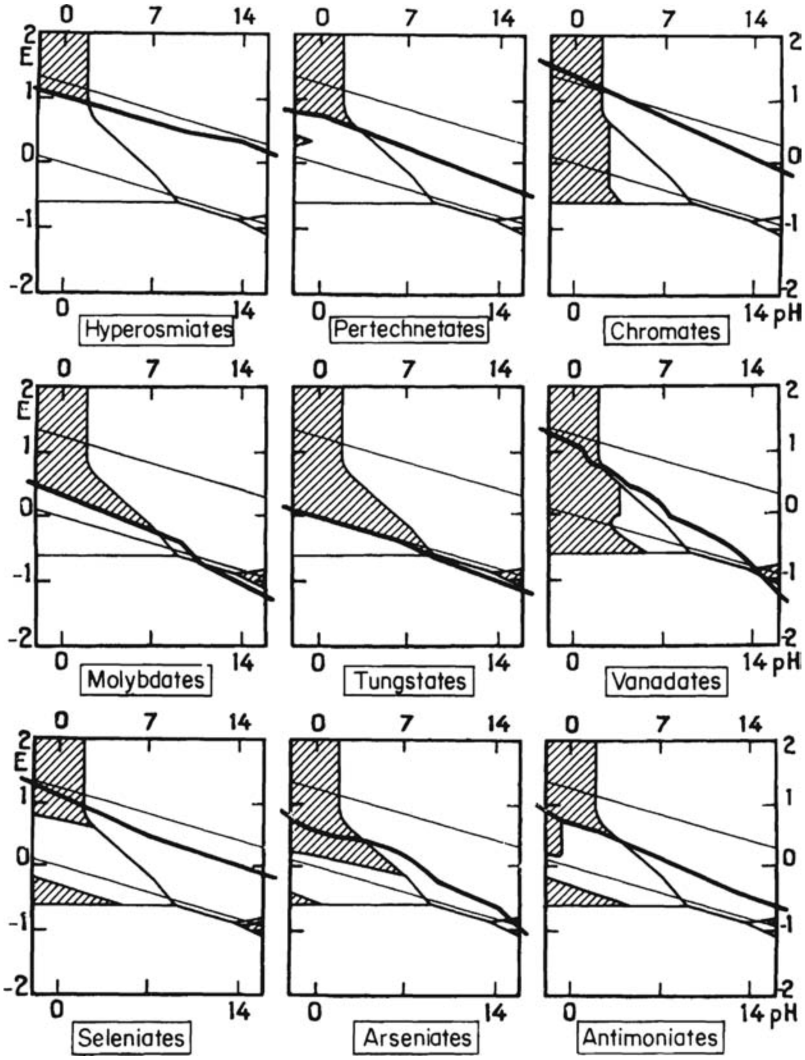

FIGURE 7.2. Oxidizing corrosion inhibitors. The hatched regions indicate theoretical corrosion domains in the presence of 0.01 *M* solutions of inhibitor. Reproduced with permission from [1]. Copyright © Marcel Pourbaix.

D. APPLICATIONS OF POURBAIX DIAGRAMS

It is possible to predict conditions under which corrosion, noncorrosion, and passivation are possible. It is also possible to make a number of other useful predictions. For example, the electrode potential for cathodic protection is represented by the equilibrium coexistence line between ferrous ion and iron in Figure 7.1. The domain of potential and pH in which anodic protection may be considered is represented by the passive region (either Fe_3O_4 or Fe_2O_3), but care should be exercised to avoid the domains where Fe^{2+}, Fe^{3+}, or $HFeO_2^-$ are stable.

If the electrode potential falls in a corrosion regime (e.g., in the region where ferrous ion is stable), it is possible to stop corrosion by adding an oxidant that would bring the electrode potential into the region of stability for Fe_2O_3 by raising the electrode potential, or by changing the pH in the alkaline direction so as to move horizontally into the passive region, or by cathodic protection that has the effect of lowering the potential into the immunity region. It should be emphasized that the predictions made by using the Pourbaix diagram should be tested prior to actual use, since the formation of a reaction product film does not necessarily mean that this film is protective. In addition, cathodic protection may result in hydrogen evolution at the cathode, which could have an adverse effect on protective coatings or might under some circumstances induce hydrogen embrittlement of certain metals.

It is also possible to predict the types of ions that have promise as oxidizing corrosion inhibitors. Superposition of the chromium–water diagram over the iron–water diagram, for example, shows that the region of stability for Cr_2O_3 coincides with a portion of the iron diagram wherein ferrous ion is the stable species.

Consequently, in the absence of an inhibitor, corrosion of iron would be anticipated in this domain of potential and pH. The effect of adding chromates is to provide a means of forming a protective Cr_2O_3 film that inhibits corrosion. Figure 7.2 suggests the influence of various oxidizing inhibitors on the corrosion of iron [1]. These predictions should be tested before actual use.

A. INTRODUCTION

The thermodynamics of aqueous corrosion is conveniently summarized for practical purposes in the diagrams devised by Pourbaix [1]. These diagrams, assembled from the Gibbs energy of formation of ionic species and phases, draw attention to the combined importance of pH (abscissa) and redox potential (ordinate) in distinguishing conditions of active corrosion, passivity, and immunity. In their original form, these isothermal diagrams indicate the regions or domains of stability of one particular metal (or element) in several possible chemical forms, including complex ions and phases, limited, however, to those chemical forms of the metal containing only hydrogen and/or oxygen. Typical diagrams of this type are shown later for Ag, Au, Cu, Fe, and Ni in Figures 8.1, 8.3, 8.5, 8.7, and 8.8. A previous chapter reviews the principles involved in constructing these classical three-element (M–H–O) diagrams from the underlying thermodynamic principles related to the equilibrium between phases and species. This chapter considers the issues that arise when *additional elements* are introduced either as species in the aqueous phase or as alloying in the metal [2].

It is important at the outset to realize that in general it is not possible to progress in the understanding of an alloy corroding in a complex aqueous medium by superimposing a series of conventional Pourbaix diagrams. The corrosion of pure silver or gold in chloride media cannot be understood with the conventional Pourbaix diagrams because important (quite stable) compounds or complex ions involving chloride are not represented in those diagrams. Likewise, the corrosion of iron–nickel alloys cannot be understood by examining conventional Pourbaix diagrams for Fe and Ni; this approach overlooks the importance of $NiFe_2O_4$ that is not found in either diagram [3]. The use of conventional Pourbaix diagrams not surprisingly, therefore, often leads to false conclusions or, worse, the belief that thermodynamic considerations may be of little value generally in matters of aqueous corrosion.

The inclusion of necessarily many more species and phases in the development of multielement diagrams leads to obstacles in diagram construction not encountered in systems of the M–H–O type. The first of these obstacles is the lack of a priori knowledge for a complex system of which species and phases form an equilibrium associated with a domain boundary on the diagram; a formal procedure is required to exclude equilibria such as between Ag_2O_2 and Ag (see Fig. 8.1), which in the traditional diagram development

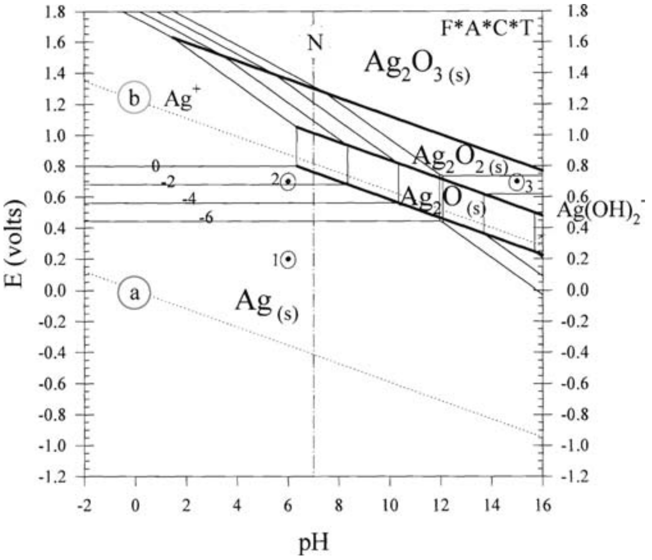

FIGURE 8.1. The Ag Pourbaix diagram at 298 K (25°C). Concentration of aqueous species range from 1 to $10^{-6}m$. Points 1, 2, and 3 should be compared with Gibbs energy changes in Table 8.2.

for Ag may be excluded because of independent knowledge that these phases cannot coexist.

A second practical obstacle in dealing with systems of several elements is that a comprehensive set of diagrams leading to a compilation such as Pourbaix's Atlas is not possible; the enormous number of diagrams resulting from the combinatorial possibilities precludes publication. An easy-to-apply systematic approach not based on any a priori assumptions and therefore amenable to computing is essential.

The third obstacle is more fundamental and subtle in nature and requires decisions about how additional elements are to be incorporated into the diagram development. To oversimplify this matter for the present, it will suffice to say that it is necessary, at the outset of diagram construction, to know whether the additional elements are associated with the corrosive media or with the alloy. The former places constraint(s) on chemical potential(s) or concentrations; the latter places constraints on mass balances. The topology of the multielement Pourbaix diagram therefore depends on how additional elements are treated.

B. COMPUTATION USING GIBBS ENERGY MINIMIZATION

The circumvention of the matters raised in Section A is to be found in the process of Gibbs energy minimization. It is helpful in understanding this process as a basis for its extension into multielement systems by first considering the treatment of a simple M–H–O system. To be more specific, consider the case of silver and the development of the diagram in Figure 8.1. The reactions (involving only H and O) whereby silver may become an ionic species, a compound, or remain in its metallic form (as a degenerate case) are

$$\mathrm{Ag} \rightarrow \mathbf{Ag} \tag{8.1}$$

$$\mathrm{Ag} \rightarrow \mathbf{Ag}^{+} + e^{-} \tag{8.2}$$

$$\mathrm{Ag} + \tfrac{1}{2}\mathrm{H_2O} \rightarrow \tfrac{1}{2}\mathbf{Ag_2O} + \mathrm{H}^{+} + e^{-} \tag{8.3}$$

$$\mathrm{Ag} + \mathrm{H_2O} \rightarrow \tfrac{1}{2}\mathbf{Ag_2O_2} + 2\mathrm{H}^{+} + 2e^{-} \tag{8.4}$$

$$\mathrm{Ag} + \tfrac{3}{2}\mathrm{H_2O} \rightarrow \tfrac{1}{2}\mathbf{Ag_2O_3} + 3\mathrm{H}^{+} + 3e^{-} \tag{8.5}$$

$$\mathrm{Ag} + 2\mathrm{H_2O} \rightarrow \mathbf{Ag(OH)_2^{-}} + 2\mathrm{H}^{+} + e^{-} \tag{8.6}$$

The Gibbs energy change for each reaction depends not only on the standard Gibbs energy of formation [4] of the reactants and products (Table 8.1) but also on the activity or to a good approximation the molal concentration m of the aqueous silver–containing species [add RT ln(m) to the standard Gibbs energy of formation] as well as the pH and redox potential. The Gibbs energy of the H^+ is given by

$$\Delta G_{\mathrm{H}^+} = -2.303RT(\mathrm{pH}) \tag{8.7}$$

and the effective Gibbs energy of the electron (which represents an unspecified redox reaction) is given by

$$\Delta G_{e^-} = -\Im(E_{\mathrm{H}}) \tag{8.8}$$

At any particular condition of E_H and pH there will be, in general, one reaction that gives rise to the largest negative

TABLE 8.1. Thermodynamic Data

Species	$\Delta G°$ (kJ/mol)
H^+	0
H_2O	– 237.2
Ag	0
Ag^+	77.0
Ag_2O	– 10.8
Ag_2O_2	27.4
Ag_2O_3	121.1
$Ag(OH)_2^-$	– 260.2
Cl^-	– 131.1
AgCl	– 109.5
$AgCl_2^-$	– 215.5
$AgClO_2$	75.7

Gibbs energy change per mole of Ag; this is the species or compound associated with the domain in which that point resides. If all of the Gibbs energy changes are positive, the E_H–pH coordinate must reside in the domain of silver immunity. As a convenience in understanding, the Gibbs energy changes in Table 8.2 for reactions (8.1)–(8.6) should be compared with arbitrarily selected points 1, 2, and 3 in Figure 8.1. The domains for all species can be located as precisely as required by repetition of the foregoing for a suitably fine matrix of E_H and pH points. The number of computations can be considerably reduced when it is realized that a domain for a particular phase/species must be contiguous. With any personal computer, this approach, which was completely impractical in the not too distant past, leads to an almost instant construction of the diagram for a particular concentration of the aqueous species. The diagram in Figure 8.1 is actually four such figures superimposed for concentrations of Ag^+ and $Ag(OH)_2^-$ of 1, 10^{-2}, 10^{-4}, and $10^{-6}m$ (strictly speaking activity) developed using data in Table 8.1. The dotted lines ⓐ and ⓑ correspond to redox potentials determined by hydrogen and oxygen saturation at one standard atmosphere, respectively.

C. ADDITIONAL ELEMENT IN THE AQUEOUS PHASE

The flexibility of the Gibbs energy minimization approach is particularly striking when, in addition to H and O, an element such as chlorine (as Cl^-) is considered in the aqueous phase. To continue with silver as the basis for discussion, the reactions to consider in addition to those above are

$$Ag + Cl^- \rightarrow \mathbf{AgCl} + e^- \quad (8.9)$$

$$Ag + 2Cl^- \rightarrow \mathbf{AgCl_2^-} + e^- \quad (8.10)$$

$$Ag + 2\,H_2O + Cl^- \rightarrow \mathbf{AgClO_2} + 4H^+ + 5e^- \quad (8.11)$$

By using the data in Table 8.1, the Gibbs energy change for each reaction can be found as indicated in Section B. Some of the Gibbs energy changes are shown in Table 8.2. In examining Table 8.2 and Figure 8.2, it will be clear than the Ag-containing phase/species associated with the lowest Gibbs energy change is the one labeling the domain at the corresponding E_H–pH coordinate in Figure 8.2.

With the mechanics of construction summarized, it is now appropriate to comment on the role of Cl^-. Chloride ion at the 1 m concentration used in developing Figure 8.2 results in a complete eclipsing of the Ag^+ and Ag_2O fields in Figure 8.1 with AgCl and $AgCl_2^-$ has become the most important Ag-containing ion in all but the most concentrated alkaline solutions. Clearly, the corrosion of silver in aqueous chloride media could not be properly understood using the classical Pourbaix diagram in Figure 8.1, as Pourbaix himself recognized.

TABLE 8.2. Gibbs Energy Minimization at 1 m Concentration for Ag-Containing Aqueous Species (and 1 m Cl^- concentration for the case of Figure 8.2)[a]

Species	Reaction	Point 1 $E_H = 0.2$ V pH = 6.0 (kJ)	Point 2 $E_H = 0.7$ V pH = 6.0 (kJ)	Point 3 $E_H = 0.7$V pH = 15.0 (kJ)
Ag	1	0	0	0
Ag^+	2	57.7	9.4	9.4
Ag_2O	4	59.7	11.4	– 39.9
Ag_2O_2	3	143.8	47.3	– 55.4
Ag_2O_3	5	255.7	111.0	– 43.1
$Ag(OH)_2^-$	6	126.4	78.2	– 24.5
AgCl	9	2.4	– 45.8	– 45.8
$AgCl_2^-$	10	27.7	– 20.6	– 20.6
$AgClO_2$	11	448.0	206.7	1.3

[a] $AgClO_3$ and $AgClO_4$ have been excluded as possible phases.

Figures 8.3 and 8.4 show the influence of chloride on the gold Pourbaix diagram. Note the solubility of Au as tetrachloraurate ion in acidic oxidizing media. This accounts for both the well-known attack of gold by aqua regia and the use of an acidic chloride electrolyte in the Wohlwill gold electrorefining process [5].

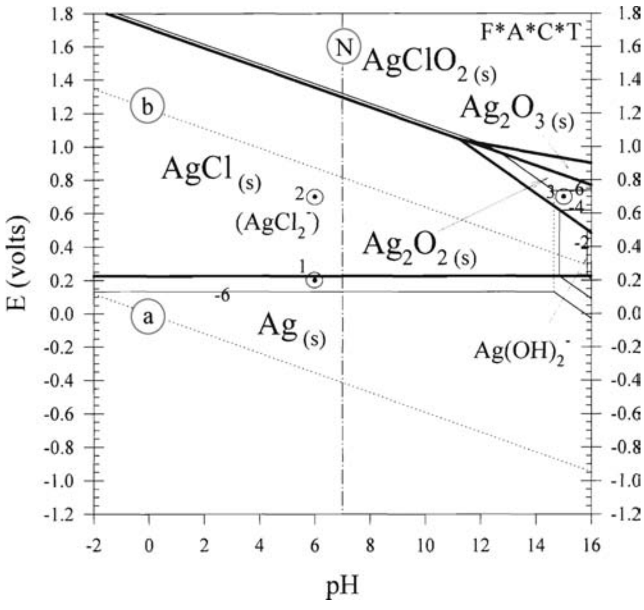

FIGURE 8.2. The Ag Pourbaix diagram at 298 K (25°C) in chloride solution at 1 m Cl^- concentration. The concentration of the Ag-containing species $AgCl_2^-$ and $Ag(OH)_2^-$ is shown at 10^{-6}, 10^{-4}, and $10^{-2}m$. Points 1, 2, and 3 should be compared with Gibbs energy changes in Table 8.2. Note that AgCl completely eclipses the Ag^+ and Ag_2O fields on Figure 8.1 for this concentration of Cl^-.

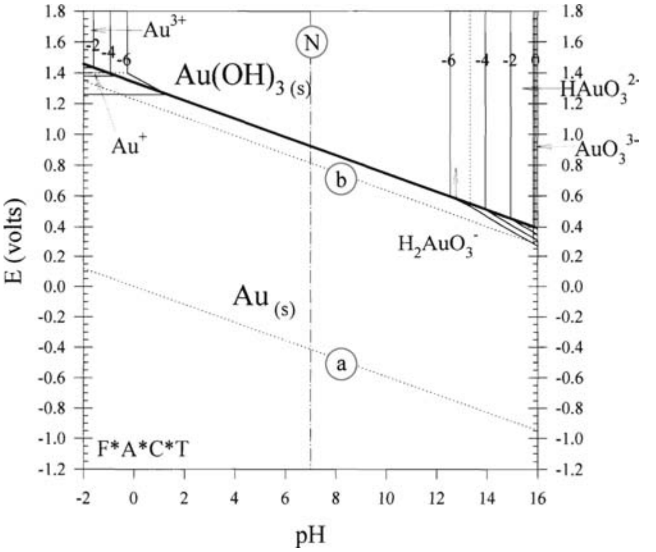

FIGURE 8.3. The Au Pourbaix diagram at 298 K (25°C). Concentration of aqueous species range from 1 to $10^{-6}m$. Gold immunity extends into the strong acid region even under oxygen-saturated conditions (line *b*).

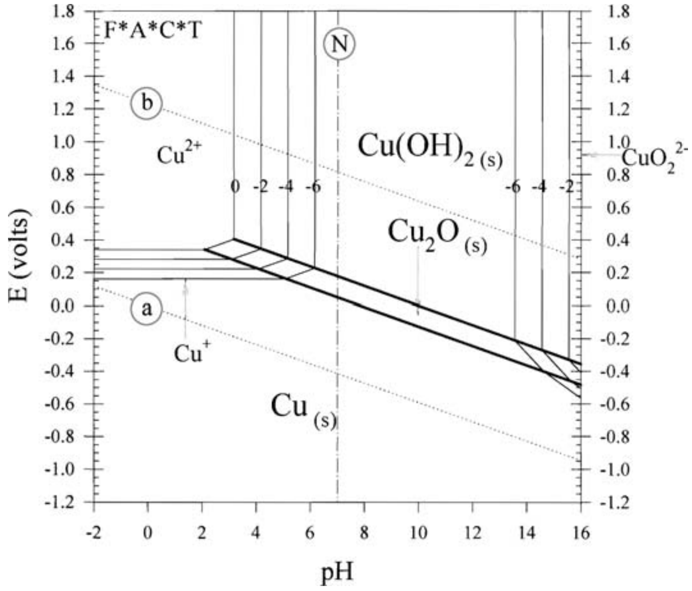

FIGURE 8.5. The Cu Pourbaix diagram at 298 K (25°C). Concentrations of aqueous species range from 1 to $10^{-6}m$. Compare with Figure 8.6 to gauge the effect of a low NH_3 concentration.

The diagrams in Figures 8.5 and 8.6 pertain to the effect of ammonia on copper corrosion. When deaeration additives such as hydrazine, N_2H_4, are added in low concentration to water, the slow chemical breakdown that consumes dissolved oxygen [6] and lowers the redox potential to slightly above line ⓐ also contributes a low concentration ($\sim 10^{-3}m$) of residual ammonia, which tends to raise the pH above neutral. Furthermore, the residual ammonia forms very stable complex ions with copper. Fortunately, as the diagrams show, the

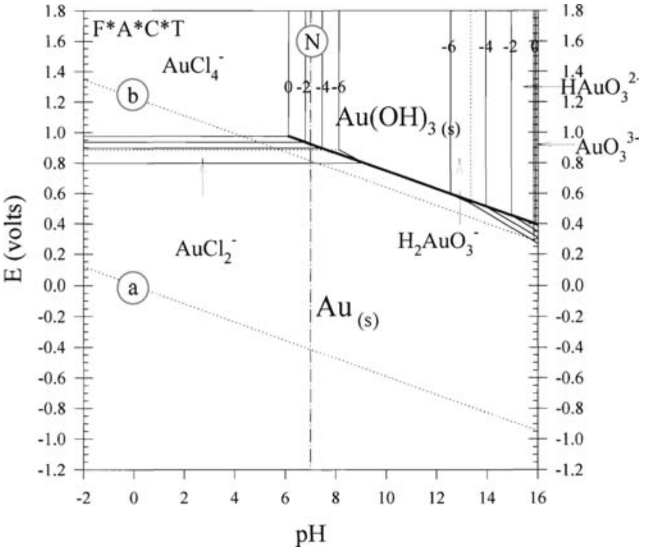

FIGURE 8.4. The Au Pourbaix diagram at 298 K (25°C) in chloride solution at 1 m Cl^- concentration. The concentration of the Au-containing species is shown at 10^{-6}, 10^{-4}, 10^{-2}, and 1 m. The domain of gold immunity does not extend into strong acid solutions for oxygen saturated conditions (line ⓑ) because of the stability of $AuCl_4^-$.

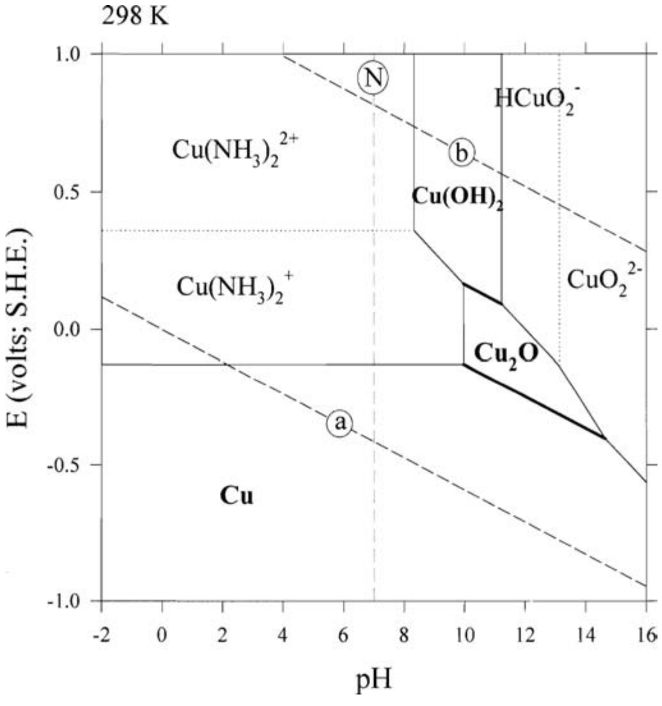

FIGURE 8.6. The Cu Pourbaix diagram at 298 K (25°C) in ammonia-containing solutions at $10^{-3}m$ NH_3. The concentration of copper-containing aqueous species is shown only at $10^{-6}m$.

stability of copper amines is not so great as to contribute to corrosion of copper. Of course, if the ammonia concentration were allowed to increase drastically, it would be necessary to recompute Figure 8.6 to examine the extent to which the copper amine fields enlarge.

The computation of Figure 8.6 is slightly different than Figures 8.2 and 8.4 because the additional species involve more than one element. The formation reactions are not based on ammonia as in

$$Cu + 2\,NH_3 \rightarrow \mathbf{Cu(NH_3)_2}^{+} + e^{-} \qquad (8.12)$$

but rather on the elements

$$Cu + N_2 + 6H^{+} + 5e^{-} \rightarrow \mathbf{Cu(NH_3)_2}^{+} \qquad (8.13)$$

At each E_H–pH coordinate, the effective hydrogen partial pressure can be calculated using

$$E_H = -\frac{RT}{2\Im}\ln(P_{H_2}) - \frac{2.303RT}{\Im}(\text{pH}) \qquad (8.14)$$

The effective N_2 partial pressure can be calculated from the equilibrium constant for

$$N_2 + 3H_2 \rightleftarrows 2\,NH_3 \qquad (8.15)$$

$$K_{eq} = \frac{(m_{NH_3})^2}{(P_{N_2})(P_{H_2})^3} \qquad (8.16)$$

The Gibbs energy changes for formation reactions such as (8.13) can now be calculated since corrections can be made for the effective partial pressure of N_2 by adding $RT\ln(P_{N_2})$.

D. ADDITIONAL ELEMENT IN THE METAL PHASE

When the metal phase is an alloy, the Gibbs energy minimization differs from that described above. In the previous sections, the voluminous nature of the aqueous phase in comparison with the limited quantity of metal corroding permits the concentration of the additional species in the aqueous phase to be considered as constant. In the case of an alloy, it is necessary to specify (and preserve in the diagram development) the molar ratio of the alloy elements that are regarded as being insignificant in total molar amount to other elements in the voluminous aqueous phase.

The general form of the corrosion reactions for a binary alloy, M_1–M_2, is modified from that described above:

$$\{rM_1 + (1-r)M_2\}_{alloy} + \{aH_2O + bH^{+} + cX^{-}\}_{aqueous}$$
$$\rightarrow m(M_1,\ M_2,\ H,\ O,\ X)^{\alpha} + n(M_1,\ M_2,\ H,\ O,\ X)^{\beta} \qquad (8.17)$$

where the two product compounds, α and β, contain M_1 and M_2 *in different proportions* and may or may not contain H, O, and additional element(s) in the aqueous phase X and where m and n are nonnegative mole numbers for the value of r that is selected for the alloy. This may be called the mass balance constraint. To establish at each coordinate which pair of compounds is most stable, it is first necessary to find from among all possible compounds the pairs that satisfy the mass balance constraint. Thereafter, the Gibbs energy change for all of these reactions (based on 1 mol of alloy) is computed. Finally, the reaction with the most negative Gibbs energy change is found, thereby identifying the most stable pair of compounds at that particular E_H and pH. The resulting diagram has domains that are doubly labeled for the case of a two-component alloy. As a special case, when there are no product compounds that contain both M_1 and M_2, the resultant diagram is the superimposition of the two conventional Pourbaix diagrams for M_1 and M_2. This, unfortunately, is indeed a special case that is the exception rather than the rule.

Figures 8.7 and 8.8 show the conventional Pourbaix diagrams for Fe and Ni. These may be compared with Figures 8.9–8.12, which show the computed Fe–Ni composite diagram at four different levels of aqueous species concentration ranging from 1 to $10^{-6}m$. The complexity of the diagram is such that it is virtually essential to provide a series of diagrams for particular concentrations of aqueous species. The compound that gives rise to the complex appearance, namely, the $NiFe_2O_4$ phase, is boldly outlined. The inability to comprehend the thermodynamics of Fe–Ni alloy using

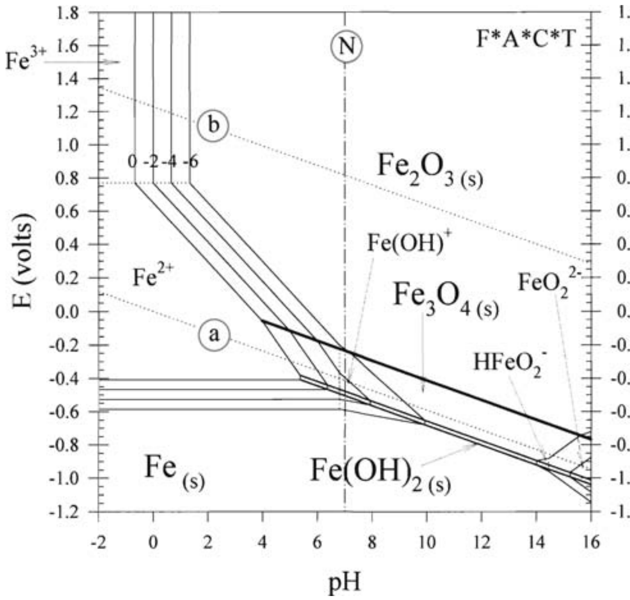

FIGURE 8.7. The Fe Pourbaix diagram at 298 K (25°C). Concentrations of aqueous species range from 1 to $10^{-6}m$.

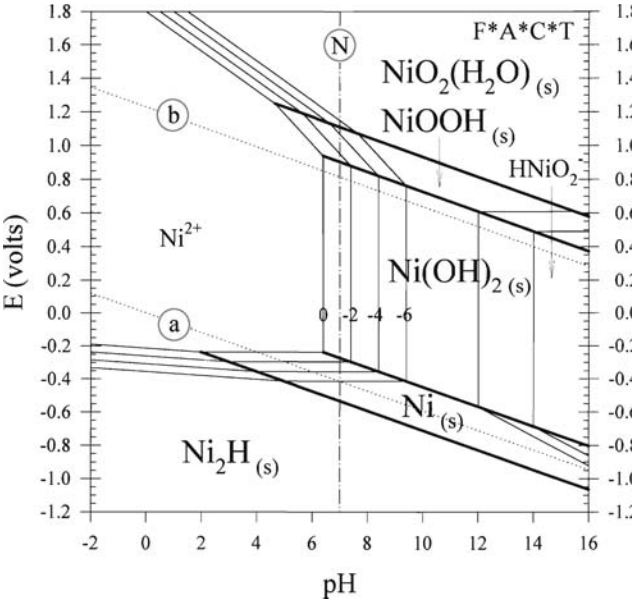

FIGURE 8.8. The Ni Pourbaix diagram at 298 K (25°C). Concentrations of aqueous species range from 1 to $10^{-6}m$.

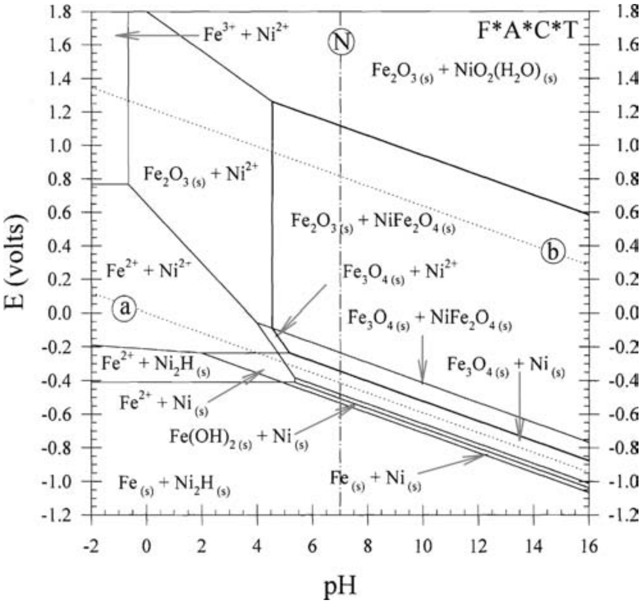

FIGURE 8.9. The Fe–Ni composite Pourbaix diagram at 298 K (25°C). The concentration of all aqueous species is 1 *m*. The molar proportion of Fe to Ni is $>2:1$. The specific proportion affects the phase proportions in each doubly labeled field but does not affect the topology until the ratio falls below 2: 1 (when, e.g., $NiFe_2O_4$ could not coexist with Fe_2O_3 for mass balance reasons). Note the placement of $NiFe_2O_4$ solid spinel, which is outlined in bold.

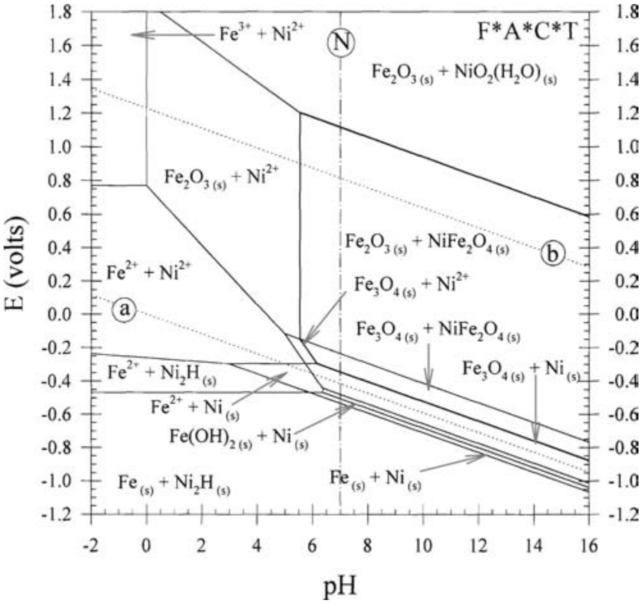

FIGURE 8.10. The Fe–Ni composite Pourbaix diagram at 298 K (25°C). The concentration of all aqueous species is $10^{-2}m$. The molar proportion of Fe to Ni is $>2:1$. Note the placement of $NiFe_2O_4$, solid spinel, which is outlined in bold.

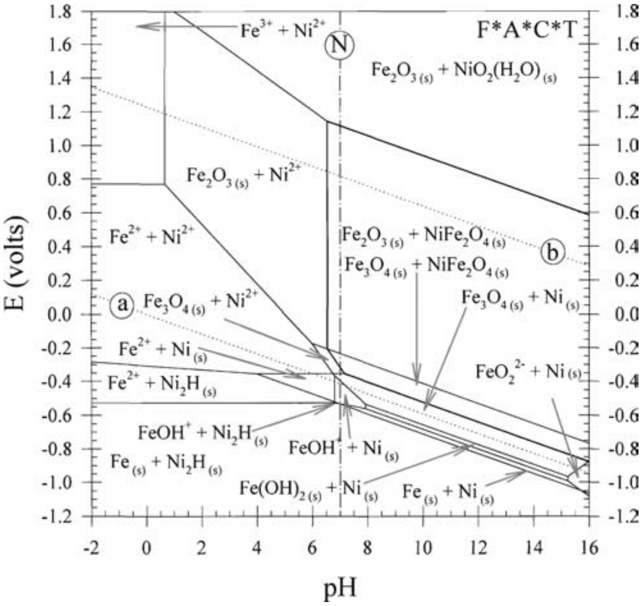

FIGURE 8.11. The Fe–Ni composite Pourbaix diagram at 298 K (25°C). The concentration of all aqueous species is $10^{-4}m$. The molar proportion of Fe to Ni is $>2:1$. Note the placement of $NiFe_2O_4$ solid spinel, which is outlined in bold.

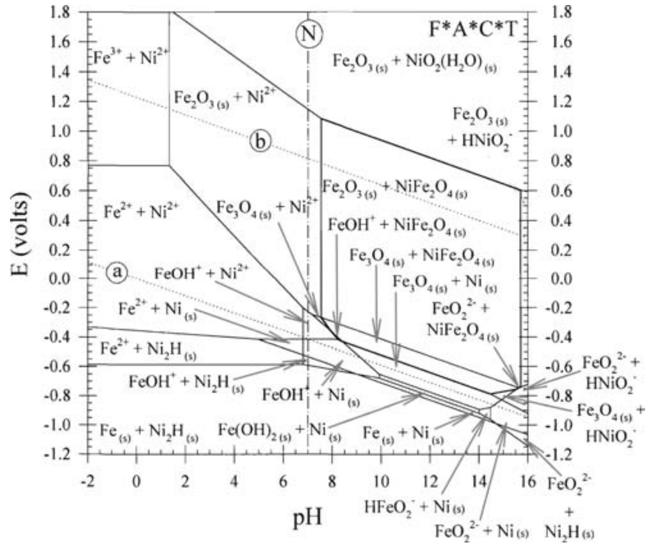

FIGURE 8.12. The Fe–Ni composite Pourbaix diagram at 298 K (25°C). The concentration of all aqueous species is $10^{-6} m$. The molar proportion of Fe to Ni is $>2:1$. Note the placement of $NiFe_2O_4$ solid spinel, which is outlined in bold.

only the conventional Fe and Ni diagrams does not require further comment [3].

E. CONCLUSIONS

Pourbaix diagrams are invaluable tools in the understanding of the thermodynamics of aqueous corrosion. However, it is usually the case that these must be specially constructed to incorporate all of the elements, whether found in the alloy or aqueous phase, that can lead to the formation of significant phases or species. The methodology of Gibbs energy minimization is particularly effective for this purpose, in that no suppositions about coexistence of phases or species is necessary and it can be extended to handle many elements as suggested in this chapter. The technique, therefore, is well suited to computational methods and is especially convenient to use when the programming is linked to a database of thermodynamic properties. In this regard, all of the figures shown were prepared using the Facility for the Analysis of Chemical Thermodynamics (F*A*C*T) [7], although certain enhancements were applied for the purposes of this chapter.

ACKNOWLEDGMENT

A. INTRODUCTION

As other chapters in this handbook indicate, redox potential–pH (or Pourbaix) diagrams contribute to a better understanding of aqueous corrosion phenomena, in particular, the depiction of the relative stability of the metallic elements in various possible phases or water-soluble species. However, to achieve this objective, it may be necessary to custom construct diagrams showing the influence of water impurities and alloying additions as discussed in Chapter 8. There is sometimes the effect of temperature to consider as well. This matter, with some attention given to the activity effect on the metallic elements caused by alloying, is the principal subject of this chapter.

The Zircaloy system provides a good basis to discuss the effect of temperature on Pourbaix diagrams. This alloy, important in nuclear energy technologies, is essentially a binary combination of Zr and Sn (0.25–2.5 wt %) [1] and is used principally to isolate the natural or isotopically enriched UO_2 fuel from direct contact with pressurized (~100 atm) heavy water in the primary heat transport system. The high hydrostatic pressure to suppress boiling creates a situation where an aqueous phase contacts the alloy at temperatures in the range 250–300°C, nearly the maximum possible (critical condition for water is 374°C at 218 atm [2]). Although heavy water, D_2O, actually contacts the Zircaloy in some designs (e.g., CANDU reactors), the very small chemical distinction between D_2O and H_2O does not detectably affect the construction of Pourbaix diagrams. Accordingly, the thermodynamic properties for H_2O may substitute for D_2O for computational purposes in the construction of the Sn and Zr diagrams.

B. THERMODYNAMIC DATA

The construction of Pourbaix diagrams at elevated temperatures follows the practice recommended in Chapter 8 except for the matter of handling the Gibbs energies for the various possible species. In Chapter 8, the standard Gibbs energies *of formation* were supplied as constants at 298 K. In the present case, a temperature-dependent formulation for the standard Gibbs energy of formation, ΔG°, is required. This formulation is generally based on experimental or estimated data for the enthalpy of formation, $\Delta H^\circ_{298\ \mathrm{K}}$, the absolute entropy, $\Delta S^\circ_{298\ \mathrm{K}}$, and the heat capacity, c_p. The heat capacity

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie
Copyright © 2011 John Wiley & Sons, Inc.

may be a function of temperature and is typically represented by a series such as

$$c_p = a + bT + cT^2 + dT^{-2} + \cdots \quad (9.1)$$

The formulation for the standard Gibbs energy (pure phase or aqueous species at unit activity, that is, approximately 1 *m*) at any temperature and pressure is

$$G^\circ_{T,P} = \Delta H^\circ_{298\ \mathrm{K}} + \int c_p\, dT - T\left(S^\circ_{298\ \mathrm{K}} + \int \frac{c_p}{T} dT\right) + \int V\, dP \quad (9.2)$$

This standard Gibbs energy (no Δ) is sometimes called the "absolute" Gibbs energy [3] in reference to the use of absolute entropy in place of the entropy of formation. However, in truth, the Gibbs energy calculated in this way remains a relative term intended only as an initial step in finding Gibbs energy *differences* for isothermal, isobaric chemical reactions.

For example, for the process

$$Sn^{4+} + 2H_2O \rightarrow SnO_2 + 4H^+ \quad (9.3)$$

the correct standard Gibbs energy *change* can be found by summing the products of the number of moles and "absolute" standard (molar) Gibbs energies for the species on the right and deducting from it a similar summation from the left. Conventions used in recording the properties in Table 9.1 result in the Gibbs energy of formation, ΔG°, for H^+ being zero at all temperatures [4]. The last term in Eq. (9.2) involving the small molar volume is typically (for nongaseous species) well within the uncertainty in the other terms when the hydrostatic pressure does not greatly exceed 100 atm. Accordingly, the $V\,dP$ term may be dropped or equivalently the hydrostatic pressure may be ignored as a practically significant variable in Pourbaix diagram construction.

A large body of experimental data have been gathered for the Gibbs energy of formation of aqueous species at 298 K or its equivalent expressed in electrochemical terms (tables of standard electrode potential). Less experimental data are available for partial molar enthalpy of formation and partial molar heat capacity of aqueous species. Partial molar properties for solutes in water are to be understood as the disturbing effect on the heat capacity of an aqueous solution property by the small addition of those solutes, typically ions. Thus, the partial molar heat capacity for aqueous species may be positive or negative. Fortunately, the effect of heat capacity on ΔG° calculated using differences in "absolute" G° is very small, so a lack of heat capacity information for an aqueous species has no major consequence on the computation of ΔG° at the modest elevated temperatures associated with Pourbaix diagram construction. The entropy (that may also be positive or negative for an aqueous species) is the main factor conferring temperature dependence to ΔG°, or equivalently in assessing the contribution of ΔH° to ΔG°. It is sometimes necessary to estimate the standard entropy based on chemical similarities and trends with other aqueous species for which measurements have been reported. The choice of the estimated entropy and its influence on diagram construction are pursued below.

C. Sn POURBAIX DIAGRAM

Data for all species of Sn involving H and O are shown in Table 9.1 [5–8]. Data in italics were estimated in a way that is

Note: Data in italics were estimated.

intended to be representative of practices that have been applied to many other high-temperature Pourbaix diagram computations [9]. In the case of Sn^{4+}, the partial molar heat capacity expression was taken to be the same as Sn^{2+} [7]. For the other aqueous ions, where there was no basis for estimation, the partial molar heat capacity was set to zero. The entropy of Sn^{4+} was estimated based on chemical similarities with other 4^+ ions (e.g., U^{4+}). The enthalpy change for Sn^{4+} was then calculated to give a Gibbs energy difference in relation to Sn^{2+} so that the redox potential [+0.151 V standard hydrogen electrode (SHE) at 298 K] would be respected for

$$Sn^{4+} + 2e^- \rightarrow Sn^{2+} \tag{9.4}$$

For $SnOH^+$, SnO_3^{2-}, and $HSnO_2^-$ the partial molar heat capacity was set to zero, the entropies were estimated, and the enthalpies of formation were calculated to duplicate features of the Sn diagram in the Pourbaix Atlas [8] at 298 K. The hydrogen–oxygen species [4, 7, 10] are included at the bottom of the table to justify the conventional placement of the *a* and *b* lines associated with redox potential conferred by 1 atm partial pressure of H_2 or 1 atm partial pressure of O_2, respectively.

The data in Table 9.1 generate the "absolute" Gibbs energies in Table 9.2 at 298 K, 373 K, and 550 K. As support for the relative significance of hydrostatic pressure, the Gibbs energy for water is given at both 1 and 100 atm; the difference is 0.2 kJ/mol. The heat capacity is also given.

A plot of G° versus T for Sn^{4+} in Figure 9.1 gives evidence of the small effect of c_p in causing departure from linear variation for aqueous species. This is particularly so when the entropy is large.

C1. Electron in Aqueous Thermodynamic Computations

The use of the electron symbol, e^-, in aqueous thermodynamics is in reference to electrons understood to be exchanged with a SHE for which the potential is defined to be zero *at all temperatures* [4] when hydrogen gas at 1 atm partial pressure coexists with hydrogen ions at pH zero. Thus, the electrochemical reaction

$$Sn^{2+} + 2e^- \rightarrow Sn \tag{9.5}$$

actually refers to the reaction

$$Sn^{2+} + H_2 \rightarrow Sn + 2H^+ \tag{9.6}$$

and, in particular, the Gibbs energy change for both processes are the same.

Equivalently, one can say that the standard Gibbs energy change for the following process [understood to be combined with Eq. (9.5) to give Eq. (9.6)]

$$H^+ + e^- \rightarrow \tfrac{1}{2}H_2 \tag{9.7}$$

is zero at all temperatures. This change may be expressed as a difference in "absolute" Gibbs energies

$$\Delta G^\circ = \tfrac{1}{2}G^\circ_{H_2} - G^\circ_{H^+} - G^\circ_{e^-} = 0 \tag{9.8}$$

But, since $G^\circ_{H^+}$ is also defined to be zero at all temperatures (Table 9.2), then

TABLE 9.2. Absolute Gibbs Energies and Heat Capacities at Selected Temperatures

Species	$G^\circ_{298\,K}$(J/mol)	$G^\circ_{373\,K}$(J/mol)	$G^\circ_{550\,K}$(J/mol)	$c_{p(298\,K)}$ (J/mol/K)	$c_{p(373\,K)}$ (J/mol/K)	$c_{p(550\,K)}$ (J/mol/K)

$H_2O_{(l,100\ atm)}$	− 306,505	− 312,396	− 330,635	75.4	76.0	83.7
$H_{2\ (gas)}$	− 38,930	− 48,955	− 74,284	28.8	29.1	29.3
$O_{2\ (gas)}$	− 61,132	− 76,736	− 115,312	29.4	29.9	31.6

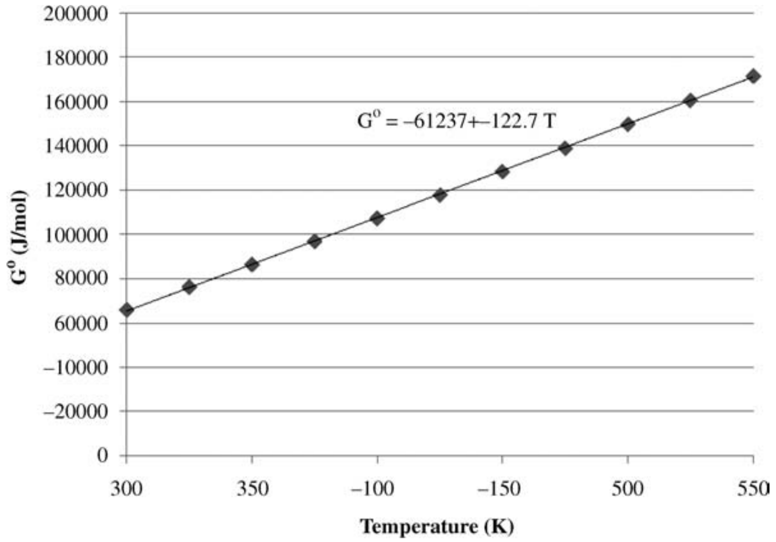

FIGURE 9.1. Plot of absolute G° [Eq. (9.2)] as a function of temperature for Sn^{4+} showing the small effect of c_p on departure from otherwise linear behavior.

$$G^\circ_{e^-} = \left\{\tfrac{1}{2} G^\circ_{H_2}\right\} \tag{9.9}$$

Thus, for example, in computing the standard reduction potential for

$$Sn^{2+} + 2e^- \rightarrow Sn \tag{9.10}$$

from thermodynamic data, such as given in Table 1, the standard Gibbs energy difference is first calculated using

$$\Delta G^\circ = G^\circ_{Sn} - G^\circ_{Sn^{2+}} - 2\left\{\tfrac{1}{2} G^\circ_{H_2}\right\} \tag{9.11}$$

where the term in braces accounts for each electron in Eq. (9.10). The standard electrode potential E°_h (-0.137 V SHE) is then found using

$$\Delta G^\circ = -2F\left(E^\circ_h\right) \tag{9.12}$$

where F is the faraday (96,485 C/mol).

C2. Development of the Pourbaix Diagram

The construction of the Pourbaix diagram from the absolute Gibbs energies in Table 9.2 is as described in Chapter 8 in this handbook except that in this case the Gibbs energy *changes* for the reactions (calculated using "absolute" Gibbs energies) must take into account the formalities in dealing with the electron as described above. The computed Pourbaix diagram for tin at 298 K is shown in Figure 9.2 for the conventional concentration for aqueous ions of 10^{-6} molar deemed to be significant in most corrosion applications [8].

As an affirmation of the methodologies involved in this construction, consider the placement of triple points, 1 and 2, so labeled in Figure 9.2. Table 9.3 provides the Gibbs energy changes for the reactions (9.13a)–(9.17a). These involve Sn^{2+}, Sn^{4+}, SnO_2, $SnOH^+$, and SnO. Details for determining the Gibbs energy change at 298 K and $10^{-6}m$ for aqueous Sn ions are shown below each reaction (9.13b)–(9.17b); note the inclusion of the term in braces for the "absolute" Gibbs energy of e^- and the addition of $-F(E^\circ_h)$ for each e^- when the redox potential is not zero [as described in Eq. (8.8) in Chapter 8]:

$$Sn \rightarrow Sn^{2+} + 2e^- \tag{9.13a}$$

$$\begin{aligned}\Delta G = {} & \left[G^\circ_{Sn^{2+}} + RT\ln(10^{-6})\right] \\ & + 2\left[\left\{\tfrac{1}{2} G^\circ_{H_2}\right\} - F(E_h)\right] - G^\circ_{Sn}\end{aligned} \tag{9.13b}$$

$$Sn \rightarrow Sn^{4+} + 4e^- \tag{9.14a}$$

$$\begin{aligned}\Delta G = {} & \left[G^\circ_{Sn^{4+}} + RT\ln(10^{-6})\right] \\ & + 4\left[\left\{\tfrac{1}{2} G^\circ_{H_2}\right\} - F(E_h)\right] - G^\circ_{Sn}\end{aligned} \tag{9.14b}$$

$$Sn + 2H_2O \rightarrow SnO_2 + 4H^+ + 4e^- \tag{9.15a}$$

$$\begin{aligned}\Delta G = {} & G^\circ_{SnO_2} - 4(2.303)RT\,\mathrm{pH} \\ & + 4\left[\left\{\tfrac{1}{2} G^\circ_{H_2}\right\} - F(E_h)\right] - G^\circ_{Sn} - 2G^\circ_{H_2O}\end{aligned} \tag{9.15b}$$

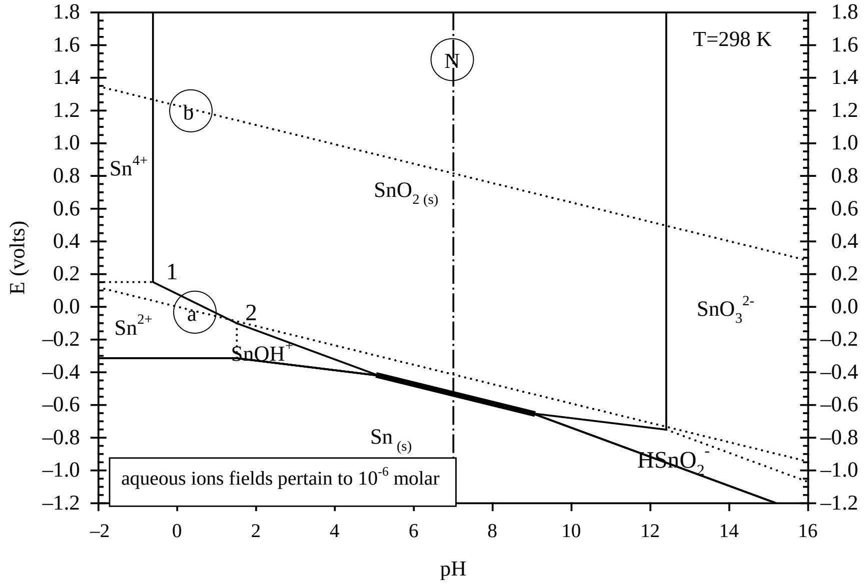

FIGURE 9.2. Pourbaix diagram for Sn at 298 K. The heaviest line represents the phase boundary between coexisting solid phases. The lighter solid lines represent conditions of a condensed phase coexisting with an aqueous solution of the adjacent ion at a concentration of $10^{-6}m$. The broken lines represent conditions where the concentrations of ions flanking those lines are equal. The downward-sloping dotted lines [(*a*) and (*b*)] correspond to H_2 and O_2 saturation at 1 atm partial pressure. The pH of neutrality is indicated with a vertical line labeled (N).

$$Sn + H_2O \rightarrow SnOH^+ + H^+ + 2e^- \tag{9.16a}$$

$$\Delta G = \left[G^\circ_{SnOH^+} + RT\ln(10^{-6})\right] - 2.303RT\,\mathrm{pH} + 2\left[\left\{\tfrac{1}{2}G^\circ_{H_2}\right\} - F(E_h)\right] - G^\circ_{Sn} - G^\circ_{H_2O} \tag{9.16b}$$

$$Sn + H_2O \rightarrow SnO + 2H^+ + 2e^- \tag{9.17a}$$

$$\Delta G = G^\circ_{SnO} - 2(2.303)RT\,\mathrm{pH} + 2\left[\left\{\tfrac{1}{2}G^\circ_{H_2}\right\} - F(E_h)\right] - G^\circ_{Sn} - G^\circ_{H_2O} \tag{9.17b}$$

An examination of Table 9.3 shows that Sn^{2+}, Sn^{4+}, and SnO_2 are equally stable at triple point 1 (same ΔG) and that no other species shown has a more negative ΔG. Similarly, Sn^{2+}, $SnOH^+$, and SnO_2 coexist at triple point 2. SnO is included in the Table 9.3 to give evidence that SnO_2 is the more stable oxide of tin at both triple points (i.e., ΔG for SnO_2 is lower than SnO).

TABLE 9.3. Gibbs Energy Change for Reactions Evaluated at Location of Triple Points 1 and 2 in Figure 9.2

Reaction	Point 1 ($E_h = 0.151$ V SHE, pH= − 0.6175)	Point 2 ($E_h = -0.101$ V SHE, pH = 1.512)
13 (Sn^{2+})	− 89,732	− 41,103
14 (Sn^{4+})	− 89,732	7,524
15 (SnO_2)	− 89,732	− 41,103
16 ($SnOH^+$)	− 77,576	− 41,103
17 (SnO)	− 41,676	− 17,361

The size of the fields for the aqueous species of tin is sensitive to the concentration to which they refer. Figure 9.3 shows the complete development of the Pourbaix diagram for the conventional series of concentrations (taken to be the same as activity following Pourbaix [8]): 1, 10^{-2}, 10^{-4}, and $10^{-6}m$.

Using the same methodology, the diagram for tin at elevated temperatures (550 K) may be constructed as shown in Figure 9.3. Notable points of comparison between the diagram at 298 and 550 K are the following:

- Lines *a* and *b*, corresponding to redox potentials resultant from saturation with H_2 and O_2, respectively, at 1 atm, are steeper at higher temperature (proportional to absolute temperature); the lines also move closer together.

TABLE 9.4. Data Used for SnO_3^{2-} in Construction of Figure 9.5

	Species	$\Delta H^\circ_{298\,K}$	$\Delta S^\circ_{298\,K}$	$\Delta G^\circ_{298\,K}$	$\Delta G^\circ_{550\,K}$
A	SnO_3^{2-}	− 697,394	100.000	− 727,209	− 752,394
B	SnO_3^{2-}	− 724,228	10.000	− 727,209	− 729,728
C	SnO_3^{2-}	− 757,024	− 100.000	− 727,209	− 702,024

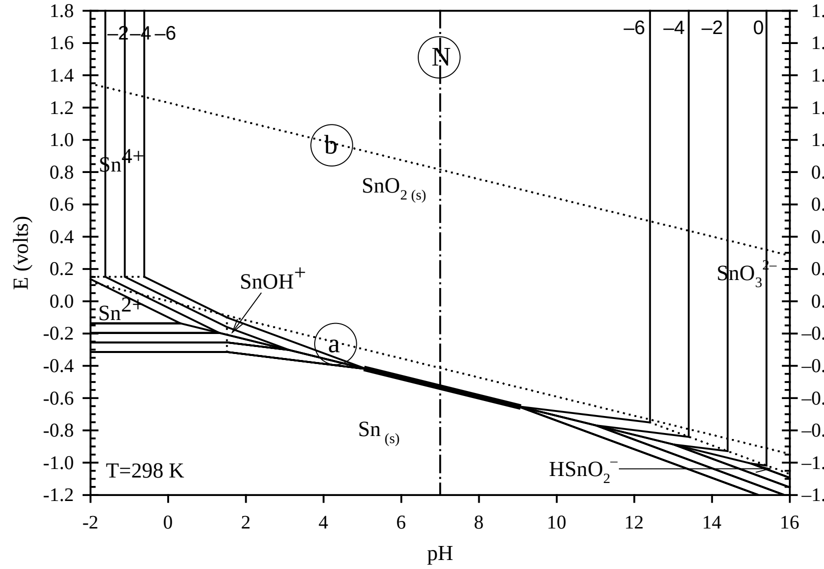

FIGURE 9.3. Pourbaix diagram for Sn at 298 K showing aqueous concentrations (activity) for the Sn species at 1, 10^{-2}, 10^{-4}, and $10^{-6}m$.

- The fields on the diagram for the aqueous species tend to shift to the left at higher temperature.
- The solubility of SnO_2 tends to increase with temperature in alkaline solution.
- Pure metallic tin is more stable as a liquid at 550 K.
- The pH associated with neutrality shifts to lower values with increasing temperature, as the equilibrium constant for the dissociation of H_2O increases with increasing temperature.

With regard to the last point, for

$$H_2O \rightarrow H^+ + OH^- \tag{9.18}$$

$\Delta G^\circ = +117{,}050$ J/mol at 550 K as calculated from the data shown in Table 9.2. This corresponds to an equilibrium constant of 7.36×10^{-12} (instead of very nearly 10^{-14} at 298 K), implying that neutrality at 550 K occurs at a pH of 5.56 instead of 7. It is apparent that care must be taken in reference

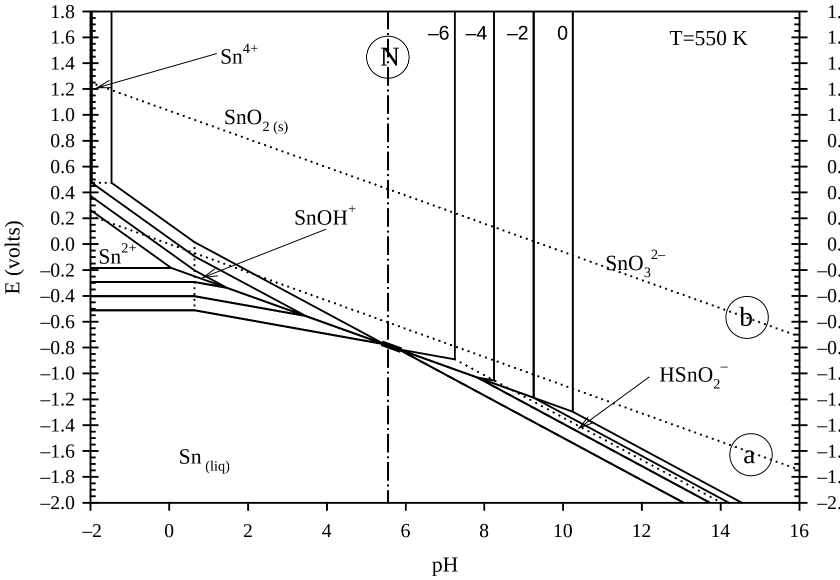

FIGURE 9.4. Pourbaix diagram for Sn at 550 K. The pressure is understood to be sufficient to suppress boiling but otherwise has a negligible effect on the placement of domain boundaries. Note that pure Sn is more stable as a liquid at this temperature.

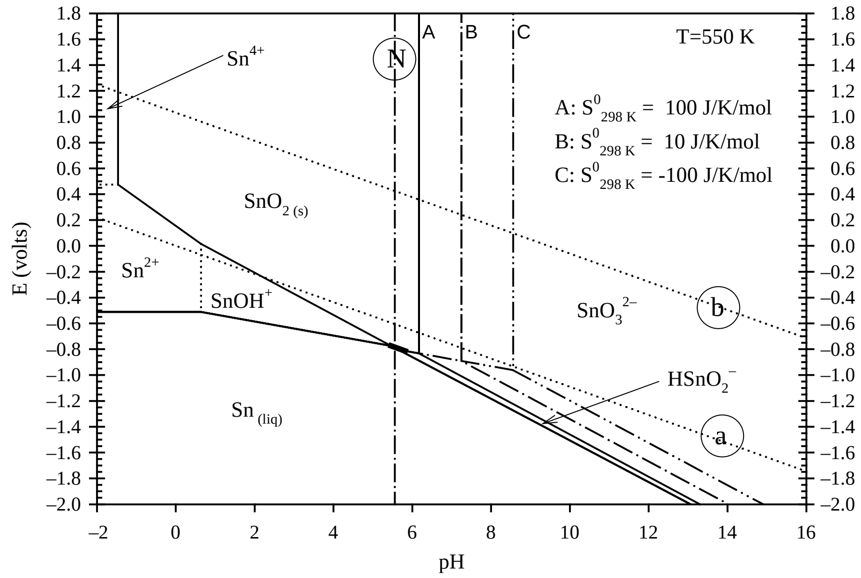

FIGURE 9.5. Pourbaix diagram for Sn at 550 K showing the effect of varying $S°$ for SnO_3^{2-}. Pure metallic tin is more stable as a liquid at this temperature. The concentration of all aqueous species is $10^{-6}m$.

to discussions concerning pH when the temperature is substantially different from 298 K. In particular, it is important to distinguish the temperature of the water when sampled from the temperature of that sample when the pH is measured.

C3. Effect of Estimated Gibbs Energies on Diagram Development

As implied above, it is generally necessary to estimate the thermodynamic properties for at least some of the aqueous species at elevated temperatures.

Table 9.4 shows the effect on diagram construction resulting from different ways of extrapolating data for SnO_3^{2-} from 298 to 550 K. In this case, $S°_{298\,K}$ was arbitrarily changed to a substantial degree from case B (used in the development of Fig. 9.4) to cases A and C, which represent a large variation. The values of $\Delta H°_{298\,K}$ were correspondingly changed to preserve the desired value of $\Delta G°_{298\,K}$. With the consequent different ways of projecting the Gibbs energy to temperatures above 298 K, the Pourbaix diagram was redeveloped as shown in Fig. 9.5 at 550 K, but just for the case, for purposes of clarity, where the concentration of the aqueous ions was $10^{-6}m$. The area of the SnO_3^{2-} field is reduced in case C as the Gibbs energy estimate becomes less negative as a consequence of the $-TS°_{298\,K}$ term in Eq. (9.2). However, in spite of this rather extreme variation in the estimated $-G°_{550\,K}$, the topology of the diagram is not affected. Therefore, in the absence of experimental data, if there is any basis to make a reasonable judgment of the way in which the Gibbs energy may project from 298 K to higher temperatures, it is still worthwhile to undertake Pourbaix diagram development to assist in the understanding of high-temperature aqueous corrosion behavior.

D. Zr POURBAIX DIAGRAMS

The Pourbaix diagrams for Zr, Figures 9.6 and 9.7, were developed using the thermodynamic data [7, 8, 10, 11] in Table 9.5 and following the same methodology as described above for Sn. Data in italics were estimated in a way that is intended to be representative of practices that have been applied to many other high-temperature Pourbaix diagram computations [9].

Zirconium hydride is an extremely stable metal hydride. As a consequence, this field eclipses the field for metallic zirconium. Nevertheless, following the practice of Pourbaix, it is customary to show the metal field in relation to the other compounds of zirconium. These diagrams are shown in Figures 9.8 and 9.9 and were obtained by simply withdrawing the data for ZrH_2 during the computational process. There is the possibility that ZrO_2 may form a monohydrate instead of the dihydrate at 550 K, but the monohydrate was not considered as a possible species effecting the construction at 550 K for lack of reliable data.

E. Zr–Sn PHASE DIAGRAM AND INTERMETALLIC COMPOUNDS

In using the calculated high-temperature Pourbaix diagrams for Zr and Sn in relation to the corrosion of Zircaloy, it is

TABLE 9.5. Data Used for Zr Pourbaix Diagram Construction

			$c_p = a + bT + cT^2 + dT^{-2}$ (J/mol/K)

Note: Data in italic were estimated.
[a] $- 584.476T^{-1/2} - 120410834T^{-3}$.

necessary to consider the phase diagram in Figure 9.10 [12]. This calls attention to compounds of Zr and Sn (i.e., Zr_4Sn, Zr_5Sn_3, and $ZrSn_2$) which cannot be depicted on either the Sn or Zr Pourbaix diagram. For zirconium–tin alloys involving low concentrations of tin, nearly pure α-Zr coexists with Zr_4Sn at temperatures below 550 K. Therefore, the matter of significance is mainly the activity of tin. The phase diagram development shown in Figure 9.10 fortunately was undertaken in such a way [12, 13] as to provide the data for these compounds as given in Table 9.6. It is therefore possible to calculate the activity of Sn from the equilibrium constant for:

$$4Zr + Sn = Zr_4Sn \qquad (9.19)$$

at any temperature. The activity of Sn with respect to both solid white tin and liquid at 298 K and 550 K is given in Table 9.7. The Gibbs energies of formation of the Zr–Sn compounds expressed with respect to the most stable form of the elements (alpha Zr and solid white Sn) are given in Table 9.6.

To account for the chemical behaviour of Sn in Zircaloy, the activities for Sn in Table 9.7 (referred to either solid or liquid) can be applied to the Gibbs energies for pure Sn at the top of Table 9.2 by the additions shown in the equation.

$$G_{Sn} = G^\circ_{Sn,solid} + RT \ln a_{Sn,solid} = G^\circ_{Sn,liquid} + RT \ln a_{Sn,liquid} \qquad (9.20)$$

Since the effect of the very low activities of Sn in Zircaloy is to substantially lower the partial molar Gibbs energy for Sn, the effect on the diagram construction is to greatly enlarge the field for Sn. This field must now be

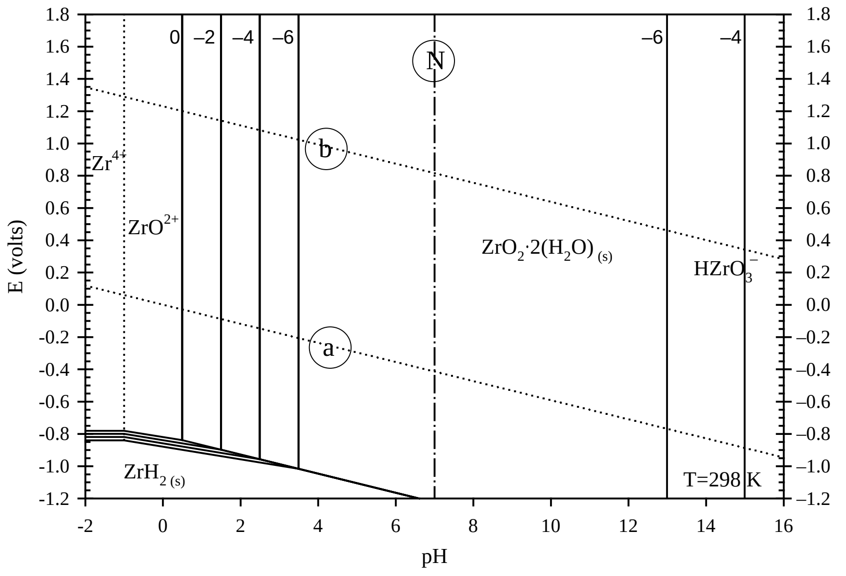

FIGURE 9.6. Pourbaix diagram for Zr at 298 K showing aqueous concentrations for the Zr species at 1, 10^{-2}, 10^{-4}, and $10^{-6}m$.

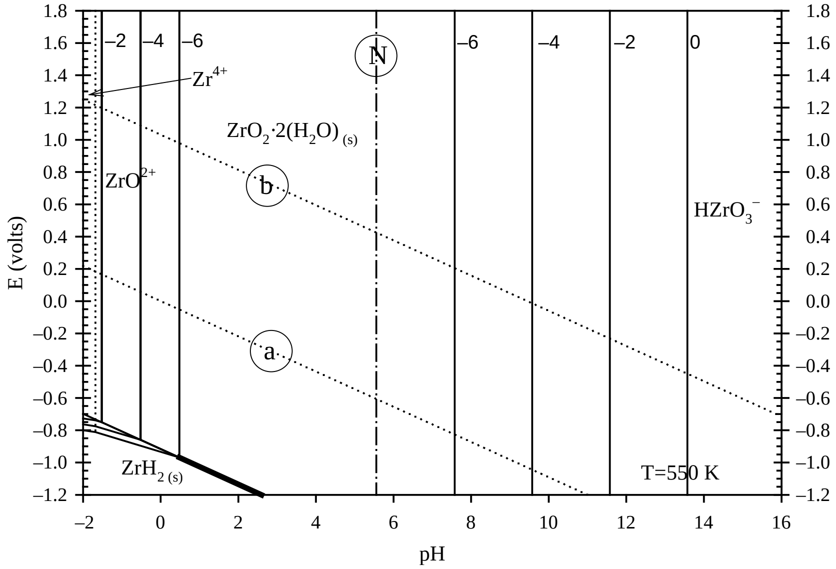

FIGURE 9.7. Pourbaix diagram for Zr at 550 K showing aqueous concentrations for the Zr species at 1, 10^{-2}, 10^{-4}, and $10^{-6}m$. The pressure is understood to be sufficient to suppress boiling but otherwise has a negligible effect on the placement of domain boundaries.

understood to refer to "Sn" that is chemically combined with Zr in Zr_4Sn coexisting with nearly pure alpha Zr. The Pourbaix diagrams are shown in Figures 9.11 and 9.12 only for concentrations of aqueous ions of $10^{-6}m$. The notable feature is that, in nearly hydrogen saturated conditions characteristic of the use of Zircaloy as nuclear fuel sheathing, Sn is only very sparingly soluble in water typically made slightly alkaline with LiOH additions (pH $\sim$ 10.5 at room temperature).

F. CONCLUSION

Since the implications of thermodynamics tend to be better respected as temperature increases, Pourbaix diagrams may have greater value in corrosion interpretation at elevated temperature than at the ambient conditions where they are much more often used. This chapter has focused on computational matters leading to generalizations in diagram appearance associated with increasing temperature as well as

the sensitivity of field placement to judgments about the way to project Gibbs energies above 298 K when experimental data may be absent. It also shows the effect of alloying and a way by which this factor may be introduced into custom-constructed Pourbaix diagrams to depict the behaviour of a solute element.

A. INTRODUCTION

Galvanic corrosion, resulting from a metal contacting another conducting material in a corrosive medium, is one of the most common types of corrosion. It may be found at the junction of a water main, where a copper pipe meets a steel pipe, or in a microelectronic device, where different metals and semiconductors are placed together, or in a metal matrix composite material in which reinforcing materials, such as graphite, are dispersed in a metal, or on a ship, where the various components immersed in water are made of different metal alloys. In many cases, galvanic corrosion may result in quick deterioration of the metals but, in other cases, the galvanic corrosion of one metal may result in the corrosion protection of an attached metal, which is the basis of cathodic protection by sacrificial anodes.

Galvanic corrosion is an extensively investigated subject, as shown in Table 10.1, and is qualitatively well understood but, due to its highly complex nature, it has been difficult to deal with in a quantitative way until recently. The widespread use of computers and the development of software have made great advances in understanding and predicting galvanic corrosion.

B. DEFINITION

When two dissimilar conducting materials in electrical contact with each other are exposed to an electrolyte, a current, called the galvanic current, flows from one to the other. Galvanic corrosion is that part of the corrosion that occurs at the anodic member of such a couple and is directly related to the galvanic current by Faraday's law.

Under a coupling condition, the simultaneous additional corrosion taking place on the anode of the couple is called the local corrosion. The local corrosion may or may not equal the corrosion, called the normal corrosion, taking place when the two metals are not electrically connected. The difference between the local and the normal corrosion is called the difference effect, which may be positive or negative. A galvanic current generally causes a reduction in the total corrosion rate of the cathodic member of the couple. In this case, the cathodic member is cathodically protected.

C. FACTORS IN GALVANIC CORROSION

Many factors play a role in galvanic corrosion in addition to the potential difference between the two coupled metals. Depending on the circumstances, some or all of the factors illustrated in Figure 10.1 may be involved. Generally, for a given couple, the factors in categories (a)–(c) vary less from one situation to another than the factors in categories (d)–(g). Effects of geometric factors on galvanic actions can, in many cases, be mathematically analyzed. On the other hand, effects of electrode surface conditions on reaction kinetics in real situations can be very difficult to determine. Compared to normal corrosion, galvanic corrosion is generally more complex because, in addition to material and environmental factors, it involves geometrical factors.

D. MATERIAL FACTORS

D1. Effects of Coupled Materials

As listed in Figure 10.1, all the factors affecting the electrode properties, such as those under categories (a)–(g), have an influence on galvanic action between any two metals. The reversible electrode potentials of the two coupled metals determine the intrinsic polarity of a galvanic couple, whereas the reactions, metallurgical factors, and surface conditions determine the actual polarity under a given situation because the actual potential (the corrosion potential) of a metal in an electrolyte is usually very different from its thermodynamic equilibrium value due to kinetic processes. For example, titanium has a very negative reversible electrode potential

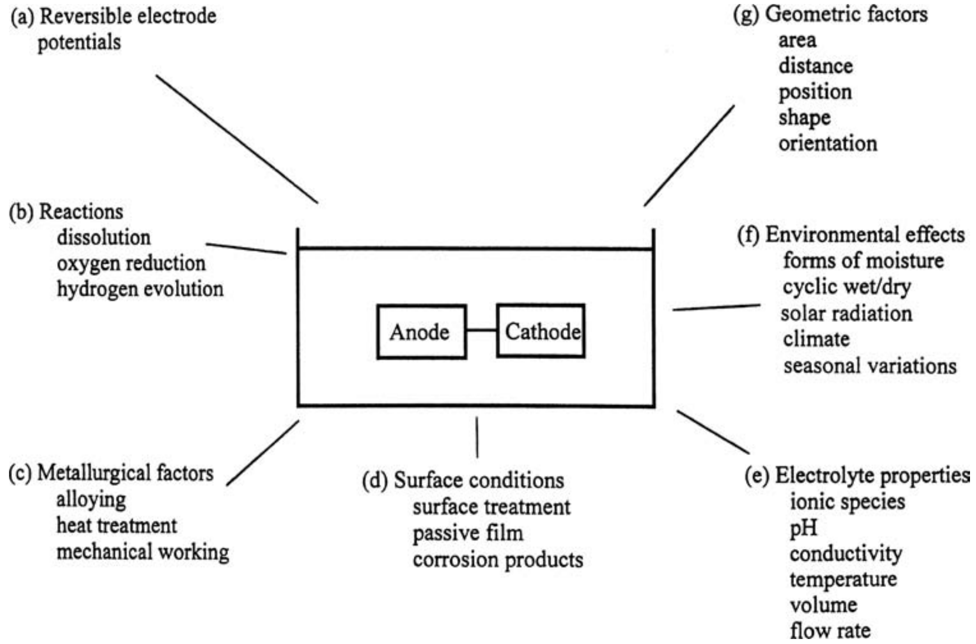

FIGURE 10.1. Factors involved in galvanic corrosion of bimetallic couple.

and has an active position in the emf series. However, titanium occupies a noble position in the galvanic series in many practical environments due to passivation of the surface.

The extent of galvanic activity is not always related to the difference in the corrosion potentials of two metals. Table 10.2 shows that, for steel, the galvanic corrosion is much higher when coupled to nickel and copper than when coupled to 304 stainless steel and Ti–6Al–4V, for which the potential differences were larger. The galvanic corrosion of zinc is the highest when coupled to steel, although the potential difference between zinc and steel is much less than between zinc and most other alloys.

Similar results have been reported on galvanic corrosion in atmospheres [2] where, in addition to the potential differences between the two metals, other factors, such as reaction kinetics and formation of corrosion products, are important in determining the galvanic corrosion rate. When the cathodic reaction is oxygen reduction and diffusion limited, different galvanic corrosion rates of an anode, coupled to different cathode materials, can be explained by the different diffusion rates of oxygen through the oxide films. When diffusion is not the limiting process, differences in galvanic corrosion rates can result from differences in cathodic efficiency of oxygen reduction in the oxide scale on the cathode surface [58], which may not depend on the corrosion potential. The difference in corrosion potentials of uncoupled metals is, thus, not a reliable indicator of the rate of galvanic corrosion.

The extent of galvanic corrosion can be ranked with actual corrosion loss data (i.e., the increase in corrosion rate relative to uncoupled conditions) [51, 58]. There is a difference between the corrosion loss determined by weight loss, which includes the loss due to local corrosion, and due to galvanic current, which measures the true loss due to galvanic action. As noted in Table 10.2, the weight loss of zinc, when galvanically coupled to other metal alloys, can be much larger than the sum of the galvanic corrosion calculated from

TABLE 10.2. Galvanic Corrosion Rate of Steel and Zinc Coupled to Various Metal Alloys Tested in 3.5% NaCl Solution[a,b]

Coupled Alloy	r_g[c] (μm/year)	r_{wl}[d] (μm/year)	ΔV[e] (mV)
	4130 Steel, $r_0 = 90$

the Faradaic current plus the normal corrosion measured in an uncoupled condition. This indicates that the local corrosion of zinc is increased by galvanic coupling to another alloy. Some of the factors that determine the relationship of galvanic current and weight loss have been discussed in the literature [51].

In general, addition of small amounts of alloying elements does not change the reversible potential of a metal to a large extent, but may change significantly the kinetics of the electrochemical processes and, thus, behavior in galvanic action. For example, significant differences have been found in the corrosion behavior of different aluminum alloys in galvanic couples [51].

For alloys with a microstructure of more than two phases, there can be significant galvanic action among the different phases. Microscale galvanic action has been studied for the active dissolution of duplex stainless steel in acidic solutions [34] and for the interaction between martensite and ferrite in grinding media [66]. Potential and current distributions on the surface of a metal, consisting of two randomly distributed phases, have been mathematically modeled by Morris and Smyrl [70].

Increased corrosion of the cathodic member in a galvanic couple may also occur (e.g., the zinc–aluminum couple). Although aluminum is cathodic to zinc in 3.5% solution, the rate of aluminum corrosion is greater when coupled to zinc than in the uncoupled condition [51]. The higher corrosion rate of the coupled aluminum is attributed to die increased alkalinity near the surface due to the cathodic reaction, since aluminum is not stable in a solution of high alkalinity. Similar effects have been reported for tin–zinc and cadmium–zinc couples, where the corrosion of tin and cadmium, being the cathodic members, in 3.5% NaCl solution increased compared to the uncoupled condition [58].

Historically, galvanic corrosion has been reported to occur mostly in bimetallic couples. With the ever-increasing use of nonmetallic materials, galvanic corrosion is now being identified in many situations where a metal is in contact with a nonmetallic material (e.g., galvanic corrosion of metals occurs in metal-reinforced polymer matrix composites and graphite metal matrix composites [49, 53], in processing of semiconducting minerals [35], in contact with conducting polymers [59], with semiconducting metal oxides [57], and with conducting inorganic compounds [8]). It has been found that minerals, in general, exhibit potentials more noble than most metals and, therefore, may cause galvanic corrosion of metals used in processing equipment [35].

D2. Effect of Area

The effect of anode and cathode areas on galvanic corrosion depends on the type of control in the system, as illustrated later in Figure 10.10. If the galvanic system is under cathodic control, variation in the anode area has little effect on the total

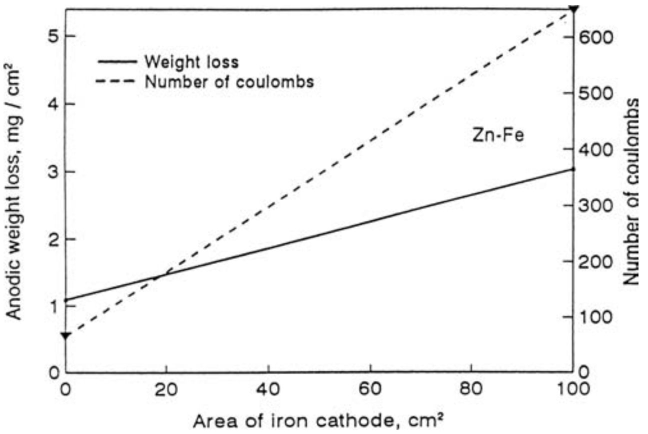

FIGURE 10.2. Effect of area of mild steel cathode on weight loss of Zn anode (area of 100 cm^2) and on number of coulombs flowing between Zn–steel couple over a 96-h period in 1 *N* NaCl solution at 25°C [38].

rate of corrosion, but variation of the cathode area has a significant effect. The opposite is true if the system is under anodic control.

Galvanic currents in many situations are proportional to the surface area of the cathode (e.g., Figure 10.2 shows that the galvanic corrosion of zinc increases with increasing iron cathode area). On the other hand, the galvanic corrosion of zinc changes only very slightly with increasing zinc anode area. These results indicate that the galvanic corrosion of zinc in the system is mainly cathodically controlled. Similar results were found for aluminum alloys, coupled to copper, stainless steels, or Ti–6A1–4V, where the total galvanic current is independent of the surface area of the anode but is proportional to the cathode area [50].

D3. Effect of Surface Condition

The surface of metals in contact with an electrolyte is generally not "bare" but is covered with a surface layer, at least an adsorption layer, but often a solid surface film. This is the most important factor that causes the difference between the intrinsic polarity and apparent polarity and between the difference in potentials and the extent of galvanic corrosion. Formation of a surface film, whether a salt film or an oxide film, may significantly change the electrochemical properties of the metal surfaces, resulting in very different galvanic action.

A corrosion product film may serve as a physical barrier between the metal surface and the environment. It may also be directly involved in the electrochemical reactions if it conducts electrical current, either as a conductor or a semiconductor. Most metal oxides, common corrosion products, are conductive materials, mainly as semiconductors [71]. Depending on the electronic structure, oxide films exhibit potentials that are generally very different from the base metals. In many situations, these oxides, rather than the

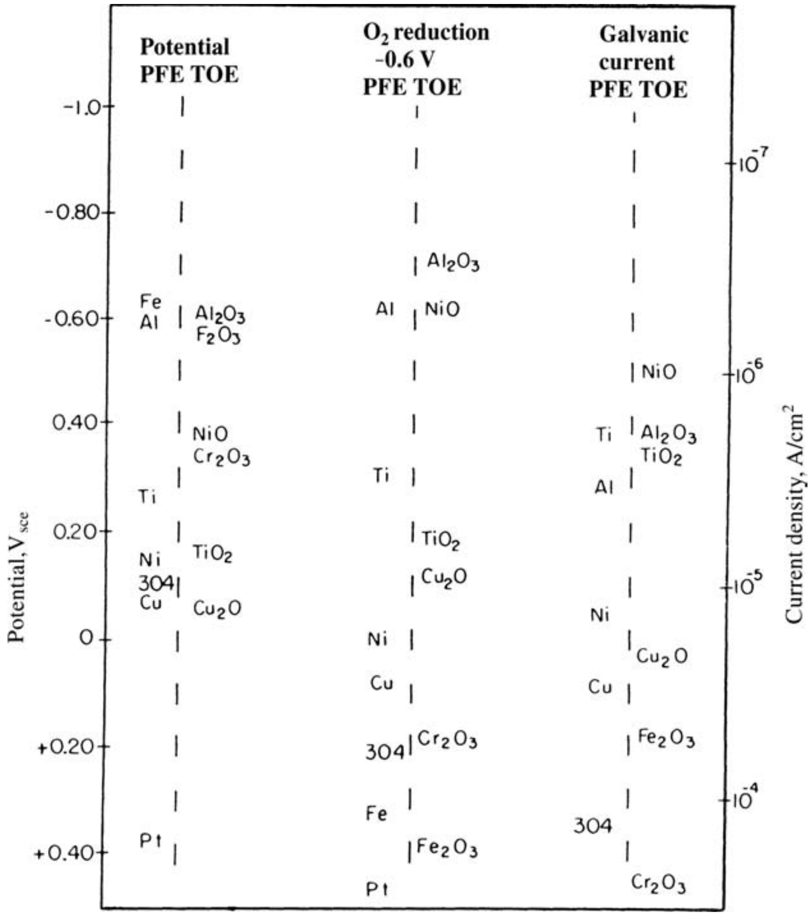

FIGURE 10.3. Corrosion potentials and oxygen reduction rates of metal oxides. PFE: passive film electrode; TOE: thermal oxide electrode [57], (Copyright ASTM. Reprinted with permission.)

metals themselves, determine the electrode potential and the position in a galvanic series. Figure 10.3 shows a galvanic series and the cathodic efficiency for O_2 reduction on a number of metal oxides [57]. The highest current densities for O_2 reduction are observed for *n*-type semiconductor oxides (Fe_2O_3) and metal-like oxides (Cr_2O_3). Insulators (Al_2O_3) and *p*-type oxides (NiO) are inefficient cathodes. The oxides, having a high cathodic efficiency and exhibiting a more noble potential value in a galvanic couple, result in a larger galvanic corrosion rate of the coupled metal.

According to Stratman and Müller [72], oxygen reduction of an iron electrode is greatly increased due to the formation of rust because oxygen can be reduced in the iron oxide scale, which is generally porous and has a large effective surface area. The corroded steel surface is, thus, a highly effective cathode when coupled to metals that have more negative potentials, such as zinc, aluminum, and magnesium [40, 73].

Surface passivation is important in the galvanic action of a bimetallic couple (e.g., aluminum is normally passivated in neutral aqueous solutions), but the extent of passivity is relatively low in solutions containing species such as chloride ions and may break down under certain conditions. When aluminum is coupled to steel, it acts as an anode in chloride solutions, whereas it acts as a cathode in tap water and distilled water [37].

When a surface film does not fully cover the entire surface, part of the metal surface is passivated and acts as the cathode, forming a local galvanic cell, increasing the corrosion rate of the nonpassivated part of the surface, and possibly causing pitting corrosion [57]. For example, galvanic current develops between a passivated zinc sample and a partially passivated zinc sample in a cell of two compartments, containing $0.1\,M$ K_2CrO_4 in one and $0.1\,M$ K_2CrO_4 and NaCl in the other, respectively [74], Pitting occurred on the sample placed in the compartment containing NaCl [74].

When considering surface condition, the effects of time should also be included. With the passage of time, two basic changes invariably occur in a corrosion system: (1) a change of the physical structure and chemical composition of the corroding metal surface and (2) a change in the composition of the solution, particularly in the vicinity of the surface [75]. Specific changes may occur in surface roughness and area,

adsorption of species, formation of passive films, saturation of dissolution products, precipitation of a solid layer, and exhaustion of reactants. Mechanistically, these changes may lead to alterations in the equilibrium potentials, the type of reactions involved, the rate-controlling process, and so on. As a result, the corrosion potential may vary greatly depending on the nature and extent of these changes.

The steady-state corrosion potential of a metal electrode depends on whether the surface is active or passive, and the time required for reaching a steady-state value varies with the conditions. The rate of galvanic corrosion may change with time as a result of changes in polarity and in potential difference between the metals in the couple. It has been reported that the potentials of various bimetallic couples, including iron, stainless steel, copper, bronze, and zinc, exposed in flowing seawater are highly variable, and the galvanic currents are reduced by about one order of magnitude within the first 120 days [26].

E. ENVIRONMENTAL FACTORS

A corrosive environment is characterized by its physical and chemical nature, which may affect the electrochemical properties. Given that the electrochemical properties of each metal are distinctive in a given electrolyte, galvanic corrosion is essentially unique for each metal couple in each environment. The combination of metal couples and environmental conditions is, thus, limitless, as can be appreciated from Table 10.1.

E1. Effects of Solution

As discussed in Section D, galvanic action of a bimetallic couple depends on the surface condition of the metals, which, in turn, is determined by environmental conditions. A metal surface exhibits different potentials in different electrolytes, as shown in Table 10.3, which lists the corrosion potentials of a number of metals in four different electrolytes of similar ionic strength. A galvanic series provides information on the polarity of a bimetallic couple but is environment-specific because the relative position of each metal changes with solution.

The extent of galvanic corrosion also varies with solution composition. The corrosion rates of zinc and steel in coupled and uncoupled conditions in several solutions [44] can be seen in Table 10.4. In all the solutions, galvanic action results in protection of the steel, but the amount of zinc corrosion

varies with solution composition. The difference in the corrosion rates in magnesium sulfate and sodium sulfate solutions indicates the significant effect of cations on the reaction kinetics.

The conductivity of the electrolyte is a very important factor because it determines the distribution of galvanic corrosion across the anode surface. When conductivity is high, as in seawater, the galvanic corrosion of the anodic metal is distributed uniformly across the surface. As the conductivity decreases, galvanic corrosion becomes concentrated in a narrow region near the junction, as illustrated in Figure 10.4. Usually, the total galvanic corrosion is less in a poorly conducting electrolyte than in a highly conducting one.

Ions of noble elements in solution may cause galvanic corrosion of a less noble metal immersed in the solution because precipitation of the noble element can cause small galvanic cells to form [76].

If there is only a limited amount of electrolyte, the composition of the electrolyte may significantly change as a result of electrochemical reactions. Massinon et al. [77, 78] found an increase of pH in a confined electrolyte after a certain time of galvanic action for a zinc–steel couple. Pryor and Keir [79] pointed out that, when the distance between the anode and cathode is small compared to the dimension of the electrodes, the galvanic corrosion is small due to the limitation in the mass transport of the reactants and reaction products.

One important solution factor is the thickness of thin-layer electrolytes, which is encountered in atmospheric environments. The thickness of an electrolyte affects corrosion processes in several different ways. First, it affects the lateral resistance of the electrolyte and, thus, affects the potential and current distribution across the surface of the coupled metals. Second, it affects the transport rate of oxygen across the electrolyte layer and, thus, the rate of cathodic reaction. Third, it changes the volume and the solvation capacity of the electrolyte and, thus, affects the formation of corrosion products.

As shown later in Figures 10.11 and 10.12, changes in potential and galvanic current across a metal surface are greater for thinner electrolytes due to the larger electrical resistance involved. Under a thin-layer electrolyte, the galvanic corrosion is the most intense at the anode area near the anode–cathode boundary, while there is very little galvanic corrosion away from the boundary, as illustrated in Figure 10.4(a). Variation of electrolyte thickness also determines the rate-controlling process for a given cell dimension. Figure 10.5 shows that, for a thinner electrolyte, the galvanic current is larger when the anode and the cathode are close, but the reverse applies when the two electrodes are far apart [80]. Since the oxygen diffusion rate under thin-layer electrolytes changes with electrolyte thickness, the change of the relative galvanic current values for small and large distances, shown in Figure 10.5, is due to the change of the rate-limiting process from oxygen diffusion at a close distance to ohmic conduction in the electrolyte at a large distance [80].

The physical position of a galvanic couple in solution can also affect the galvanic action between coupled metals. Shams El Din et al. [74] found a large potential variation near the solution surface between a zinc anode and a copper cathode that were half-immersed in solution, due to the higher oxygen concentration near the surface than in the bulk solution.

E2. Atmospheric Environments

Galvanic corrosion occurs commonly in atmospheric environments as different combinations of materials are used in buildings and structures exposed to indoor and outdoor atmospheres. A test program of galvanic corrosion in atmospheres was started as early as 1931 by the American Society for Testing and Materials (ASTM) [2]. Since then, a number of extensive exposure programs have been carried out all over the world [81–84]. The various aspects of atmospheric galvanic corrosion have been discussed in a comprehensive review by Kucera and Mattsson [2].

Galvanic corrosion under atmospheric environments is most often evaluated by weight loss measurement. In other environments, potentials and/or galvanic currents of coupled metals can be measured, but it is very difficult to measure in situ potentials of metals under atmospheric conditions due to the thin layer of the electrolyte.

Data in Table 10.5, reported by Kucera and Mattsson [2], show the galvanic corrosion rates of a number of metal alloys, in the form of wire coupled to bolts of various metals. Depending on the bolt metal and the type of atmosphere, the galvanic corrosion rate of the wire can be many times that of the normal corrosion rate. For example, the galvanic corrosion of zinc is as much as five times the normal corrosion in a rural atmosphere and three times that in a marine atmosphere [85]. The amount of corrosion shown in Table 10.5 does not appear to relate to differences between the reversible potentials of the coupled metals. Steel and copper, as cathodic members of a couple, cause the most galvanic corrosion of the coupled anodic material.

Galvanic corrosion in atmospheres is usually restricted to a narrow region of the anode metal near the bimetallic junction because of the high resistance of thin-layer electrolytes formed by rain and water condensation [80, 86, 87]. Even for the most incompatible metals, direct galvanic action will not extend more than a few millimeters from the junction. Because of the very narrow range of galvanic action, geometrical factors of the coupled metals, such as shape and size, generally do not have a strong effect on galvanic corrosion in atmospheric environments.

Galvanic action is most significant in marine atmospheres because of the high conductivity of seawater. Compared to other types of moisture formed under atmospheric conditions, rain is particularly effective in causing galvanic corrosion. The galvanic corrosion rate is several times that of the normal corrosion rate in an open exposure, whereas they are similar when under a rain shelter because the electrolyte layer formed by rain is thicker and has a smaller lateral electric resistance than the moisture formed by condensation [2].

E3. Natural Waters

Natural waters are commonly classified as seawater and freshwater, such as river, lake, and underground waters. A distinct difference between seawater and freshwater is that seawater has a high conductivity due to its high salt content, whereas freshwaters generally have low conductivities. In comparison to other environments, waters as corrosion

environments are homogeneous (e.g., seawater is almost constant with respect to time and geographic location). The galvanic action in seawater, due to its high conductivity and uniformity, is long range and spreads uniformly across the entire surface area of a metallic structure. The galvanic effect in freshwaters is generally much less than in seawater because of the lower conductivity [14].

Table 10.6 presents the galvanic series of some commercial metals and alloys obtained in seawater [88]. As discussed previously, such a galvanic series differs from the emf series and is specific to seawater. A galvanic series of a number of common alloy couples in flowing seawater has also been reported [26, 89, 90].

Galvanic corrosion in seawater has been extensively investigated, as indicated in Table 10.1. Table 10.7 shows the data on the galvanic action of various bimetallic couples after long-term exposure in seawater and freshwater [14]. Galvanic action is much stronger in seawater than in freshwater. In seawater, the corrosion rate of an anodic metal, such as zinc or steel, is larger by a factor of 5–12 than in the uncoupled condition, whereas the increase is a factor of only 2–5 in freshwater. The data also indicate the great effect of the relative sizes of the anode and cathode; a factor of 6–7 times more corrosion was observed on the anode by changing the anode from the strip to the plate for the same bimetallic couple (e.g., 316 stainless steel/carbon steel, phosphor bronze/carbon steel, and 316 stainless steel/phosphor bronze). Table 10.7 also indicates that the corrosion of the cathodic member was generally decreased, in varying degrees, as a result of the galvanic corrosion of the anodic member.

F. POLARITY REVERSAL

The normal polarity of some galvanic couples under certain conditions may reverse with the passage of time. This phenomenon was first reported by Schikorr in 1939 on a zinc–steel couple in hot supply water with iron becoming anodic to zinc, which has been a serious problem for galvanized steel hot water tanks [91]. It has subsequently been extensively investigated [10, 12, 43].

Polarity reversal is invariably caused by the change of surface condition of at least one of the coupled metals, such as formation of a passive film. The degree of passivity, the nature of the redox couples in the solution, and the stability of the system determine the polarity and its variation with time. For a zinc–steel couple, the change in the zinc electrode potential is chiefly responsible for the reversal of polarity since the potential of the steel remains relatively unchanged with time in hot water [12]. It has generally been found that polarity reversal does not occur in distilled water up to 65°C and without the presence of oxygen [12, 43, 92].

Depending on the conditions, it may occur rather quickly, taking several minutes, or rather slowly, taking many days. In addition to temperature, other factors, such as dissolved ions, pH, and time of immersion, affect the polarity of a zinc–steel couple. The necessary conditions for polarity reversal of a zinc–steel couple are passivation of the zinc surface and sufficient reducing species, such as dissolved oxygen, in the water to provide cathodic depolarization.

Polarity reversal of an aluminum–steel couple has also been found to occur in natural environments where aluminum alloys are used as anodes for cathodic protection of steel. The general mechanism is similar to that occurring with a zinc–steel couple. However, unlike zinc, aluminum is normally passivated by a thin oxide film in most natural environments. The potential of aluminum depends on the degree of passivity, which is sensitive to the ionic species

in the environment. For example, carbonate and bicarbonate ions promote passivity and, thus, produce more noble potential values, whereas ions like chloride give the opposite effect [15]. In practice, sacrificial aluminum anodes are alloyed with various elements to prevent reversal of polarity.

The consequence of polarity reversal can be serious. In the zinc–steel and the aluminum–steel couples, zinc and aluminum serve as sacrificial anodes for protecting the steel. Polarity reversal results in the loss of cathodic protection of steel, causes galvanic corrosion of the steel, and shortens the life of the steel structure.

G. PREVENTIVE MEASURES

The essential condition for galvanic corrosion to occur is two dissimilar metals that are both electrically and electrolytically connected. Theoretically, prevention of galvanic corrosion can be achieved by avoiding the use of dissimilar metals in an assembly, by electrically separating the dissimilar metals with an insulating material or by physically insulating the environment from the metal surface with a coating impermeable to water. In reality, however, complete prevention is often not practical, as dissimilar metals need often to be used in direct contact and exposed to a corrosive environment and there is no absolutely impermeable coating. Thus, measures to minimize the possibility and extent of galvanic corrosion must be implemented All the factors listed in Figure 10.1 can be considered and controlled in order to reduce galvanic corrosion. Some practical approaches are as follows:

(a) Avoid combinations of dissimilar metals that are far apart in the galvanic series applicable to the environment.
(b) Avoid situations with small anodes and large cathodes.
(c) Isolate the coupled metals from the environment.
(d) Reduce the aggressiveness of the environment by adding inhibitors.
(e) Use cathodic protection of the bimetallic couple with a rectifier or a sacrificial anode.
(f) Increase the length of solution path between the two metals. This method is beneficial only in electrolytes

of low conductivity, such as freshwaters, because strong galvanic action exists several meters away in highly conductive media, such as seawater.

The use of these approaches must meet the specific requirements of each application [93, 94]. Sometimes one is sufficient, but a combination of two or more may be required in other situations. It must be emphasized that the most effective and efficient way to prevent or minimize galvanic corrosion is to consider the problem and take measures early in the design stage.

H. BENEFICIAL EFFECTS OF GALVANIC CORROSION

As a result of galvanic corrosion of the anodic metal, the corrosion of the cathodic, coupled metal or alloy is generally reduced (i.e., cathodically protected). This effect has been well utilized in the application of sacrificial anodes, coatings, and paints for corrosion protection of many metal components and structures in various environments.

Sacrificial anodes, mainly made of zinc, aluminum, and magnesium and their alloys, are widely used in corrosion prevention underwater and underground for structures such as pipelines, tanks, bridges, and ships. Each alloy possesses a unique set of electrochemical and engineering properties and has its own characteristic advantages as an anode for galvanic protection of a more noble alloy, mostly steel, in a given situation [95, 96]. Anodes can be designed for composition, shape, and size according to specific applications [95].

Galvanized (i.e., zinc coated) steel is a typical example of a metallic coating that provides a barrier layer to protect the steel and also sacrificially protects the locations where discontinuities occur in the coating [39, 97]. The combination of barrier and galvanic protection by the zinc coating results in very effective corrosion protection of steels. Table 10.8 shows that galvanic corrosion resulted in a reduction of the corrosion of steel by 3 times in rural, 40 times in industrial, and 300 times in seacoast industrial atmospheres. On the other hand, the galvanic corrosion of zinc, an increase of corrosion by a factor of 1.6–3 compared to uncoupled conditions, is very little compared to the reduction of steel corrosion. Galvanic protection of the steel is more effective in industrial and marine atmospheres than in rural ones, suggesting that the pollutants in the atmospheres are beneficial to the galvanic protection of steel, although they are very harmful to the normal corrosion of the uncoupled steel.

The protection distance of steel by a zinc coating in atmospheric environments is limited to a region only a few millimeters from the zinc coating because of the high resistance of thin-layer electrolytes formed in the atmosphere [87]. The protection distance, as a function of electrolyte thickness and surface area of steel, is shown in Figure 10.6. Figure 10.7 shows the protection distance as a function of separation distance and width of steel determined in an atmospheric environment [86]. The data indicate that the largest protection distance is ~1 mm, implying that the width of a scratch on a zinc-coated steel, which is fully protected is ~2 mm in the atmosphere. However, the actual protected area, which also includes the areas under partial protection, is considerably larger [86].

I. FUNDAMENTAL CONSIDERATIONS

I1. Electrode Potential and Kirchhoff's Law

The direction of galvanic current flow between two connected bare metals is determined by the actual electrode potentials (i.e., corrosion potentials of the metals in a corrosion environment). The metal which has a higher (i.e., more positive, more noble, or more cathodic) electrode potential is the cathode in the galvanic couple, and the other is the anode.

The polarity of galvanic couples in real situations may be different from that predicted by the thermodynamic reversible potential in the emf series, because the corrosion potentials are determined by the reaction kinetics at the metal– electrolyte interface. Thus, the actual position of each metal or alloy in a specific environment forms a galvanic

TABLE 10.8. Corrosion of Galvanic Couples in Different Atmospheres after 7 Years Exposure[a]

series that generally differs from the emf series. Also, as has been discussed earlier, the relative positions of two coupled metals in a galvanic series indicate only the polarity or the flow direction of the galvanic current, but not the magnitude of the current or the rate of corrosion, which is also determined by many other factors. The fundamental relationship in galvanic corrosion is described by Kirchhoff's second law:

$$E_c - E_a = IR_e + IR_m \qquad (10.1)$$

where R_e is the resistance of the electrolytic portion of the galvanic circuit, R_m the resistance of the metallic portion, E_c the effective (polarized) potential of the cathodic member of the couple, and E_a the effective (polarized) potential of the anodic member. Generally, R_m is very small and can be neglected. Both E_a and E_c are functions of the galvanic current I; hence, the potential difference between the two metals, when there is a current flow through the electrolyte, does not equal the open-circuit cell potential.

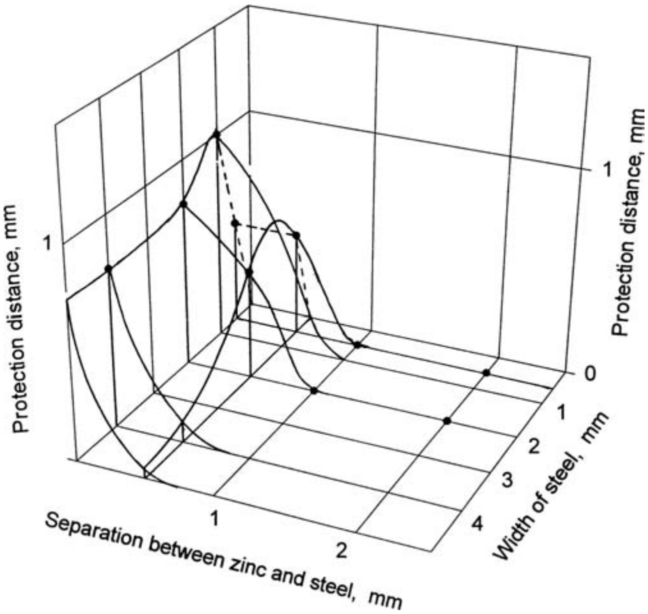

FIGURE 10.7. Protection distance of zinc–steel couple as function of steel width and separation distance under natural atmospheric exposure.

I2. Analysis

Although the mathematical description of galvanic corrosion can be very complex because of the many factors involved, particularly geometric factors, it can be simplified for certain situations. Following is an analysis of coplanar, coupled metals, as illustrated in Figure 10.8(a). Such a geometry applies to a wide range of situations. The distance between anode and cathode (d) may equal zero (e.g., metal joints or a coated metal with the coating partially removed), as shown in Figure 10.8(b). On the other hand, when one metal is used as a sacrificial anode to cathodically protect another metal, the distance between the anode and cathode may be very large, as shown in Figure 10.8(c), that is, $d \gg (x_{ae} - d)$ and $d \gg x_{ce}$ (where $x_{ae} - d$ and x_{ce} are the lengths of anode and cathode, respectively).

The basic current and potential relationships for the geometrical arrangement shown in Figure 10.8(a) can be expressed as follows:

$$I_a = I_c \qquad (10.2)$$

and

$$E_{c,corr} - E_{a,corr} = \eta_a(x^a) - \eta_c(x^c) + \Delta V_R(x^a, x^c) \quad x^a \leq 0, \; x^c \geq 0 \qquad (10.3)$$

where $E_{a,corr}$ and $E_{c,corr}$ are the uncoupled corrosion potentials of the anode and cathode, respectively; η_a and η_c, the overpotentials of the anode and cathode, respectively, in the couple; and ΔV_R, the ohmic potential drop across the electrolyte between x^a on the anodic surface and x^c on the

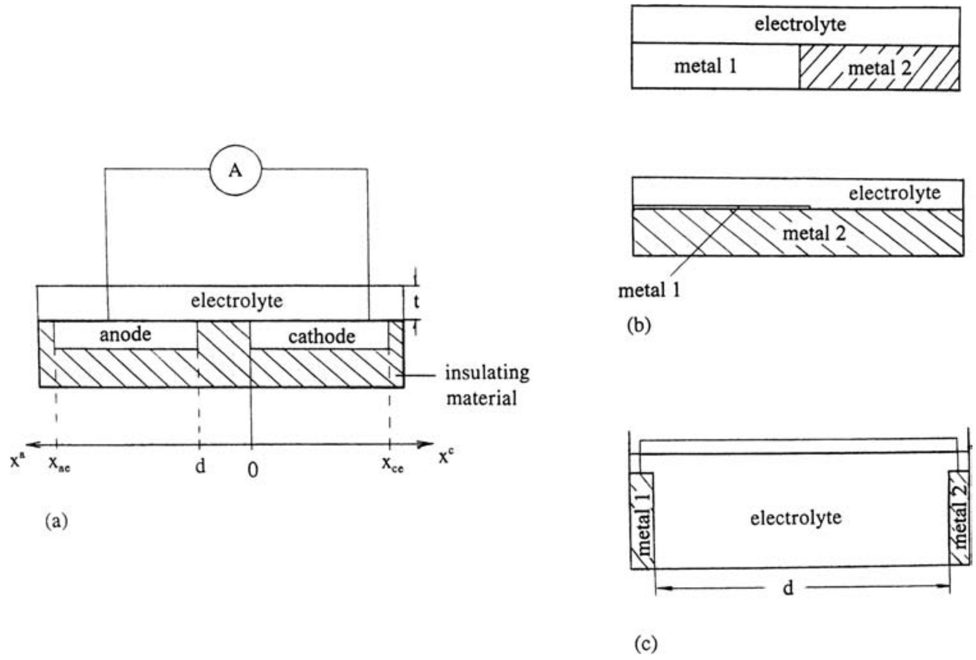

FIGURE 10.8. (a) General geometry of bimetallic couple; (b) bimetallic joint and a metal partially coated with metallic coating; and (c) anode coupled to distant cathode.

cathodic surface; I_a, the total anodic current; and I_c, the total cathodic current. Then,

$$I_a = \int_d^{x_{ae}} i_a(x^a) l \, dx^a \tag{10.4}$$

$$I_c = \int_0^{x_{ce}} i_c(x^c) l \, dx^c \tag{10.5}$$

where l is the width of the electrodes, and $i_a(x^a)$ and $i_c(x^c)$ are the anodic and cathodic current densities, respectively. When both the anodic and cathodic reactions are activation controlled, they can be expressed by the Butler–Volmer equation:

$$I_a = i_{0a}\,\theta_a\{\exp[\beta_{aa}\eta_a(x^a)] - \exp[-\beta_{ac}\eta_a(x^a)]\} \tag{10.6}$$

$$I_c = i_{0c}\,\theta_c\{\exp[\beta_{ac}\eta_c(x^c)] - \exp[-\beta_{cc}\eta_c(x^c)]\} \tag{10.7}$$

where i_{0a} and i_{0c} are the exchange currents for the anodic and cathodic reactions, respectively; β_{aa}, β_{ac}, β_{ca}, and β_{cc}, the kinetic constants; and θ_a and θ_c, the area factors, varying between 0 and 1. Here $\theta = 1$ when the whole surface is fully active and θ is close to zero if the surface is fully passivated. When the cathodic reaction is limited by oxygen diffusion in the electrolyte, Eq. (10.7) is replaced by

$$i_c = 4\mathcal{F} D_O C_{O2}/\delta \tag{10.8}$$

where $\mathcal{F}$ is the Faraday constant; D_O, the diffusion coefficient of oxygen in the electrolyte; C_{O2}, the oxygen concentration in the bulk electrolyte; and δ, the thickness of the diffusion layer.

The total ohmic potential drop in the electrolyte between any two points on the surface of the anode and the cathode for the situation in Figure 10.8(a) consists of three parts:

$$\Delta V_R(x^a, x^c) = \Delta V_a(x^a) + \Delta V_c(x^c) + \Delta V_d \tag{10.9}$$

where ΔV_a, ΔV_c, and ΔV_d represent the ohmic potential drop in the electrolyte in the x direction across the anode, across the cathode, and across the distance between the anode and cathode, respectively. These potential drops can be further expressed by

$$\Delta V_a(x^a) = \int_d^{x^a} j_a(x^a)\, dR(x^a) \tag{10.10}$$

$$\Delta V_c(x^c) = \int_0^{x^c} j_c(x^c)\, dR(x^c) \tag{10.11}$$

$$\Delta V_d = I_a R_d = I_c R_d \tag{10.12}$$

where $R_d = \rho d/tl$, with ρ the resistivity of the electrolyte; t the electrolyte thickness; d the distance between the anode and cathode; l the width of the electrodes; and j_a and j_c the sums of the current from x^a to x_{ae} on the anode and from x^c to

x_{ce} on the cathode, respectively, given by the following Eqs. (10.13) and (10.14):

$$j_a(x^a) = \int_{x^a}^{x_{ae}} i_a(x^a) l \, dx^a \qquad (10.13)$$

$$j_c(x^c) = \int_{x^c}^{x_{ce}} i_c(x^c) l \, dx^c \qquad (10.14)$$

The factors listed under categories (a)–(f) in Figure 10.1 contribute to galvanic action through the electrochemical reaction kinetics given by Eqs. (10.6) and (10.7). For example, changing the pH of the solution may cause a change of the kinetic parameters, i_{0a}, i_{0c}, β_a, or β_c On the other hand, the geometric factors under category (g) affect galvanic corrosion through the parameters in all the equations from (10.4) to (10.14).

Equations (10.4)–(10.14) describe a general situation. It can be simplified for specific applications and geometry. For example, for Figure 10.8(b), representing the galvanic action of a metal joint or a partially coated metal, the term ΔV_d in Eq. (10.9) becomes zero. For the geometry in Figure 10.8(c), representing galvanic action of two metals separated by a large distance [i.e., $d \gg (x_{ae} - d)$ and $d \gg x_{ce}$], I_a and I_c in Eqs. (10.4) and (10.5) become $i_a A_a$, and $i_c A_c$ with $A_a = l(x_{ae} - d)$ and $A_c = l x_{ce}$, the areas for the anode and the cathode, respectively. In addition, ΔV_a and ΔV_c in Eq. (10.9) can be taken as zero because they are very small compared to ΔV_d. In such a case, the geometry in the galvanic cell (i.e., shape and orientation of electrodes, and size of the electrode) becomes insignificant in the galvanic action of the couple, and the galvanic corrosion of the anode, as well as the galvanic protection of the cathode surface, become uniform. Thus, the galvanic action can be fully described by the polarization characteristics of the anode and the electrolyte resistance without consideration of geometric factors.

I3. Polarization and Resistance

In a galvanic couple, it is important to know the relative contributions from the polarization of the coupled metals and the electrolyte resistance, as described by

$$E_{c,corr} - E_{a,corr} = \Delta V_c + \Delta V_a + IR \qquad (10.15)$$

which is essentially Eq. (10.3) simplified when geometric factors are not considered.

Equation (10.15) can be graphically illustrated by the anodic and cathodic polarization curves shown in Figure (10.9). When the solution resistance, R, is infinite, no current flows, and $E_c - E_a$ equals the difference in corrosion potentials of the separated (not coupled) metals (i.e., $E_{c,corr} - E_{a,corr}$). As R decreases, I increases and $E_c - E_a$ becomes smaller because of polarization. When R

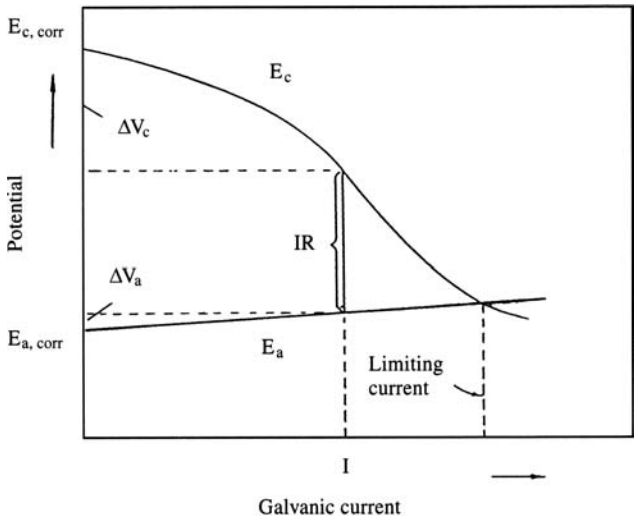

FIGURE 10.9. Graphic estimation of galvanic current.

is zero, $E_c - E_a$, becomes zero and the galvanic current reaches the maximum, known as the "limiting galvanic current," which is at the intersection of the polarization curves of the anode and cathode. The exact shapes of the anodic and cathodic polarization curves depend on the electrochemical reaction kinetics of each metal in the electrolyte and, thus, are functions of pH, temperature, solution concentration, diffusion, formation of passive films, and so on. Often, the anodic dissolution of a nonpassivated metal is activation controlled with a relatively small Tafel slope, while the cathodic reactions on the other metal surface, on the other hand, can either be activation or diffusion controlled depending on the conditions, particularly solution pH and aeration conditions.

The controlling mechanisms in a galvanic corrosion system depend on the relative extent of the anodic and cathodic polarization, on the potential drop in the solution, and on the total potential difference between the coupled metals. If the anode does not polarize and the cathode does, then, in solutions of low resistivity, the current flow is controlled entirely by the cathode. Such a situation is considered to be under cathodic control [Fig. 10.10(a)]. If the anode polarizes and the cathode does not, the status is reversed and the system is said to be under anodic control [Fig. 10.10(b)]. If neither electrode polarizes and the current flow is controlled by the resistivity of the path, mostly in the electrolyte, then the system is said to be under resistance control [Fig. 10.10(c)]. In most situations, a galvanic system is under mixed control, by anodic and cathodic polarization and electrolyte resistance [Fig. 10.10(d)].

The relative magnitude of polarization resistance and solution resistance determines the effective dimension of a galvanic cell, which can be estimated using the polarization parameter, L_i:

$$L_i = 1/\rho |d\eta_i / dI_i| \qquad (10.16)$$

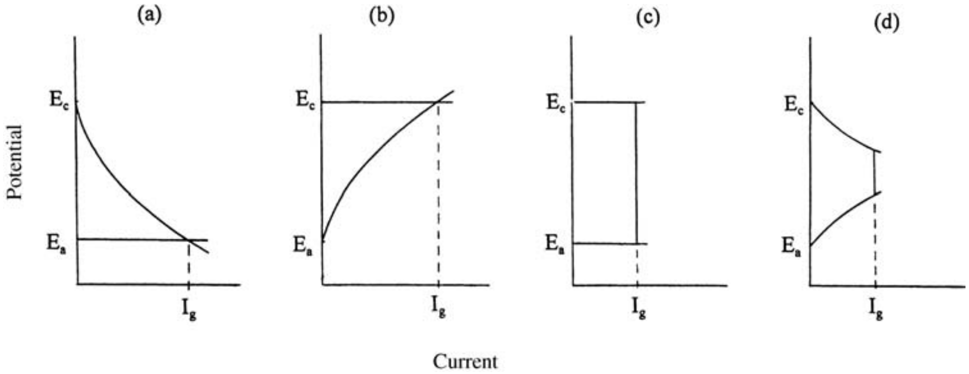

FIGURE 10.10. Schematic illustration of anodic and cathodic polarization carves for four different controlling modes: (a) cathodic control, (b) anodic control, (c) resistance control, and (d) mixed control.

where ρ is the specific resistivity of the electrolyte; I_i is the current density, and η_i is the overpotential of the anode or the cathode. The polarization parameter, defined by Wagner [98], has the dimension of length and provides an electrochemical yardstick for classifying electrochemical systems. It has been widely used to describe the behavior of galvanic corrosion cells [99–102]. Whether the anode and cathode behave "microscopically" or "macroscopically" is determined by the ratio of the dimension of either electrode C_i, divided by the polarization parameter L_i [100]. Mathematical modeling has indicated that, when the ratio, C_i/L_i, is small, the variation of current density across an electrode is small (i.e., the electrode behaves microscopically), On the other hand, when the characterizing ratio is large (i.e., when the electrode dimension is much larger than L_i), the electrode process can be regarded as macroscopic, and the variation of current density across the electrode surface is large.

I4. Potential and Current Distributions

The galvanic action between two metals is governed essentially by the potential distribution across the surface of each electrode. The galvanic current distribution can be determined from the potential distribution when the potential–current relationships for the electrodes are known. Potential distribution can be calculated theoretically or determined experimentally.

Theoretically, a complete description of the potential distribution on the surfaces of a galvanic couple can be obtained by solving Laplace's equation:

$$\nabla^2 E(x, y, z) = 0 \tag{10.17}$$

This equation is derived from Ohm's law, which states that, at any point in the electrolyte, the current density is proportional to the potential gradient

$$I = \sigma \nabla E \tag{10.18}$$

and from the electroneutrality law, which states that, at any point in the electrolyte, the net current under the steady state must be zero

$$\nabla I = 0 \tag{10.19}$$

Many numerical models, with varying mathematical methods and in geometrical and polarization boundary conditions, have been developed for different galvanic systems, as listed in Table 10.9.

These numerical models provide many useful insights to galvanic corrosion. As an example, McCafferty [111] modeled the potential distribution of a concentric circular galvanic corrosion cell, assuming a linear polarization for both the anodic and the cathodic reactions. Figures 10.11 and 10.12 show the results of the potential distribution and current distribution, respectively, as a function of electrolyte thickness. In the bulk electrolyte, the potential variation across the electrodes is small, but both the anode and the cathode are strongly polarized; thus, the actual electrode potentials are far away from E_a^0 and E_c^0. Under a thin-layer electrolyte, the potential variation is large from the anode to the cathode, but both the anode and cathode are only slightly polarized, except for the areas near the boundary between the anode and the cathode. The galvanic current increases with increasing electrolyte thickness. Also, the current is distributed on the electrode surface more uniformly in bulk solutions than in thin-layer solutions where the current is more concentrated near the contact line in the thin electrolyte. According to the calculations of Doig and Flewitt [55], the potential distribution is uniform in the thickness direction under a thin layer of electrolyte (e.g., 1 mm), whereas it is nonuniform under a thick layer of electrolyte. Similar results were reported by Morris and Smyrl [114] for a galvanic cell with coplanar electrodes. The potential distribution under more general geometrical conditions has also been modeled [99, 105].

The results of numerical modeling can be used to predict the galvanic action for the entire surface area of coupled

metals. For galvanic corrosion in a real structure made of different metals, the boundary conditions must be simplified because it is not possible to include all the conditions experienced by a structure during service, particularly the geometry and the electrode polarization conditions [104, 105, 115]. The geometry of a structure, no matter how complex, is generally fixed for a given situation and is independent of the materials and environmental conditions; the polarization properties of the metals, on the other hand, depend on the interaction of the metals with the environment. The polarization characteristics of a metal electrode are generally different for the anode and for the cathode and they vary in different potential ranges. Sometimes, they also vary with the physical elements in the galvanic system, such as electrolyte thickness [80]. In addition, the electrode properties of the coupled metals usually change with time due to changes on the surfaces and in the solution. These elements must be considered when using a numerical model for predicting long-term behavior is a real galvanic system. More detailed discussion on the advantages and limitations of numerical modeling of galvanic corrosion can be found in the literature [104–106].

The potential distribution on the surface of a galvanic couple can also be experimentally determined by placing a reference electrode close to the metal surface and scanning across the whole surface area of the galvanic couple. Rozenfeld [54] showed that the potential variation on the surface of a coplanar zinc–copper couple greatly increases with decreasing electrolyte thickness on top of the surface, as shown in Figure 10.13. The sharpest potential changes take place on the copper cathode, whereas the anode, except for a very narrow region near the junction, does not polarize. Using this experimental approach, data on potential distribution and galvanic action of the system can be obtained, but this method can be impractical in many situations (e.g., when the structure is so complex that not all the surface area is accessible by a reference electrode).

F. Summary
References

A. DEFINITION

Dealloying is a corrosion process whereby one constituent of an alloy is removed leaving an altered residual structure. It was first reported in 1886 on copper–zinc alloys (brasses) and has since been reported on virtually all copper alloys as well as on cast irons and many other alloy systems [1, 2]. Other terms for dealloying include parting, selective leaching, and selective attack. Terms such as dezincification, dealuminification, denickelificaton, and the like indicate the loss of one constituent of the alloy, but the general term dealloying has gained wider use in recent years.

B. HISTORY

During World War I the dezincification of brass condenser tubes was a major problem that kept more British ships out of action than the efforts of the German navy. This problem lessened with the development of more corrosion-resistant alloys, and dealloying is no longer a major problem for most marine operators.

Cast iron gas mains also dealloyed in soil and produced weakened pipes that could not withstand increased pressures. These pipes leaked as demands for natural gas increased and gas company operators increased pressures on their lines. The continued use of cast iron water piping results in occasional reports of dealloying caused by corrosive waters or corrosive soils.

In recent years research has concentrated on using dealloying as a means of producing high-surface-area substrates for catalysis and other purposes [3–8]. The subject of deliberate dealloying as a manufacturing process has been reviewed in the American Society for Metals (ASM) International *Metals Handbook* [9] and will not be discussed further in this chapter.

C. MECHANISM

Dealloying has been shown to occur by at least two different mechanisms. Sometimes the entire alloy dissolves, and one constituent redeposits on the corroded metal surface. In other circumstances diffusion removes only the more corrosion-susceptible constituent, leaving an altered porous matrix. Both mechanisms have been shown to occur simultaneously on the same metal surface [10].

Figure 11.1 shows copper deposits on the surface of dezincified alpha brass. Similar deposits have been reported on cupronickels and Monel [11, 12].

Figure 11.2 is a more typical picture of dealloying showing a porous discolored structure surrounded by unattacked metal. This picture is from a corroded scuba tank valve, and the porous chrome plating allowed seawater to penetrate the protective chrome plating and corrode the underlying brass.

Dealloying is also a problem with cast irons. While both diffusion and noble metal deposition are discussed as

mechanisms associated with dealloying in copper-based alloys, the mechanism of dealloying in cast irons involves the dissolution of the iron-rich phases, leaving a porous matrix of graphite and iron corrosion products. Figure 11.3 shows a porous graphite plug in a cast iron water pipe.

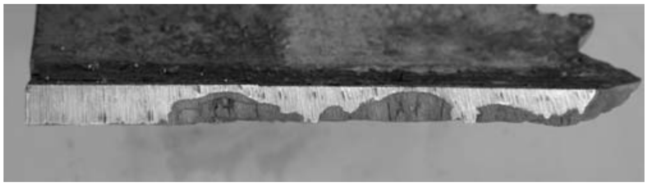

FIGURE 11.3. Dark, graphitic corrosion on the exterior of a cast iron water main. Arrow points to graphitic corrosion (dealloyed) region. (Photo courtesy Testlabs International Ltd., Winnipeg, Manitoba, sole owner of the photograph.)

FIGURE 11.4. Microstructure of gray cast iron.

Gray cast iron, which is considered obsolete for most corrosion-related applications, is most susceptible to this problem. Figure 11.4 shows the microstructure of gray cast iron. The dark regions are graphite flakes, essentially pure carbon, while the lighter phases are essentially pure iron. While carbon is only 2–4% by weight of the alloy, the volume percent is much higher, and the almost continuous graphite matrix maintains the original profile of the cast iron, but with much reduced mechanical integrity. This is a form of selective phase attack, which is discussed further in the section on copper alloys.

At one time it was assumed that only certain alloys would undergo dealloying, and the concept of a "parting limit" was popular. The idea was that some alloys, for example, the 60Cu–40Zn duplex alpha-plus-beta-phased brasses, were more susceptible to this corrosion than the single-phased alpha brasses containing 30% zinc or less. Many authorities claimed that "red brasses" having zinc contents of 15% or less would not dezincify and suggested a parting limit somewhere between 15 and 30% zinc. In recent decades dealloying has been reported in brasses down to 2 wt %, and the concept of parting limits has been generally discarded, although it is still believed in some circles [9, 13].

Parrish and Verink [14] proposed that the potential differences between the equilibrium potentials for copper and nickel could be used to explain the dealloying of copper–nickel alloys. They superimposed the potential–pH (Pourbaix) diagrams for these two pure metals and hypothesized that the potential region between the two equilibrium potentials would be a region where dealloying was likely to occur in copper–nickel alloys [14]. This concept has been applied to other systems [15] and has gained widespread acceptance as a means of explaining why dealloying can occur [16]. The shaded area in Figure 11.5 shows the potential–pH region where dealloying is thought to occur

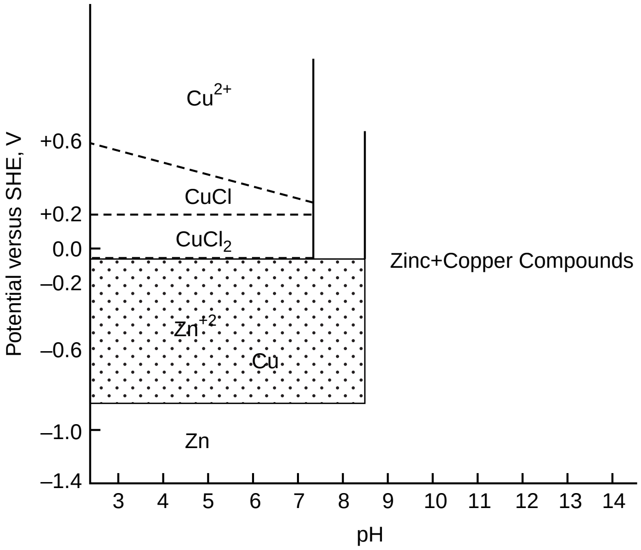

FIGURE 11.5. Superimposed potential–pH diagrams for copper and zinc. Shaded region indicates dezincification susceptibility.

for copper–zinc (brass) alloys. Pure copper is immune from corrosion in this region, and pure zinc will corrode producing zinc ions at low pHs. The result is a copper-rich dealloyed surface.

The concepts described in the preceding paragraph are also used in varying ways by the researchers working on producing high-surface-area dealloyed structures for manufacturing processes [5].

D. CONTROL OF DEALLOYING CORROSION

Almost any method that will lower corrosivity of an environment will reduce the rate of dealloying, but most dealloying is controlled by proper alloy selection.

D1. Copper Alloys

The three most common alloy systems used in corrosion service are copper–zinc brasses, bronzes (historically copper–tin alloys, but now more often aluminum bronzes), and cupronickels.

Single-phase alpha brasses (30% zinc or less) and duplex alpha-plus-beta brasses (typically 40% zinc) are the only forms of copper–zinc alloys that have engineering significance. The problems with dezincification of marine service brass condenser tubes led to extensive research in the early part of the twentieth century. Single-phase admiralty and duplex naval brasses, containing tin additions of approximately 1%, were found to reduce most forms of corrosion, to include dezincification. These became standard tubing alloys in the 1920s and 1930s.

Dealloying of brasses is normally controlled by the use of alloys with small additions of arsenic, antimony, or phosphorus. Bengough and May reported, in 1922, that small additions of arsenic would prevent dezincification of alpha brasses (usually about 30% zinc) but would not protect the beta phases of duplex alloys (60Cu–40Zn alloys) [17]. The reasons for arsenic protecting alpha brass but not the beta phase of duplex alloys have remained controversial but may be related to differential solubilities of arsenic in the alpha and beta phases [18]. The toxicity of arsenic has led to research into alternatives for arsenic [19].

In freshwater systems aluminum brass (approximately 70Cu–29Zn–1Al) is a common tubing material, for example, for condensers using freshwater for cooling. The aluminum is primarily useful for erosion resistance and, like tin in admiralty and naval brasses, lowers most corrosion rates but does not specifically affect dealloying.

Duplex brasses were at one time used in high-pressure condensers on some marine vessels, but cupronickels have largely replaced brasses for condenser tubes. Brasses and bronzes are, however, still used for pumps and fittings on these systems, and dealloying remains a problem.

Cupronickels have largely replaced brasses for marine piping applications. Both cupronickels (90–10 and 70–30 Cu–Ni) and Monels (approximately 70Ni–30Cu) have been reported to dealloy by a redeposition process, usually in stagnant conditions; but this is rare [1, 10, 11].

Pumps and fittings in copper-based piping systems are typically made of bronzes, multiphased alloys with high erosion resistance. At one time most bronze casting alloys had tin as the primary alloying addition, but the high cost of tin has led to the development and widespread use of alternative aluminum bronzes, which are cheaper and have most of the corrosion resistance and other properties of copper–tin bronzes. Common alloys include copper–manganese–aluminum and nickel–aluminum bronzes. Unfortunately, both of these alloy systems can form corrosion-susceptible phases that can lead to selective phase attack, a form of dealloying. This is a foundry control problem, but it can also occur when welding is necessary for repairs [20, 21]. The extent to which this attack occurs depends on the electrochemical potential difference between the phases. Since these alloys are usually used in castings, which are relatively thick compared to wrought products like tubing, the consequences of corrosion may be relatively minor, but loss of sealing surfaces and loss of strength can become problems. Figure 11.6 shows selective phase attack on a nickel–aluminum bronze casting in seawater service.

D2. Cast Irons

Gray cast iron has a long history of dealloying. At one time this was a common material used for buried pipelines and similar applications.

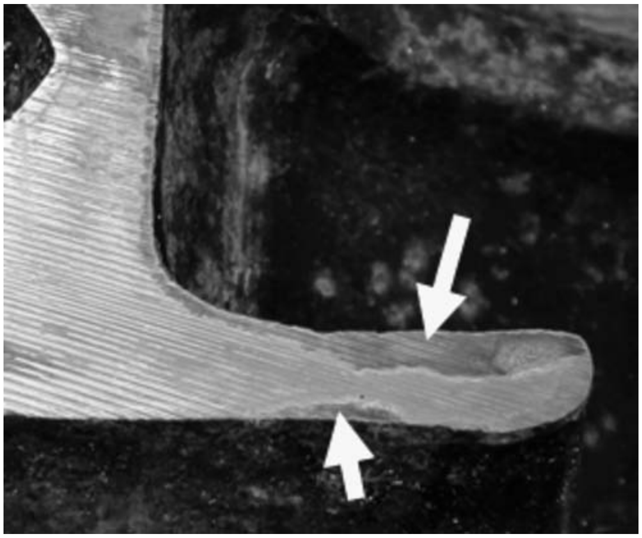

FIGURE 11.6. Selective phase attack of nickel–aluminum bronze [22]. (Photo courtesy Defence R&D Canada – Atlantic.)

The development of malleable and nodular (marketed in North America as “ductile cast iron”) cast irons has caused gray cast iron to become obsolete for corrosive environment applications such as water piping and buried pipelines. The rounded graphite second phases in malleable or nodular cast iron present less grain boundary area to act as cathodes for galvanic corrosion of the high-iron phases in these metals. This improves their corrosion resistance somewhat. Buried water lines made from nodular (ductile) cast iron piping have been in use for several decades, and many utilities are reporting dealloying of this metal, which was once considered to be immune to dealloying.

Dealloying of cast irons is called “graphitic corrosion” because the previous term for this corrosion, “graphitization,” is also applied to foundry heat treatment processes.

E. INSPECTION

Inspection for dealloying has been very difficult because this form of corrosion usually leaves a surface profile similar to uncorroded metal. The only way of finding dealloying has been by visual inspection for color changes or by mechanical probing to identify a loss of integrity.

Several researchers have reported on attempts to develop methods of in situ nondestructive inspection for dealloying, but they have not achieved widespread acceptance [20, 22].

F. SUMMARY

Dealloying has been known to occur in copper and iron-based alloys since the nineteenth century. At one time this was a major problem, but advances in alloy chemistry have caused the incidence of dealloying to be greatly reduced in recent years.

Much modern research on dealloying is now focused on deliberately causing dealloying to produce high-surface-area structures for catalysis and other purposes. It remains to be seen if this will lead to significant commercial applications.

A. INTRODUCTION

All metals and alloys (it is commonly held that gold is an exception) have a thin protective corrosion product film present on their surface resulting from reaction with the environment. If such a film did not exist on metallic materials exposed to the environment, they would revert back to the thermodynamically stable condition of their origin—the ores used to produce them. Some of these films—the passive films—on some, but not all, metals and alloys have special characteristics that enable them to provide superior corrosion-resistant metal surfaces. These protective "passive" films are responsible for the phenomenon of passivity.

B. IMPORTANCE OF PASSIVITY TO CORROSION CONTROL TECHNOLOGY

As mentioned in the introduction, if the passive film did not exist, most of the technologies that depend on the use of metals in any society could not exist because the phenomenon of passivity is a critical element controlling corrosion processes. One of these corrosion processes is the destruction of passivity (breakdown) that leads to a large part of the corrosion failures of metal and alloy structures—localized attack such as pitting, crevice corrosion, stress corrosion, corrosion fatigue, and others. The passivity of metallic materials, however, is not only of predominant significance to corrosion science and engineering. For example, semiconductor device technology depends on the superior passive films that form on silicon [1].

The development of the stainless steels in the third decade of the twentieth century is regarded as a major application of the phenomenon of passivity. The consequence of this has significantly contributed to modern technology by providing the design engineer with engineering materials such as the large number of iron and nickel base alloys as well as other alloy systems that exhibit superior corrosion resistance—this effort continues to the present day.

C. DEFINITIONS

Two types of passivity have been defined by Revie and Uhlig [2]:

Type 1—"A metal is passive if it substantially resists corrosion in a given environment resulting from marked anodic polarization" (low corrosion rate, noble potential).

Type 2—"A metal is passive if it substantially resists corrosion in a given environment despite a marked thermodynamic tendency to react" (low corrosion rate, active potential).

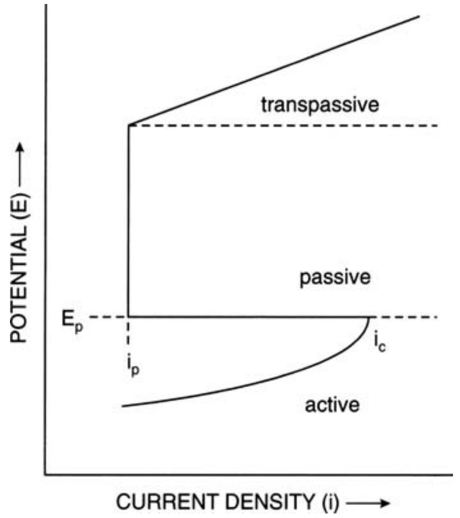

FIGURE 12.1. Schematic and idealized anodic polarization curve for passive metal. Three different potential regions are identified: the active, the passive, and the transpassive. When the current density reaches the critical current density for passivation i_c, at the passivation potential E_p, the potential above which the system becomes passive and exhibits the very low passive current density i_p.

Only type 1 passivity will be covered here. Metals or alloys exhibiting type 1 passivity are nickel, chromium, titanium, iron in oxidizing environments (e.g., chemical passivating solutions such as chromate), stainless steels, and numerous others. Type 2 passivity examples are lead in sulfuric acid and iron in an inhibited pickling acid.

A polarization curve [current density (rate) vs. potential (driving force)], of the sort shown in Figure 12.1 distinguishes a type 1 passive system. The curve in Figure 12.1 epitomizes the definition of type 1 passivity proposed by Wagner [3] who extended the type 1 definition by stating that a metal becomes passive when its potential is increased in the positive or anodic (oxidizing) direction to a potential where the current density (rate of anodic dissolution) decreases (in many cases by orders of magnitude) to a value less than that observed at a less anodic potential. This decrease occurs even though the driving force for anodic dissolution is brought to a higher value because of the formation of the passive film.

Another definition of passivity has been provided by the NACE/ASTM Committee J01, Joint Committee on Corrosion "passive—the state of a metal surface characterized by low corrosion rates in a potential region that is strongly oxidizing for the metal" [4].

D. CORROSION SCIENCE AND ENGINEERING

Although virtually all of the progress in the development of alloys that exhibit superior corrosion behavior has resulted from empirical rather than fundamental research, this section will briefly go into those fundamental aspects that have a bearing on corrosion engineering. It will concentrate on the basic aspects that are concerned with the film responsible for passivity, its formation and breakdown and its nature. Detailed discussions of the fundamental aspects of the passive film and the electrochemistry of passivation can be found in a number of sources [5–10].

D1. Nature and Properties of the Passive Film

Because it is generally accepted that a film is responsible for the phenomenon of passivity, the nature and properties of the passive film that make it protective are significant issues. For the purposes of this chapter this important, and still controversial, subject cannot be covered in any detail. Instead, some of the large number of publications [5–10] that review and discuss the concepts and research that go extensively into the nature (e.g., composition and thickness) and properties (e.g., structure, electronic properties, and mechanical properties) of the passive film should be referred to by those who want to go into this aspect of passivity.

D2. Thermodynamics

Passivity has been defined by the fact that it lowers the rate of corrosion, sometimes drastically—a kinetic consideration. However, before addressing the kinetics of passivation, the thermodynamic aspects must be discussed. This is needed when considering type 2 passivity, which involves any kind of corrosion product film rather than the special type 1 "passive film." This is so because thermodynamics provides a guide to the conditions under which passivation by any kind of corrosion product film, type 1 or 2, becomes possible. A most worthwhile and practical guide produced by corrosion science is the potential–pH diagram, the Pourbaix diagram. Pourbaix's *Atlas of Electrochemical Equilibria in Aqueous Solutions* [11] describes applications of these potential–pH equilibrium diagrams to corrosion science and engineering for most of the metals. An application that is especially valuable for the field of corrosion is the establishment in the Pourbaix diagrams of the theoretical conditions or domains of corrosion, immunity, and passivation. A simplified diagram for the iron–water system is given in Figure 12.2. Thermodynamic data enable the determination of the potential–pH conditions for *immunity* where no corrosion is possible, for *passivation* where a corrosion product film forms that may confer protection against corrosion, and for *corrosion* where corrosion or activation is expected. Whether a given system's film is protective (passive) or not is a kinetic consideration and not a thermodynamic one that depends on the nature of the passive film. Pourbaix's book presents a set of simplified diagrams like the one shown in Figure 12.2 for the majority

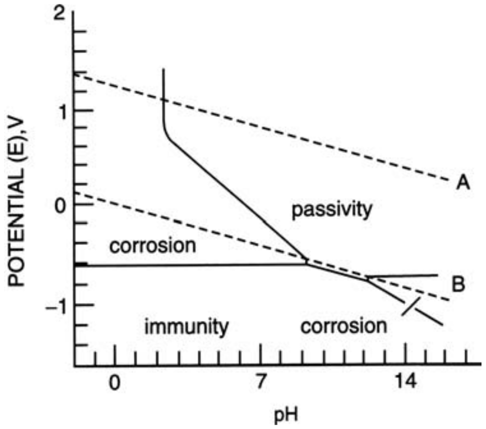

FIGURE 12.2. Simplified potential–pH equilibrium diagram (Pourbaix diagram) for iron–water.

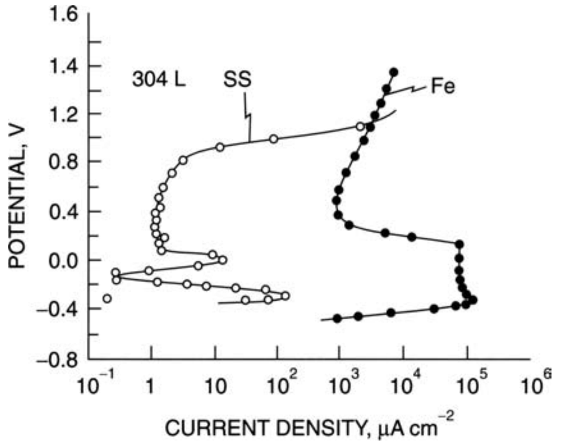

FIGURE 12.3. Anodic polarization curves for iron and 304L stainless steel in 1*N* H_2SO_4. (Adapted from Fontana and Greene [13].)

of metals that enable one to identify the conditions for corrosion, passivation, and immunity. These equilibrium diagrams could be called "road maps of the thermodynamically possible conditions for passivity."

Consequently, to identify the active, passive, and transpassive regions of an active–passive polarization curve (Fig. 12.1), one need only examine the potential–pH diagram for a given system. For example, the transpassive region lies at potentials above the oxygen evolution potential–pH line (line *A* in Fig. 12.2). Another valuable use of the diagrams in passivity considerations is their use to explain the reasons for loss of the protective nature of the passive film in the transpassive region. For example, the protective layer on stainless steels contains chromium as Cr(III); when the potential is raised above the transpassive potential, Cr (III) is oxidized to Cr(VI) and the protective Cr(III) in the passive film is removed because it becomes the soluble chromate ion, as the potential–pH diagram for chromium shows. Usually, the passive regions of the polarization curves exist at potentials in the equilibrium diagrams where passive films are stable. It should finally be mentioned that the thermodynamically based Pourbaix diagrams sometimes fail to predict a passive region in a polarization curve. Hoar [12] sought to explain how iron can passivate in sulfuric acid solutions under conditions where the diagrams would predict an active condition, by proposing the existence of metastable passive regions.

D3. Kinetics

Passivity affects the kinetics of the corrosion process because it produces a protective (passive) film that acts as a barrier to attack of the metal surface by the environment. The passive film substantially lowers the rate of corrosion, even though from thermodynamic (corrosion tendency) considerations active corrosion should be expected. The hypothetical anodic polarization curve (Fig. 12.1) that is the basis for the definition of type 1 passivity describes in a general way the kinetics of passivity. Anodic polarization curves for iron and 304L stainless steel in H_2SO_4 (Fig. 12.3) show the three general features of the schematic curve for a passive system (Fig. 12.1): (1) The current initially increases with an increase in potential. (2) When the potential reaches the value of the passivating potential E_p, the critical current density for passivation i_c is reached. (3) The current density (corrosion rate) decreases markedly (more for the corrosion-resistant stainless steel than for the iron) to the passive current density i_p, signaling the onset of passivity. As Figure 12.1 shows, the potential cannot be increased indefinitely because at sufficiently high values the current density starts to increase, resulting in either the initiation of pitting or entry into the transpassive region. In the transpassive region oxygen evolution and possibly increased corrosion are observed.

Since corrosion is the result of the interaction of the anodic and cathodic reactions, the corrosion potential of a metal surface is determined by the intersection of the anodic and cathodic polarization curves, the intersection occurring where the anodic and cathodic reaction rates are equal to the corrosion rate. Therefore, the corrosion rate of a metal capable of exhibiting passivity, will be determined by the location of the intersection of the cathodic polarization curve and the passive metal anodic polarization curve of the type shown in Figure 12.1. Three possible cases can arise from the intersection of different cathodic curves with the passive anodic polarization curve (shown schematically in Fig. 12.4): (1) A cathodic reaction arising from oxidizing conditions, polarization curve *A*, sets the corrosion potential in the passive region (low corrosion rate). (2) A cathodic reaction, the result of reducing conditions, curve *C*, places the corrosion potential in the active region (high corrosion rate). (3) The cathodic reaction, polarization curve *B*, locates the

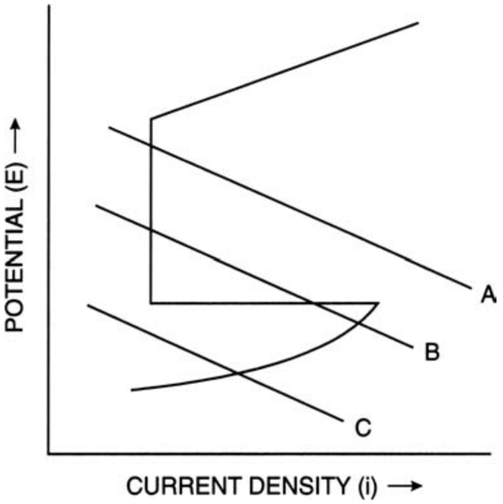

FIGURE 12.4. Intersection of three possible cathodic polarization curves (straight lines *A*, *B*, and *C*) with anodic polarization curve for system capable of exhibiting passivity. The corrosion rate depends on the current density at the intersection. Curve *A* produces a passive system, curve *C* an active system, and curve *B* an unstable system that can exhibit both low and high corrosion rates.

corrosion potential in both the passive and active regions, where the surface will oscillate between active and passive states, creating unstable conditions.

D4. Breakdown of Passivity

Another possible anodic–cathodic intersection site exists when conditions exist that lead to breakdown of passivity, localized attack, and then to pitting. The part of the passive anodic polarization curve shown in Figure 12.5 at potentials above the potential for breakdown, E_{bd} (called by some the critical breakdown or pitting potential E_{pit}), is the potential below the transpassive region at which the current density increases above i_{pass}. The intersection of cathodic curve 1 with the anodic curve of such a system results in breakdown and pitting while no breakdown occurs when the anodic polarization curve is intersected by cathodic curve 2 at a potential below E_{bd}.

The breakdown of passivity (the breaching of the protective barrier provided by the passive film) initiates the most damaging kinds of corrosion, the localized forms of corrosion, pitting, crevice corrosion, intergranular attack, and stress corrosion. A 1982 review by Kruger and Rhyne [14] extensively reviewed the corrosion science and engineering of the breakdown processes that are brought about by the chemical alteration of the passive film or the environment so that the film becomes unable to effectively prevent destructive local attack. Other reviews of breakdown have been given by Kruger [15], Galvele [16], and by Janik-Czachor [17].

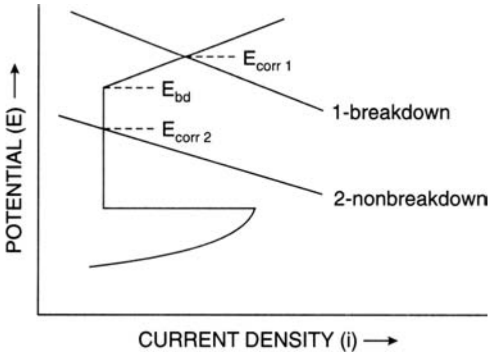

FIGURE 12.5. Anodic polarization curve for system capable of exhibiting passivity but is subject to breakdown at potentials above breakdown potential E_{bd} where pitting is initiated. The intersection of cathodic curve 1 with the anodic curve of a system exhibiting passive results in the breakdown of passivity that leads to pitting, while the intersection of cathodic curve 2 at a potential below E_{bd} results in no breakdown.

Hoar [18] stated that four conditions (that are usually but not always) considered to be required for the breakdown that initiates localized attack: (1) *Critical Potential*—a certain critical potential E_{bd} must be exceeded. (2) *Damaging Species*—damaging species (examples are chloride or the higher atomic weight halides) are needed in the environment to initiate breakdown and propagate localized corrosion processes like pitting. (3) *Induction Time*—an induction time exists, which starts with the initiation of the breakdown process by the introduction of breakdown conditions and ends when the localized corrosion density begins to rise. (4) *Local Sites*—the presence of highly localized sites where breakdown takes place. Various models for initiation have been developed that satisfy these four conditions [15–17].

E. USING PASSIVITY TO CONTROL CORROSION

Using the phenomenon of passivity to control corrosion entails employing methods that bring the potential of the surface to be protected to a value in the passive region. Some of the tactics that can be used to do this are:

1. A current can be applied by means of a device called a potentiostat, which can set and control the potential at a value greater than the passivating potential E_p. This method of producing passivity is called anodic protection.
2. For environments containing the damaging species, such as chloride ions that cause local corrosion, the potentiostat or other devices that control the potential can be used as in tactic 1 to set the potential to a value

in the passive region below the critical potential for pitting E_{pit}.

3. Alloys or metals that spontaneously form a passive film, for example, stainless steels, nickel, or titanium alloys, can be used in applications that require resistance to corrosion. Usually a pretreatment such as that described in tactic 4 is desirable.
4. A surface pretreatment can be carried out on an alloy capable of being passivated. The use of such a pretreatment has been standard practice for stainless steels for many years. The passivating procedure involves immersion of thoroughly degreased stainless steel parts in a nitric acid solution followed by a thorough rinsing in clean hot water. The most popular solution and conditions of operation for passivating stainless steel is a 30-min immersion in a 20 vol % nitric acid solution operating at 120°F (49°C). However, other solutions and treatments may be used, depending on the type of stainless being treated [19].
5. The environment can be modified to produce a passive surface. Oxidizing agents such as chromate and concentrated nitric acid are examples of passivating solutions that maintain a passive state on some metals and alloys.

A. INTRODUCTION

Localized corrosion of passive metals includes various types of corrosion phenomena, such as pitting, crevice corrosion, intergranular attack as well as stress corrosion cracking. The latter form of corrosion is discussed in Chapter 14 and will not be addressed here, but it has to be pointed out that crack initiation quite often starts at sites where localized corrosion processes occur. Therefore localized corrosion and stress corrosion cracking are quite often correlated.

Since Part I of this book is devoted primarily to the fundamental aspects of corrosion, the scope of this chapter will also be limited to the fundamentals of localized corrosion of passive metals, where several detailed mechanisms for the different stages of localized corrosion have been extensively studied. Pitting and crevice corrosion are the two major forms of localized corrosion. They are often treated separately, especially when dealing with more practical aspects of localized corrosion. The different morphological appearance of the two types of corrosion suggest different mechanisms, a point of view that does not hold when looking at the electrochemical fundamentals of these processes. Therefore this chapter is focused mainly on pitting corrosion phenomena. With respect to intergranular corrosion, the structural aspects of the various alloys are of primary importance. Since this form of localized corrosion depends strongly on the alloy under consideration, the readers are referred to Part III of this book where the various metals and alloys are treated separately.

B. PHENOMENOLOGICAL ASPECTS

During pitting corrosion of passive metals and alloys, local metal dissolution occurs leading to the formation of cavities within a passivated surface area. In practice, pitting corrosion of passive metals is commonly observed in the presence of chlorides or other halides. Therefore the question arises whether the presence of specific, so-called localized, corrosion-inducing anions, such as halides, are always required for pitting to take place. Some results indicate that pitting may also occur in pure water as in the case of carbon steel in high-purity water at elevated temperature or aluminum in nitrate solutions at high potentials. In all these forms of localized corrosion, active and passive surface states are simultaneously stable on the same metal surface over an extended period of time, so that local pits can grow to macroscopic size.

†Retired

Therefore, from an electrochemical point of view, more appropriate questions would be: What are the necessary requirements to initiate pits and what is required to stabilize a heterogeneous electrode state consisting of simultaneously active and passive surface areas, exhibiting significantly different dissolution rates?

B1. Electrochemical Potential

Electrochemical studies of pitting corrosion usually indicate that stable pitting occurs only within or above a critical potential or potential range. Therefore the susceptibility of passive metals to pitting corrosion is often investigated by electrochemical methods. Most commonly, potential current curves are measured either by applying potentials stepwise (potentiostatically) or by applying a constant potential sweep rate (potentiodynamically) and recording the resulting current. Typical potential current curves exhibit an active–passive transition and subsequently a sudden current increase within the passive potential range, as shown schematically in Figure 13.1. The following values are often determined and used to characterize metals and alloys with respect to pitting and crevice corrosion: (1) the critical current density i_{crit}, characterizing the active–passive transition, (2) the pitting potential E_p where stable pits start to grow, and (3) the repassivation or protection potential E_{rep} or E_{pp} (after reversal of the potential sweep direction) below which the already growing pits are repassivated and the growth is stopped.

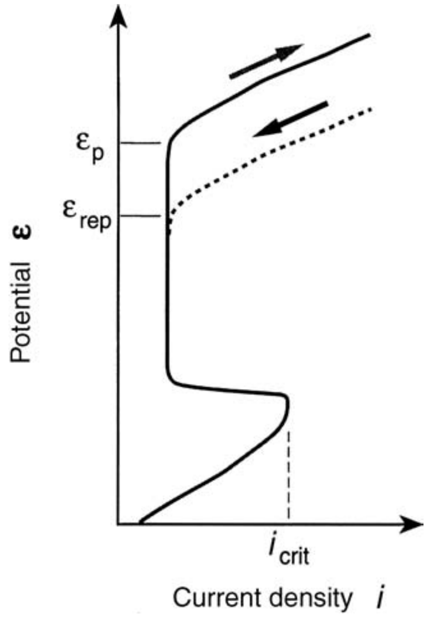

FIGURE 13.1. Schematic polarization curve for metal showing active–passive transition as well as pitting in the passive potential range: $E > E_p$, pitting will occur; $E < E_{rep}$, growing pits will repassivate.

More detailed reviews of the various electrochemical methods used to measure the susceptibility to pitting corrosion are given by Szlarska-Smialowska [1] and Sedriks [2]. Obviously, these quantities mentioned above can be measured as functions of the alloy composition or of the composition of the environment. Without discrediting the practical value of such investigations, especially in comparing alloys as well as environments with respect to their pitting-susceptibility or pitting-promoting tendency, they give neither any direct insight into the mechanisms of localized corrosion processes nor can the values be used as true limiting potential values to prevent localized corrosion processes in engineering applications.

B2. Effects of Alloying and Microstructure

The alloy composition as well as the microstructure can have a strong influence on the pitting resistance of an alloy, as shown, for instance, by Horvath and Uhlig [3], who demonstrated the beneficial effect of chromium and molybdenum in stainless steels. The pitting potential was found to increase dramatically with chromium contents $\gtrsim 20$ wt %, whereas molybdenum is effective at minor concentrations of 2–6 wt %, but only in the presence of chromium. Similar effects have also been reported for small amounts of alloyed nitrogen or tungsten. Various explanations have been given to explain the strong influence of molybdenum on the pitting behavior of stainless steels, which is also well confirmed in engineering practice. It was suggested that molybdenum is adsorbed on the surface as molybdate or acts by blocking active surface sites, inhibiting active metal dissolution and finally favoring repassivation [4–6]. Other models suggest that molybdenum, as well as other elements, improves the cation-selective properties of the passive film, hindering the migration of aggressive anions, such as chlorides, to the metal surface [7, 8] or reduce the flux of cation vacancies in the passive film [9]. Though the exact mechanism is not clear yet, most of the research done so far favors an effect on the growth stage rather than on the initiation stage of localized corrosion. Recent results, applying microelectrochemical techniques, confirmed that even in the superaustenitic stainless steels molybdenum strongly improves the repassivation behavior but has no influence on pit initiation [10, 11].

Similar effects can also be observed on aluminum, where small additions of alloying elements may increase the pitting potential as long as the structure is single phase. Aluminum–copper alloys, widely used in the aircraft industry, are well known and intensively studied examples with respect to their pitting behavior [12]. The pitting potential increases with increasing copper concentration as long as copper is in solid solution. Since aluminum usually exhibits rather low solubility limits, alloying elements tend to form second-phase intermetallic compounds, such as Al_2Cu. In the presence of

Al_2Cu the pitting resistance decreases to values of aluminum with small copper concentrations. The corresponding decrease in pitting potential is explained by the existence of a copper-depleted zone around these particles, where pits would initiate first.

Localized corrosion of passive metals almost always initiates at local heterogeneities, such as inclusions and second-phase precipitates as well as grain boundaries, dislocations, flaws, or sites of mechanical damage. In the case of stainless steel surfaces, pit initiation occurs almost exclusively at sites of MnS inclusions, which are found in commercial as well as in high-purity alloys. A more detailed discussion of this subject will follow. To prevent inclusions and precipitates, nonequilibrium single-phase conditions can be attained by special preparation techniques, such as rapidly quenching or physical vapor deposition. The resulting microstructure is either nanocrystalline or amorphous. It was recently shown that sputter-deposited aluminum alloys containing only a few atomic percent of metal solute such as Cr, Ta, Nb, W, Mo, or Ti exhibit a strong increase of E_p of 0.2–1V [13–17]. Similar results were also obtained with sputter-deposited stainless steels, where nonequilibrium single-phase structures with molybdenum concentrations up to 14 wt % could be obtained [18, 19]. In both cases, the increase in pitting resistance was explained by the reduced pit initiation tendency as well as by a more protective passive film, favoring rapid repassivation.

B3. Effect of Temperature

Increasing temperature usually also increases the pitting tendency of metals and alloys. At low temperature, high pitting potentials are observed. In the case of stainless steels, a strong decrease of pitting potentials in the temperature range between 0 and 70°C of ~ 0.5 V can be observed as shown in Figure 13.2 [20, 21]. This strong dependence on temperature has led to experimental techniques which allow stainless steels to be ranked according to their pitting susceptibility. A critical pitting temperature (CPT) has been defined, below which a steel in an aggressive Cl^--containing solution, usually a $FeCl_3$ solution, would not pit regardless of potential and exposure time [20, 22].

Furthermore, the CPT used to characterize the pitting resistance of alloys is often correlated with the composition of stainless steels, especially with Cr, Mo, and N [1, 2, 20]. The effect of temperature on the pitting behavior of other metals and alloys such as Ni, Al, Ti, and its alloys has also been studied but to a lesser extent. Important earlier results are summarized in [20]. Nevertheless most of the investigations on temperature effects of localized corrosion deal with the significance of temperature to evaluate and compare pitting susceptibilities of different metals and alloys rather than with the more fundamental aspects of temperature effects on pit initiation and pit growth mechanisms.

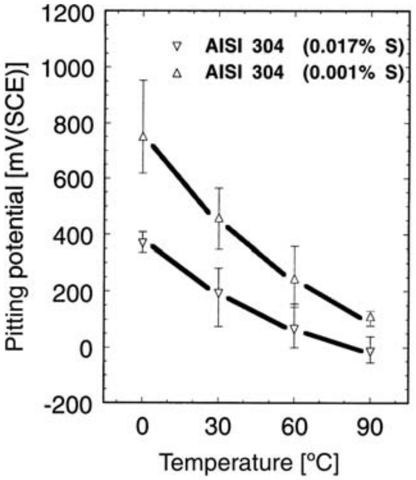

FIGURE 13.2. Effect of temperature on pitting potential E_p of 304 stainless steel (SS) in 0.1*M* NaCl with different sulfur contents [21].

B4. Stochastic Aspects

Corrosion processes are based mainly upon deterministic approaches, such as the electrochemical theory of corrosion. Localized corrosion events, however, due to their unpredictable occurrence, cannot be explained without using statistical methods to evaluate the experimental data. Stochastic aspects of pitting corrosion were studied in the late 1970s, especially by authors in Japan [23–26]. Recently, a convincing review of statistical and stochastic approaches to localized corrosion was published by Shibata [27]. He evaluated large numbers of pitting potential values using a Gaussian distribution, whereas the Poisson distribution was found to be a better approach for pit generation. The results indicate that different pit generation rates can be observed as a function of time. He proposed two groups of models considering either pit generation events alone or assuming pit generation and subsequent repassivation processes. The latter model could be fitted more satisfactorily to the various cases studied experimentally. More detailed information will be given in Chapter 27.

C. STAGES OF LOCALIZED CORROSION

The different stages of localized corrosion can best be explained and discussed in connection with its potential dependence. In Figure 13.3, a typical potential current curve of a passive metal, such as stainless steel, measured in chloride solutions, shows the different stages of pitting corrosion.

At lower potentials, pit initiation is followed by rapid repassivation. This stage is usually referred to as metastable pitting. The resulting current transients differ widely with

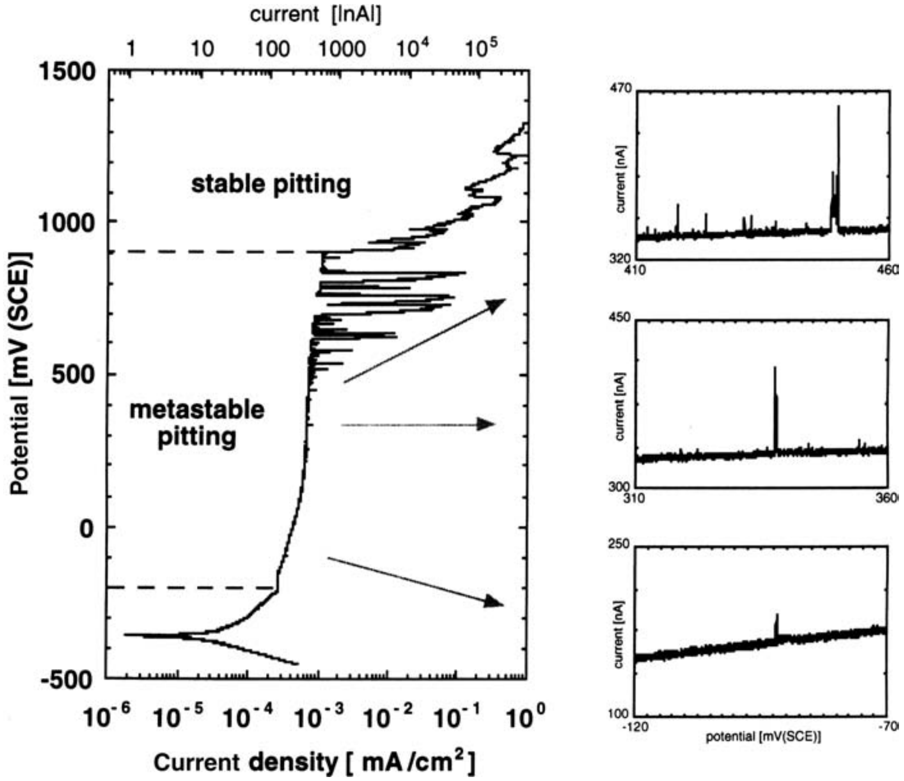

FIGURE 13.3. Typical potential current curve of stainless steel in chloride solution showing different stages of localized corrosion (see text).

respect to the peak current height as well as the lifetime. Small current transients in the femtoampere (fA) and picoampere (pA) range, corresponding to pits of nanometer and micrometer size can be detected only by applying micro- and nanoelectrochemical methods, as will be discussed later. Increasing the potential generally leads to larger current transients with higher peak currents and longer lifetimes, indicating an extended pit growth period. Above a certain potential or potential range, a transition to stable pit growth occurs. Even above the pitting potential, repassivation may still occur, showing the stochastic character of localized corrosion processes. Whether well-defined pitting potentials can be determined depends on a variety of factors, such as the type of metal, the chloride concentration, and the temperature. The higher the chloride concentration or the temperature, the more precise the resulting pitting potentials usually are. Furthermore the use of crevice-free experimental techniques may also be very decisive in obtaining reproducible results.

Metastable pitting is usually not considered as a real corrosion risk from an engineering point of view. Nevertheless, studies of metastable pitting as a precursor to stable pitting may provide valuable insights into fundamental aspects of pitting corrosion, since pit initiation as well as the trans formation of metastable into stable pits are key factors in localized corrosion processes. Investigations of metastable pitting also allow a statistical evaluation of corrosion data necessary to study stochastic pitting models.

With respect to engineering application, studies of metastable pitting may also substantially improve the evaluation of metal–environment systems. The occurrence of metastable pitting below the pitting potential indicates a potential corrosion risk, especially when crevice conditions cannot be completely excluded. Furthermore the repassivation behavior of metals and alloys can easily be studied, which is very important for developing highly corrosion-resistant alloys.

D. METASTABLE PITTING: PIT INITIATION AND REPASSIVATION

A number of models have been proposed to describe the initiation of localized corrosion of passive metals based either on the breakdown processes of the passive film itself or on structural defects or heterogeneities of the underlying metal or alloy such as dislocations, grain boundaries, second-phase precipitates, or nonmetallic inclusions. Certainly a strict differentiation of the two approaches is not always possible, since film breakdown and structural parameters of the underlying metal may be correlated.

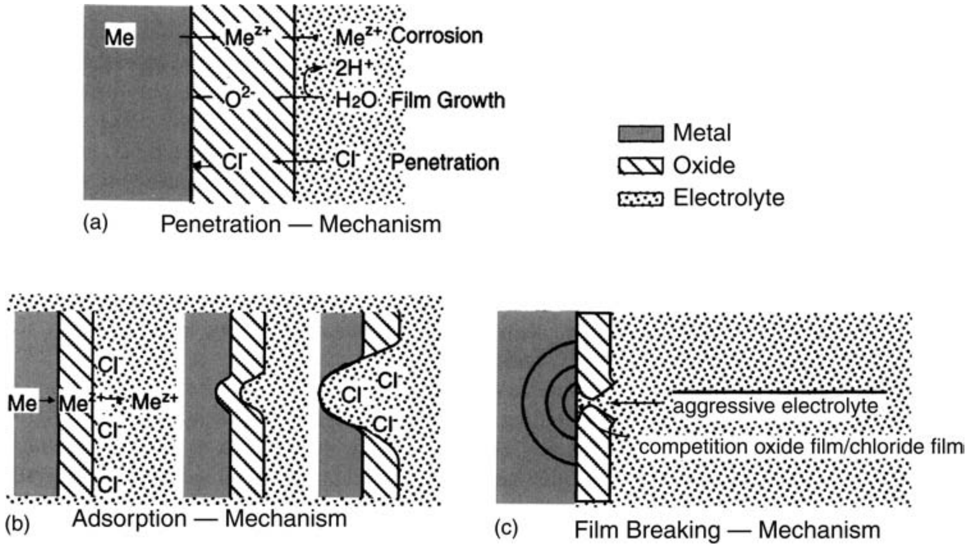

FIGURE 13.4. Models for pit initiation leading to passive film breakdown. [After Strehblow and co-workers [28–30]. Reproduced with permission from H. Kaesche, *Die Korrosion der Metalle*, 3rd edition. Springer, Berlin, Germany, 1990, Fig. 12.12a–c, p. 308. Copyright © Springer.]

D1. Passive Film Breakdown

Theoretical models that describe the initiation process leading to passive film breakdown may be grouped into three classes: (1) adsorption and adsorption-induced mechanisms, where the adsorption of aggressive ions like Cl^- is of major importance, (2) ion migration and penetration models, and (3) mechanical film breakdown theories, as shown in Figure 13.4 [28–30].

In the case of the cluster adsorption model, originally proposed by Heusler and Fischer [31] several years ago for iron, localized adsorption of chlorides leads to an enhanced oxide dissolution at these sites with subsequent thinning of the oxide film until finally a complete removal is achieved and active dissolution starts. During the latter years further refinements of this model were obtained evaluating the measured induction times statistically [32]. Further evidence for the stochastic nature of these initiation processes were also obtained on stainless steels [10]. For the mechanical breakdown of passive films models have been discussed, where the breakdown is either the principal step, giving the environment direct access to the metal surface, as shown by Sato [33], or an additional step combined with other processes as in the case of the defect model as pointed out by Macdonald and co-workers [34, 35]. A critical review of these mechanisms is given in [36].

Most of the theoretical models for pit initiation have not been sufficiently verified experimentally. Since the relationships used to test the different models are very general in nature, such as the correlation between pitting potential and chloride concentration or the quantitative prediction of induction times, they do not really cover specific model-sensitive aspects. Furthermore, the pitting potentials proposed in these models are actually critical pit initiation potentials, which often do not correspond with the experimentally determined pitting potentials, at which the transition to stable pit growth takes place. Pit initiation processes, on the other hand, often occur at much lower potentials, as was recently shown on stainless steels by applying a new microcapillary technique to measure current transients in the picoampere and femtoampere range [10, 37, 38].

Recently, new results on the initiation and formation of porous semiconductors were obtained [39]. In case of *n*- and *p*-type GaAs, local dissolution can be electrochemically triggered in chloride-containing solutions resulting in a porous structure. In contrast to pitting corrosion of passive metals, local dissolution can be achieved not only by the presence of an oxide film (*p*-type GaAs) but also by depletion conditions in the semiconductor space-charge layer (*n*-type GaAs). In the latter case, the presence or absence of an oxide film is not significant for the pitting process. This is of particular significance since the previously discussed theoretical approaches ascribe a key role in the localized nature of pitting to the properties of a surface oxide film.

D2. Structural Parameters

Numerous investigations during recent years have shown that the sites of pit initiation on passive metal surfaces may generally be related to defect structures of the underlying metals. Detailed summaries are given in [1, 2], In case of Ni single crystals, for instance, it has been clearly demonstrated that the emerging points of screw dislocations are especially

susceptible sites for pit nucleation [40]. Furthermore, the shape as well as the pit density depend markedly on the crystallographic orientation of the surface exposed.

Pits in aluminum, titanium, and their alloys are typically associated with intermetallic phases in these alloys. Aluminum contaminated with iron exhibits an increased pitting susceptibility due to the presence of $FeAl_3$ particles that act as local cathodes on the metal surface [41–43]. Recent investigations using microsensors to measure local pH distributions revealed a buildup of hydroxide ions over $FeAl_3$ due to the cathodic reaction on the particle surface. This may lead to alkaline dissolution of the matrix at the particle interface [44]. Preferential attack can also occur on the surface of intermetallic phases, such as on Mg_2Al_3 and MgSi in Al–Mg and Al–Mg–Si alloys [45, 46], In Ti–Al alloys it is assumed that particles of Ti_3Al_2 are effective in initiating pitting corrosion [47].

On the other hand, nonmetallic inclusions may also act as potential nucleation sites [48–50]. Sulfide inclusions in stainless steels are particularly susceptible. Figure 13.5 shows the initial stage of localized corrosion on stainless steel at the site of a MnS inclusion [11]. This is observed not only in austenitic [51–53] but also in ferritic [54, 55] stainless steels. These inclusions are often manganese sulfides or manganese-containing sulfide compounds [53–56]. It has been suggested that, at low manganese levels in steel, CrS is the thermodynamically stable sulfide, while above some level of manganese the stable sulfide is an iron–manganese spinel, which appears to be a better initiation site for pitting than CrS. In a recent survey, Srivastava and Ives [57] summarized the different types of attack on nonmetallic inclusions in stainless steels from a phenomenological point of view.

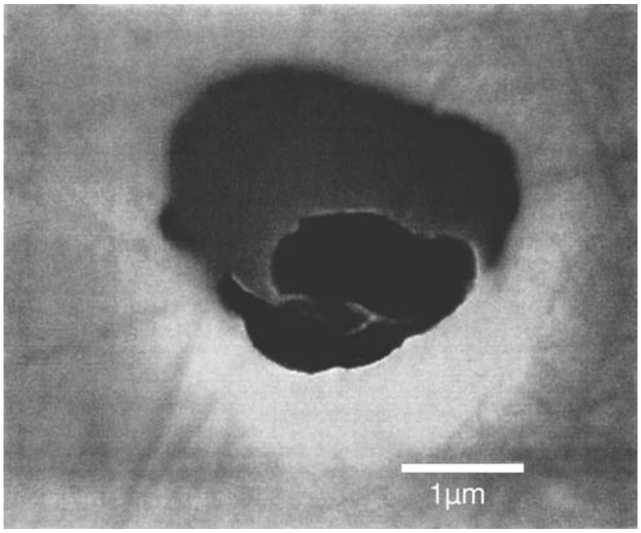

FIGURE 13.5. Pit initiation and early pit growth at MnS inclusion in 304 SS [11].

Powerful electrochemical techniques have been developed for studying localized phenomena on passive metal surfaces, such as the scanning methods, extensively applied and discussed by Isaacs and co-worker [58, 59]. To improve the local resolution substantially, small area measurements are usually carried out, using either the photoresist techniques for masking off small areas or embedded wires with small cross sections (diameter ~50 µm) [60]. Recently, a new microelectrochemical technique applying microcapillaries as electrochemical cells has been developed by Suter and co-workers [10, 11, 37, 38]. Only small surface areas with a few micrometers or even nanometers in diameter are exposed to the electrolyte.

This leads to a strongly enhanced current resolution, down to picoamperes and femtoamperes. Therefore local processes in the micrometer and nanometer range can easily be studied. In the case of stainless steels, the pit initiation process due to the oxidative dissolution of active MnS inclusions as a precursor of pitting corrosion can be investigated directly as shown in Figure 13.6.

Additionally, the results clearly indicate that the dissolution of inclusions takes place even in chloride-free solutions,

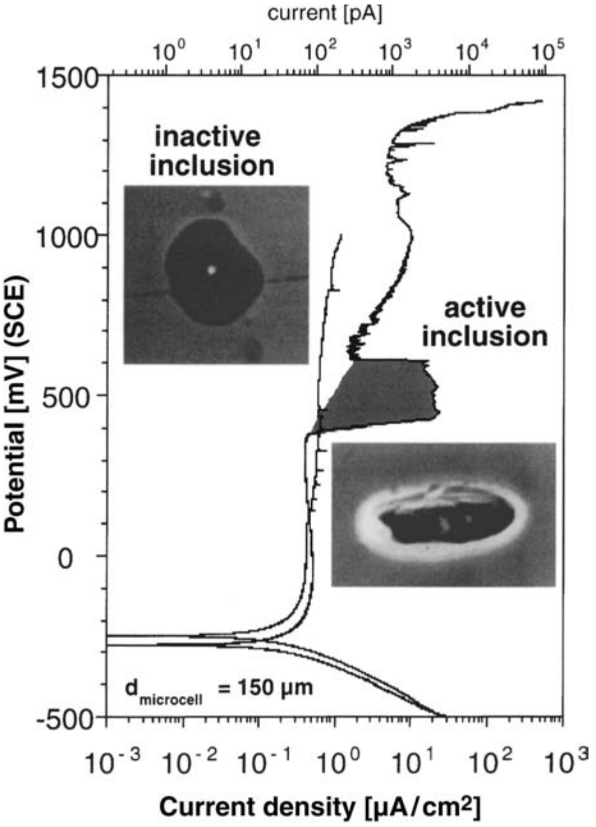

FIGURE 13.6. Local potentiodynamic polarization curves at active and at inactive MnS inclusion site with corresponding scanning electron microscopy (SEM) photographs taken after polarization measurements [38].

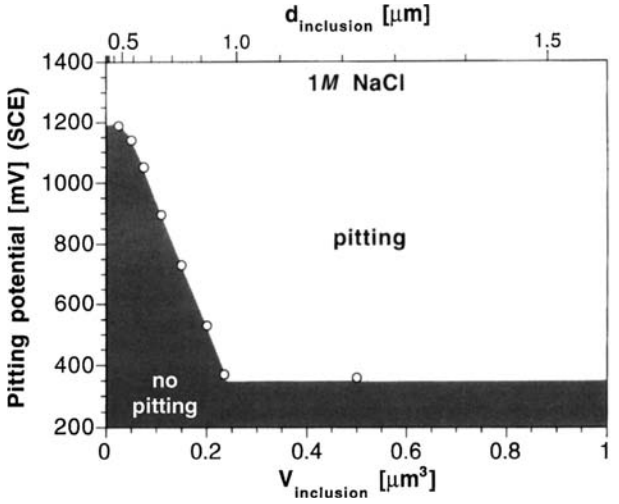

FIGURE 13.7. Correlation between pitting potential and inclusion size [10].

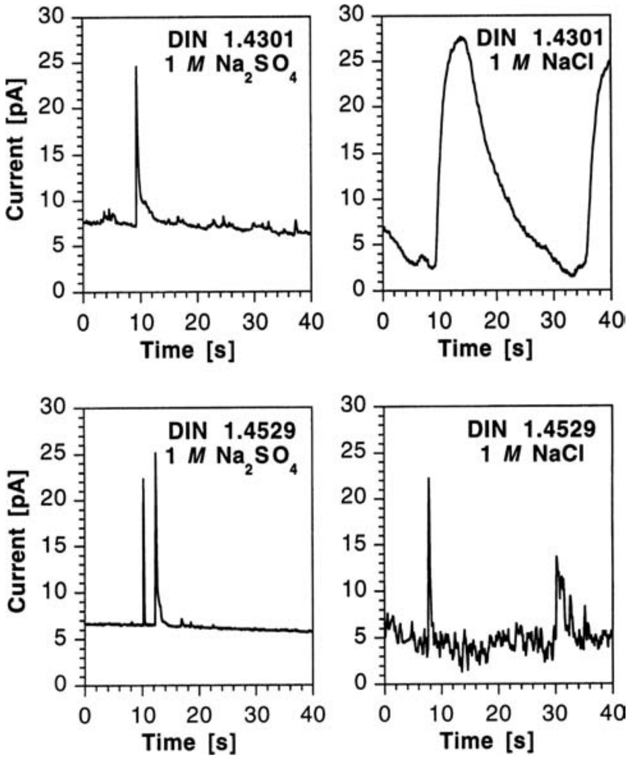

FIGURE 13.8. Microtransients of DIN 1.4301 (0% Mo) and DIN 1.4529 (6.4% Mo) stainless steels in chloride-free and chloride-containing solutions [10].

whereas chlorides are required for metal dissolution and stable pit growth processes.

The results in Figure 13.6 show that the microcapillary technique also makes it possible to distinguish between active and inactive inclusions with respect to pit initiation. An increase of the sulfur content drastically increases the number of large current transients due to an increasing number of large MnS inclusions, verified by microstructural investigations [37, 38]. Similar effects have also been observed on iron in contact with Cl^--containing borate solutions [61].

Noise analysis obtained from microelectrochemical investigations of stainless steels under potentiostatic conditions revealed that the current noise, expressed as standard deviation σ_i of the passive current, increases linearly with the size of the exposed area, whereas the pitting potential decreases. Computer simulations showed [10, 38] that the current noise, largely caused by the dissolution of small inclusions, can be correlated to the size of the inclusions. Therefore the pitting potential is also related to the size of active inclusions [62], as shown in Figure 13.7. Specifically the size of the inclusions in stainless steels has to be kept below $\sim 1\ \mu m$ to improve substantially the pitting resistance of stainless steel. This effect was already observed much earlier by simple immersion tests [63].

The effect of molybdenum on the pitting behavior of stainless steels can also be studied by microelectrochemical techniques and then compared to molybdenum free alloys having approximately the same impurity level, as shown in Figure 13.8 [10]. Molybdenum in superaustenitic stainless steels has only a minor effect on the initiation process. The superior corrosion resistance of these high-molybdenum-containing alloys rather has to be attributed to a considerably improved repassivation behavior.

D3. Stability of Passive Films

The stability of passive films plays an important role with respect to the pitting behavior of passive alloys. Fast and effective repassivation of locally activated metal surfaces only occurs if a stable passive film is formed. Since pit initiation can hardly be neglected on commercial alloys in real environments, rapid repassivation in which a passive film of high stability is formed, is very important to obtain highly corrosion-resistant alloys. In order to understand the importance of the chemical and electrochemical stability of passive films with respect to localized corrosion, the behavior of naturally grown as well as synthetically prepared thin oxide films has to be studied [64, 65]. In several contributions Schmuki and co-workers [66, 67] showed that the semiconductive properties and the chemical stability of the thin oxide films of iron and chromium correlate quite well with those of naturally grown films. The results indicate that the presence of Fe(II), acting as doping species in iron oxide, strongly effects its stability. The good correlation between the semiconductive properties and the stability of passive films was

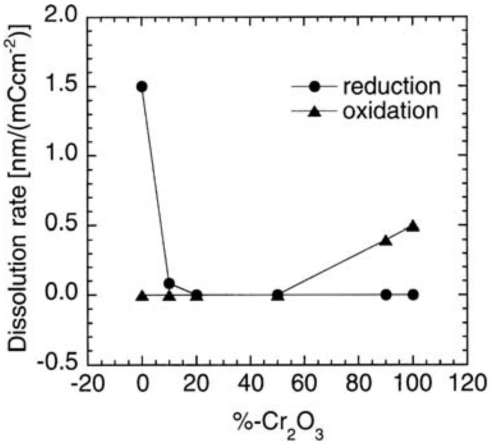

FIGURE 13.9 Dissolution rate of sputter-deposited Fe/Cr oxide films as function of Cr_2O_3 content during galvanostatic reduction and oxidation in borate buffer, pH 8.4. Dissolution rates determined from the drop of the edge height of XANES spectra during the experiment. (Reproduced by permission of The Electrochemical Society, Inc. [70]).

additionally confirmed, using in situ X-ray absorption near-edge spectroscopy (XANES) techniques [68, 69]. The experiments showed that the mixed oxides are far more stable than the pure oxides as shown in Figure 13.9.

The presence of sufficient amounts of chromium oxide protects iron oxide against reductive dissolution, whereas iron oxide protects chromium oxide from oxidative dissolution. During anodic polarization of iron oxide films in acidic solutions, a deleterious effect of chloride anions compared with sulfates was found. In HCl solutions of increasing concentration, not only the increased acidity but also the increased chloride concentration accelerates the dissolution markedly [70].

E. PIT GROWTH

When the active state within pits and crevices is maintained over an extended period of time, rapid metal dissolution usually occurs. The resulting pit and crevice geometries as well as the surface state within the pits vary markedly from open and polished hemispherical pits on free surfaces to etched crack-like shapes within crevices, depending largely on the type of rate-controlling reactions during the growth stage.

The kinetics of pit growth is not only of scientific interest but is also of great engineering importance for commercial corrosion-resistant materials, since the possibility of local breakdown should not be ignored under practical conditions. Sufficient knowledge of the mechanisms of growth and stability is therefore a necessary requirement in order to predict the corrosion behavior of passive metals correctly as well as for developing new corrosion-resistant materials.

E1. Growth Kinetics

Although pit growth is experimentally much easier to study and quantify than pit nucleation, substantive information on pit growth mechanisms was mainly obtained during the last two decades. In earlier research on aluminum [71–79], iron [80], and stainless steels [81, 82] under open-circuit conditions, studies were limited to the description of growth rate by a simple power law $d_p = at^b$, whereby d_p is the pit depth, t is time, and a and b are constants, with the latter averaging in many cases ~0.5. Values of $b < 1$ clearly indicate a decreasing growth rate with time as shown, for example, on aluminum in various tap waters [79]. A comprehensive literature survey, summarizing the rate laws of various metals and alloys is given in [83]. Numerous investigations have confirmed that the presence of chlorides is necessary for pit growth and that the growth rate increases with increasing chloride concentration [84–90]; other anions, however, behave differently.

To overcome the problems associated with accurate pit current density measurements, special techniques have been developed to determine pit growth kinetics. Hunkeler and coworkers [83, 91, 92] used the time for pits to penetrate metal foils of different thickness to determine the growth rate of the fastest growing pits. Using this simple method pit growth rates in aluminum as well as stainless steels were measured and several parameters, such as the potential, the composition of the electrolyte, and the temperature, were varied. Another elegant approach to study the growth kinetics involved the investigations of two-dimensional pits in thin metal films as demonstrated by Frankel et at. [93–96]. The measurements of lateral pit growth rates from analysis of images of the growing two-dimensional pits provides a very simple and direct way via Faraday's law, with no need for any further assumptions. Investigations were carried out on different materials such as nickel and aluminum alloys. The study of single pits, formed in different ways have also been performed either by masking off a small area, implanting an activating species at a small spot, or using single-pit electrodes, such as embedded wires [60, 97–99].

E1.1. Diffusion Control. Several detailed studies on the kinetics of growing pits, performed in the 1970s, recognized the presence as well as the importance of salt layers during pit growth [100–104]. In Figure 13.10, the pit and crevice growth of 304 SS in a chloride-containing solution as a function of the potential, using the foil technique as mentioned above, is shown [105, 106]. At high potentials, where pits grow on open surfaces as well as crevices, a potential independent growth rate is observed, suggesting diffusion-controlled growth mechanism.

When lower potentials are applied, the mode of localized corrosion changes to etch-type crevice corrosion with a strong potential dependence. Below a critical growth rate,

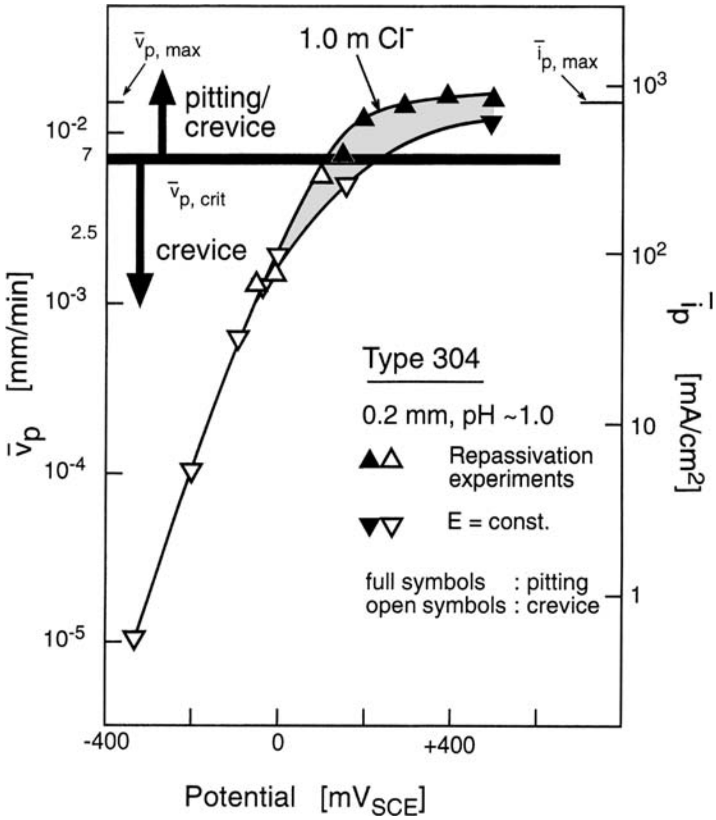

FIGURE 13.10. Mean pit and crevice growth rate $\bar{v}_p$ vs. potential of type 304 SS [105, 106, 112]. (Reproduced with permission from *Advances in Localized Corrosion*, p. 70, Copyright © NACE International. All rights reserved.)

depending on the chloride concentration, etch-type crevice corrosion is the only stable form of localized corrosion, since saturation conditions and salt film formation are not attained. Concerning the practical significance of diffusion-controlled pit growth, it must be pointed out that this type of pit growth is not often observed on stainless steels since it usually requires high potentials and/or high chloride concentration.

In the case of unidirectional, single-pit growth using wire electrodes, the diffusion-controlled pit growth can easily be calculated using Fick's first law. Excellent experimental proof was obtained on stainless steel and nickel, for which a parabolic rate law was observed [107]. Additionally, it was found that if the bulk electrolyte contains the corresponding diffusing metal ion in solution, the pit growth is much faster in less concentrated solutions, as expected from theoretical considerations [108].

E1.2. Ohmic/Charge Transfer Control. As pointed out by Beck [109], pitting on titanium and aluminum occurs at high ohmic limited current densities. Generation of large amounts of hydrogen bubbles within the pit strongly increases the mass transport rate. Therefore the fluid flow of the bulk electrolyte has little effect on pit growth under such conditions [110]. Further and more detailed support for ohmic-controlled pit growth on aluminum was obtained by Hunkeler [83]. For small Tafel constants, as in the case of aluminum, and sufficiently large pits ($>10\,\mu m$), contributions from charge transfer as well as ohmic transport outside the pit may be neglected, and a simple parabolic rate law [92] can be derived in which the preexponential factor depends directly on the electrolytic conductivity of the bulk electrolyte. Due to the generation of hydrogen bubbles during pitting of aluminum, no significant change in the composition of the electrolyte within the pit takes place, in contrast to situations in which diffusion processes control pit growth. These findings are in excellent agreement with the evaluation of long-term pit growth measurement under open-circuit conditions on aluminum in tap water of known conductivity, as shown in Figure 13.11 [111, 112]. The experimental values fit very nicely into the parabolic rate law. The resulting potential difference of $\sim 15\,mV$ is in good agreement with the open-circuit conditions in the absence of strong oxidants.

For materials such as stainless steels or nickel, the charge transfer reaction cannot be neglected, as shown in Figure 13.10. A semilogarithmic relationship between current density and potential is observed at low potentials, indicating that mixed ohmic/charge transfer control is probably effective. Similar results obtained by Newman [6] using

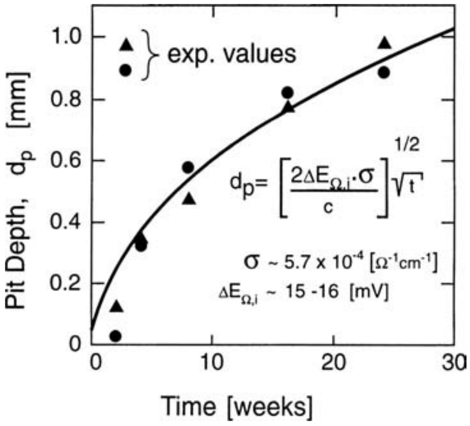

FIGURE 13.11. Pit growth on aluminum in tap water at open-circuit conditions [111]. (Reproduced with permission. Copyright © NACE International. All rights reserved.)

artificial pit electrodes showed that molybdenum in stainless steels ennobles the anodic dissolution reaction in the pit environment.

F. STABILITY OF LOCALIZED CORROSION

The concepts of stability of pitting and crevice corrosion are based mainly on either compositional changes of the electrolyte within the pit, salt film formation, or sufficiently large ohmic potential drops within pits. Various authors have suggested that critical concentrations of ionic species must be exceeded for stable pit growth to occur. Galvele [113–115] considered localized acidification as the main reason for stable pit growth. Sato [116, 117] pointed out that two models of metal dissolution have to be distinguished: (1) active or etching dissolution, which occurs at lower potentials, and (2) transpassive or brightening dissolution, which occurs at relatively noble potentials. For etch pitting, a critical hydrogen ion concentration should be reached, whereas for brightening pits, the necessity of a critical concentration of aggressive anions, such as chlorides, was proposed. On the other hand Vetter and Strehblow [118, 119] concluded from theoretical considerations that during the early stage of growth of an open hemispherical pit, the metal chloride concentration within the pit increases, but not sufficiently for precipitation to occur, which they considered as a possible requirement for the stability of pits. Instead, they proposed that an ion-conducting salt layer on the metal surface results from adsorption of aggressive anions, such as chlorides.

The significance of an ohmic potential drop within pits was also questioned by the same authors [118, 119]. For iron, they estimated potential drops of $\sim$18 mV, which again cannot in any case explain the stability of growing pits. However, several groups at about this time also measured large potential variations within crevices and pits [120–124], Pickering and Frankenthal [121–123] explained the large potential drops by the presence of high resistance paths caused by gas bubbles inside the pits. More recently, Pickering and co-workers [125, 126] showed that the ohmic (IR) drop, rather than a composition variation, was responsible for stabilizing crevice corrosion in some systems which exhibit active/passive transitions in the bulk solution. Most of these experiments were performed on iron or nickel in sulfuric acid, where the metal at open-circuit conditions is in the active state. Therefore, these results may not be sufficiently general to apply to localized corrosion processes of originally passive metal surfaces, where an activation process has to occur first and the active state has to be stabilized even without an active–passive transition under bulk conditions.

The effect of salt films formed within the pit during the initiation or growth process has been discussed frequently [84, 118, 119]. Beck and Alkire [103] and Beck and Chan [127] demonstrated convincingly that the formation of salt films on stainless steels may be important for the stability of growing pits. In using a flow cell, it was shown that with increasing flow velocity the dissolution current increases at first, before at the highest velocity the current drops drastically due to the removal of the salt film and the subsequent repassivation of the surface. Further support for the importance of salt film formation was also obtained from evaluation of metastable pitting on stainless steels [128]. Transition from metastable to stable pit growth occurs only when salt-film precipitation takes place.

Additional results showing the significance of a salt film were obtained from electrochemical impedance spectroscopy. The investigation of the anodic dissolution of artificial pit electrodes indicated that, in the case of stainless steel and nickel, significant ohmic potential drops are present within the salt film during diffusion controlled pit growth. The thin, conducting salt film stabilizes the active metal surface at the pit bottom and prevents the repassivation process [108]. Furthermore, a critical potential for salt-film formation E_{sf} can be determined, below which no salt film can form. The critical potential for salt-film formation amounts to $-0.19\,V_{sce}$ and $-0.08\,V_{sce}$ for 302 stainless steel and nickel, respectively, and does not depend significantly on the bulk concentration. For 304 SS, the lowest potential, E_{pi}, where pit initiation occurs and current transients (metastable pitting) have been found by microelectrochemical measurements [11] coincides with the critical potential for salt-film formation, E_{sf}, as well as with the photoelectrochemically determined flatband potential E_{fb} [129], below which no chloride adsorption takes place. Further investigations are necessary to clarify whether these values coincide accidentally or a possible correlation exists.

The above discussion of pitting corrosion leads to the following concept of localized corrosion. At potentials even below the pitting potential but above E_{pi} a nonzero

probability of pit initiation exists, depending largely on the type, size, amount, and chemical properties of these local heterogeneities. Once a pit begins to grow in the presence of aggressive anions, such as chlorides a thin salt film may be formed after a transition time. As long as the salt film is present, stable dissolution occurs, and the growth rate is diffusion controlled. If the potential is then lowered, pits may continue to grow if the composition of the pit electrolyte, the current density, and the potential at the pit bottom are such that repassivation is not possible. The growth process in this case is then mixed ohmic/charge transfer controlled [98, 105, 107]. Under these conditions, the ohmic potential drop inside and outside of the pit may play an important role.

G. SUMMARY

Localized corrosion is an important but complex problem responsible for many corrosion failures in engineering applications. The local breakdown of passivity of commercially available engineering materials, such as stainless steels, nickel, or aluminum, occurs preferentially at sites of local heterogeneities, such as inclusions, second-phase precipitates, or even dislocations. The size, shape, distribution, as well as the chemical or electrochemical dissolution behavior (active or inactive) of these heterogeneities in a given environment, determine to a large extent whether pit initiation is followed either by repassivation (metastable pitting) or stable pit growth, Microelectrochemical techniques, combined with statistical evaluation of the experimental results allow to gain more insight into the mechanisms of these processes.

In addition to the local activation or pit initiation process, the stability of the passive film is decisive for the corrosion resistance of passive metals and alloys. Fast and effective repassivation, necessary for highly corrosion-resistant alloys, may only occur if highly stable films are formed during repassivation. Therefore, further investigations should be focused not only on the initiation of localized corrosion, but also on the stability of passive films. The stability of passive films is often reflected by the semiconductive properties of these films. Therefore electrochemical impedance spectroscopy, photoelectrochemical methods as well as in situ analytical techniques are very valuable tools to study the chemical and electrochemical behavior of these passivating oxide films.

A. INTRODUCTION

Metals and alloys subjected to tensile stresses and exposed to certain environmental conditions may develop cracks that would not occur in the absence of either of those controlling parameters. Not all environments that are corrosive to a particular metal promote stress corrosion cracking (SCC), but even some apparently innocuous substances, such as water, may induce cracking in some materials [1], the composition and structure of which can play a critical role in the incidence or otherwise of SCC. The manifestation of the cracks may create the impression of brittleness in the metal because the cracks often propagate with little attendant deformation, although almost invariably the properties of the metal conform to ductility specifications.

The incidence of SCC appears to have increased over the last few decades, possibly because as the problem of general corrosion has been overcome, by control of environmental factors and the use of inherently more corrosion-resistant materials, the probability of more localized forms of corrosion has increased. Those trends have been accompanied by moves toward higher operating stresses, deriving from the more efficient use of materials, and the more extensive use of welding as a method of fabrication. The result gives rise to residual stresses, as do other methods of fabrication involving inhomogeneous deformation, and unless such stresses are relieved, they can promote SCC, the incidence of which is probably greater from the presence of residual than from operating stresses alone. An example of SCC resulting from residual welding stresses is shown in Figure 14.1. Here liquor seeping from the cracks reveals the positions of the latter, which are associated with a longitudinal weld where the principal tensile residual stresses would be parallel to the weld and of the order of the yield stress in this nonstress relieved structure [2]. The low rate of growth of those cracks, the facts that they are visible, and because the operating pressure is relatively low, would allow appropriate action to be taken. But invariably that is not the case since the cracks may grow undetected. This was the case in the failure shown in Figure 14.2, which is from a buried high-pressure gas pipeline that failed in service and where the main fracture is apparent from the separation of the fracture surfaces toward the top of the photograph. But secondary cracks, emanating from the soil side, are also apparent [3]. These cracks are not associated with a weld and the operating stresses undoubtedly played a major role in the failure. Both Figures 14.1 and 14.2 show the presence of multiple cracks, which would be seen to be even more prevalent if examined at higher magnifications. Multiple cracking frequently also accompanies SCC failures.

Stress corrosion cracking may be associated with intergranular or transgranular paths through the metal and, in some cases, with a mixture of those modes. Examination of metallographic sections from the steels involved with Figures 14.1

FIGURE 14.2. Secondary SCC on outer surface of high-pressure gas transmission pipeline near origin of SCC failure [3].

and 14.2 revealed intergranular cracks, with a typical example in Figure 14.3. An example of an essentially transgranular crack, in a different pipeline steel from that involved with Figure 14.3 and exposed to a different environment [4], is shown in Figure 14.4. Figure 14.5 shows an example of mixed-mode cracking in an arsenical α brass exposed to water containing a small amount of sulfur dioxide [5]. In the same system, cracks may initiate in the intergranular mode, then change to transgranular as the stress concentration increases with increasing crack depth, and even revert to intergranular if the crack bifurcates and reduces the stress concentration. Since the most common mode of failure of metals is transgranular (e.g., by overload or fatigue), but not high-temperature creep, intergranular SCC is sometimes regarded as unusual and has often been associated with the collection of segregates or precipitates at grain boundaries. That is undoubtedly so in some cases, of which the propensity for intergranular SCC in sensitized austenitic stainless steels, due to the precipitation of chromium carbides in boundaries and the impoverishment of the surrounding material in chromium is probably the best-known instance [6]. However, as the examples quoted above involving pipeline steels indicate, a change in environment may result in a change of crack path, while the examples involving brass indicate that a change in the stressing conditions may also result in a change in cracking mode. Thus, while electrochemical heterogeneity due to segregates or precipitates at grain boundaries may play a role in some instances of intergranular SCC, the incidence of the latter or otherwise is dependent on the environmental and stressing conditions.

The interactions between environmental and stressing conditions upon the paths of cracks indicate the possible problems in deducing some mechanistic hypothesis for SCC based upon limited studies of a particular system. Mechanisms of SCC have been, and continue to be, widely discussed. Most suggested mechanisms invoke either a process of localized embrittlement of the metal in the vicinity of the crack tip or of localized dissolution in that region [7]. There are variations on both of these themes, so that, for example, while hydrogen ingress may result in the embrittlement of some metals, and the mechanism of such embrittlement is a matter of debate, the formation of films with certain properties may induce cleavage which, once initiated, continues to advance into the underlying metal before arresting. Such film-induced cleavage may involve dealloyed layers in some alloys, but those layers may play the same role as oxide films, in preventing lateral dissolution on the crack sides and concentrating dissolution in the crack tip region, when bare metal is exposed by straining in the adjacent metal. Such strains may be associated with transgranular cracking where bare metal slip steps emerge through films in the crack tip region, or they may induce intergranular cracking, especially if electrochemical heterogeneity causes preferential dissolution at the grain boundaries. It is possible that with some environments, both dissolution and hydrogen ingress may facilitate crack growth. It is not surprising that mechanistic aspects of SCC are the subject of almost annual conferences, but for our present purposes the emphasis is on assisting the practicing engineer predict those combinations of metal and environment that promote SCC and how they may be

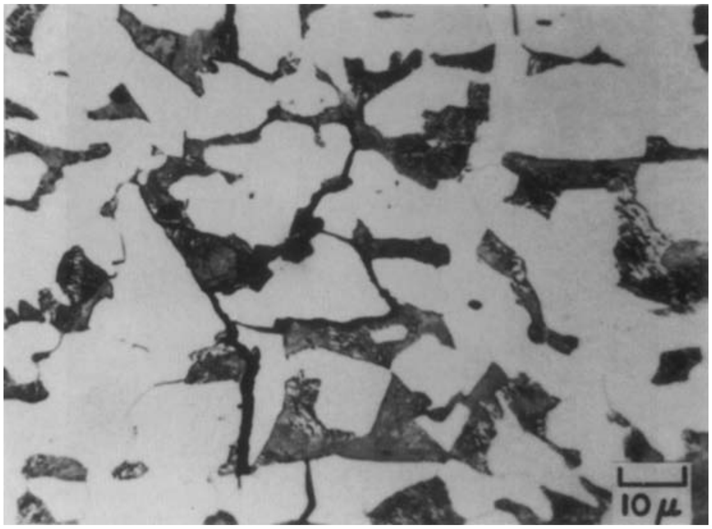

FIGURE 14.3. Intergranular cracks in pipeline steel [3].

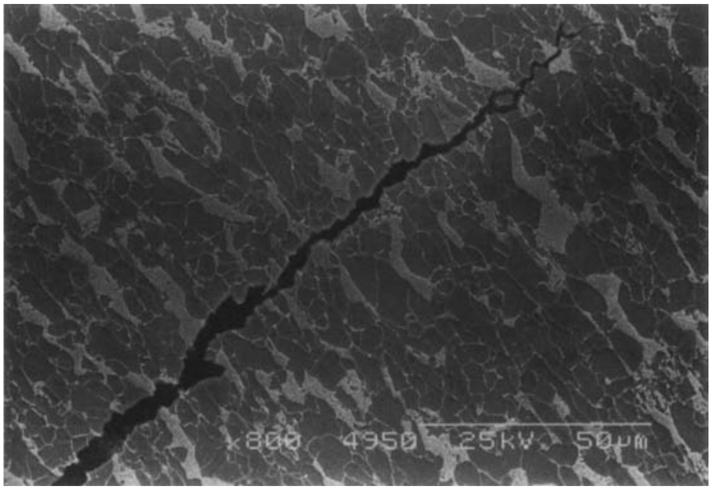

FIGURE 14.4. Transgranular cracking in different pipeline steel from that of Figure 14.3 produced by different environment [4].

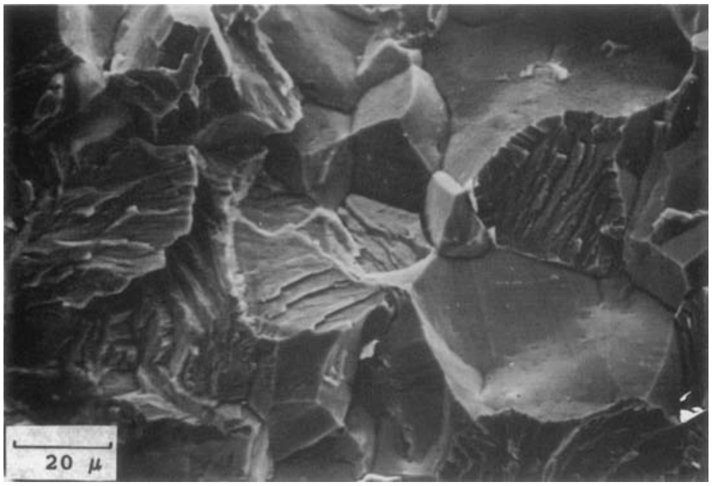

FIGURE 14.5. Mixed-mode SCC in α brass exposed to $H_2O + SO_2$ [5].

controlled or avoided in particular engineering structures. Complete mechanistic understanding of SCC would assist in achieving such goals, but in the absence of such understanding it is still possible to make some advances in relation to practical control.

B. ENVIRONMENTAL CONDITIONS FOR SCC

Until about four decades ago, it was thought that SCC occurred only in particular alloys exposed to a few very specific environments (e.g., ferritic steels exposed to hydroxides or nitrates, brasses exposed to ammoniacal environments, and austenitic stainless steels or aluminum alloys to chlorides). While the concept of solution specificity remains, since not all environments corrosive toward a particular alloy promote SCC, the number of environments that will promote that mode of failure has increased considerably in recent times. It is impossible to list here all of the environments that have been shown to promote SCC in the commonly used alloys, but, in terms of predicting whether or not a particular metal–environment combination is likely to suffer SCC, certain circumstances need to obtain. Where crack growth is by a localized dissolution process, potent solutions will need to promote a critical balance between activity and passivity since a highly active condition will result in general corrosion, while a completely passive condition cannot lead to SCC. For most engineering alloys, inactivity at exposed surfaces is due to the presence of adherent oxide films on those surfaces. Then, it is not surprising that the alloys of high inherent corrosion resistance (e.g., austenitic stainless steels that readily develop protective films) require an aggressive ion, such as a halide, to promote SCC. Alternatively, metals of low inherent corrosion resistance (e.g., C steels) require the presence of an environment that is itself partially passivating for SCC. Such steels can fail in solutions of anodic inhibitors (e.g., nitrates, hydroxides, carbonates, or phosphates).

The SCC is influenced not only by the presence of particular ions and their concentration but also by the electrode potential, so that cracking occurs only within certain potential ranges for particular metal–environment combinations. Figure 14.6 shows the cracking domains for ferritic steels exposed to various environments (also involving different temperatures, another parameter that can influence SCC), and pH and potential dependent cracking domains have been shown to exist for other alloys. The boundaries of such domains would be expected to relate to particular reactions involving film formation. For each of the systems shown in Figure 14.6, the upper boundaries correspond to the formation of Fe_2O_3, with ductile failure in slow strain rate tests at potentials above the cracking domain. There are two exceptions in that at potentials high enough to form Fe_2O_3, nitrates and high-temperature water promote cracking from within pits. The initiation of cracks from pits has been

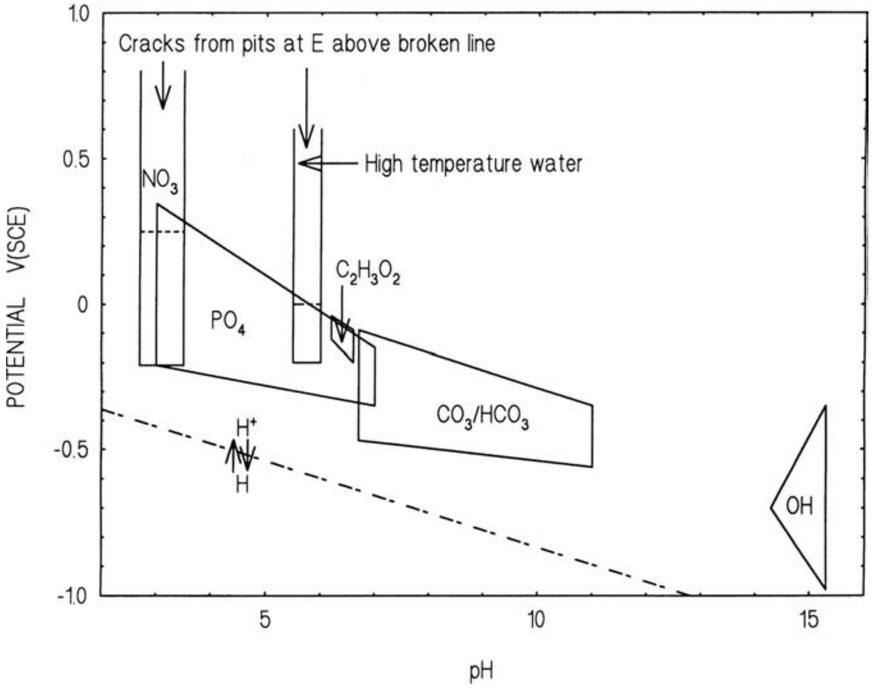

FIGURE 14.6. SCC potential–pH domains for ferritic steels in various environments, the latter at a variety of temperatures, together with equilibrium potentials for discharge of hydrogen at 25°C.

observed in many systems and while that has sometimes been related to stress intensification at the base of pits, it is probably at least as likely to relate to changes in the composition of the solution and potential within the pits. With some bulk solutions, lowering of the pH and potential will occur in pits, so that the SCC domain for the bulk solution may be irrelevant and indeed the mechanism of cracking may change. Thus, Figure 14.6 shows that the cracking domains are above the equilibrium potentials for hydrogen discharge from the solutions of various pH values, but even the buffered solutions (OH, CO_3/HCO_3, $C_2H_3O_2$, and PO_4), which do not cause pitting at the concentrations involved with Figure 14.6, can promote hydrogen-related cracking if the potential is reduced sufficiently for hydrogen discharge. However, where acidification of the localized environment within a pit occurs, hydrogen discharge is likely to be facilitated.

While it is possible to predict cracking domains from thermodynamic data for some of the systems to which Figure 14.6 refers, there are difficulties with such predictions when the bulk environment is changed within a pit or crack enclave. Moreover, even successful predictions have followed from experimental determination of the cracking domain boundaries and, at present, there is no theoretical approach to determining whether or not a particular metal–environment combination, for which there is no prior experience, will promote SCC. However, there are some relatively rapid experimental approaches to determining the potency of systems for SCC, where the bulk environment is itself the potent solution. The latter may derive from the bulk solution, which itself may be incapable of promoting SCC, by concentration in a crevice or at a heat transfer surface. In these circumstances predictability may be more difficult, unless the possibility of such concentration is recognized. The instances of SCC in pipelines mentioned in the context of Figures 14.2–14.4 illustrate the point. The transgranular cracking (Fig 14.4) is due to the presence of a dilute groundwater containing CO_2 (pH $\approx$ 6.5), while the intergranular cracking (Figs. 14.2 and 14.3) is due to the generation of a relatively concentrated carbonate–bicarbonate solution derived from groundwater but concentrated due to the flow of cathodic current at the pipe surface and ion transport, as well as heat transfer in the crevice between the pipe and a disbonded coating. Where crack advance is by dissolution, the crack tip must be active, but as the crack advances the crack sides must become relatively inactive, otherwise the sides will extend laterally and the geometry will be changed to that of a pit. Figure 14.4 shows evidence of corrosion on the crack sides increasing in moving away from the tip, so that the amount of activity acceptable on the crack sides will depend on the rate of crack growth. Transitions from electrochemically active to relatively inactive behavior may be expected to be reflected in the current response of the bare metal exposed to the appropriate environment. Thus, dissolution will be associated with the passage of relatively high anodic current densities, but with the passage of time this current will decay if filming occurs. Very rapid rates of decay are not likely to permit much dissolution and so are not likely to be indicative of conditions conducive to SCC. Very slow rates of decay are more likely to be indicative of insufficient development of inactivity to retain crack geometry. There are various techniques for measuring these features, including scratching or rapidly straining electrodes previously filmed at particular potentials. A convenient way of anticipating the range of potentials in which SCC may occur is through potentiodynamic polarization curves determined at different sweep rates [8]. If the potential of an initially film-free surface is rapidly changed ($\approx$ 1 V/min) over an appropriate range, then the currents passed at the surface will indicate ranges of potential in which relatively high anodic activity is likely. The rapid sweep of the potential range has the object of minimizing film formation. If the experiment is repeated at a slow rate ($\approx$ 10 mV/min) of potential change allowing filming, comparison of the two curves will indicate ranges of potential within which high anodic activity in the film-free condition reduces to insignificant activity at the slow sweep rate, thereby identifying the range of potentials in which SCC is likely. The method correctly anticipates SCC of ferritic steels in a number of very different environments, but is only applicable where air-formed oxide films can be reduced. Thus for metals with very stable films one resorts to scraping or rapid straining as a means of creating bare metal. For systems where cracks may be initiated from pits, measurement of the pitting potential can give an indication of the minimum potential for cracking, while for systems where hydrogen-induced cracking is possible calculation of the equilibrium potential for hydrogen discharge, from the pH of the solution, will give an indication of the highest potential for such cracking. However, in the application of any of these approaches to estimating potentials for cracking it is well to remember that the surfaces in plant may differ appreciably in terms of potentials from those measured in the laboratory, the latter usually on carefully polished surfaces, in the same environment. Consequently, a laboratory SCC test at open circuit potential may not give an adequate indication of the propensity for cracking in a particular system. A few additional tests at controlled potentials, defined by some appropriate electrochemical measurements, are therefore necessary. This is especially so if cracking does not occur at open circuit.

In relation to the stressing of specimens for assessing the propensity for SCC in any system, slow strain rate tests (SSRTs) offer a rapid method of arriving at a result [9, 10]. These, which may be conducted on initially plain or precracked specimens, are simply tensile tests conducted at relatively slow strain rates, typically of the order of $\sim 10^{-6}$/s for steels and Cu or Ni alloys, and 10^{-5}/s for Ti or Mg alloys. Failure will usually occur in 1 or 2 days and various parameters may be employed for quantifying the results, particularly those related to ductility, although

fractographic or metallographic examination of the failed samples should be conducted. Obviously, the stressing and/or straining conditions in SSRTs are beyond those likely to be experienced in service. Strain rate effects in the latter are considered later, but where the objective of the laboratory test is to give a "go–no go" result quickly, then SSRTs are particularly useful.

C. ROLE OF STRESS IN SCC

It is usual to consider the role of stress, or the stress intensity factor in the case of precracked specimens, in terms of its influence upon the time to failure in a given system. Figure 14.7 shows some typical results [11], which indicates that there is a stress, often referred to as the threshold stress, below which failure does not occur in an extended test time. The threshold stress is not only a function of alloy composition and structure, but also of the environmental conditions, including solution composition, potential, and temperature, so that it is not a unique property of a material in the sense of a yield or tensile strength. Moreover, while the threshold stress is sometimes defined as the stress below which cracking does not occur, this is not necessarily so and it is better defined as the stress above which total failure occurs, since for some systems cracks have been shown to initiate below die threshold but to cease to propagate after some growth. It is difficult to explain why cracks should cease to propagate on any stress-based argument, since stress concentration or intensification would be expected to increase with crack growth under constant load. A feasible explanation is that it is not stress per se but the strain rate it engenders that is the controlling factor, and that cracks cease to propagate when the crack tip strain rate falls below some critical value related to the rate of film growth. Such an explanation is consistent with the influence of the relative times at which the stress and the environmental conditions for cracking are established, creep at constant load prior to the establishment of the environmental conditions delaying or preventing cracking in laboratory tests. Obviously, it is also consistent with the demonstration of the influence of applied strain rate upon cracking for a wide variety of combinations of metal and environment, for some of which it has been shown that sufficiently slow rates of straining can result in ductile failure without impairment of the tensile strength of the alloy despite its exposure to a potent cracking environment.

There is another important consequence of the significance of strain rate in facilitating crack growth and it relates to cyclic, as opposed to static, loading. Hysteresis effects are well known to accompany cyclic loading and the cyclic stress–strain curves of materials often fall appreciably below their monotonic loading counterparts, reflecting the fact that cyclic loading facilitates microplastic deformation [12]. It follows from such observations that load cycling may produce SCC at significantly lower stresses than those needed with static loading. Figure 14.8 shows this to be so for a pipeline steel exposed to a carbonate–bicarbonate solution by comparison of the data for static and cyclic loading conditions [13]. In the absence of cyclic loading ($\Delta K = 0$), the threshold stress intensity factor, $K_{I_{scc}}$, is $\sim 21\ MN/m^{3/2}$, and cyclic loading at the frequency of 11 Hz did not alter that

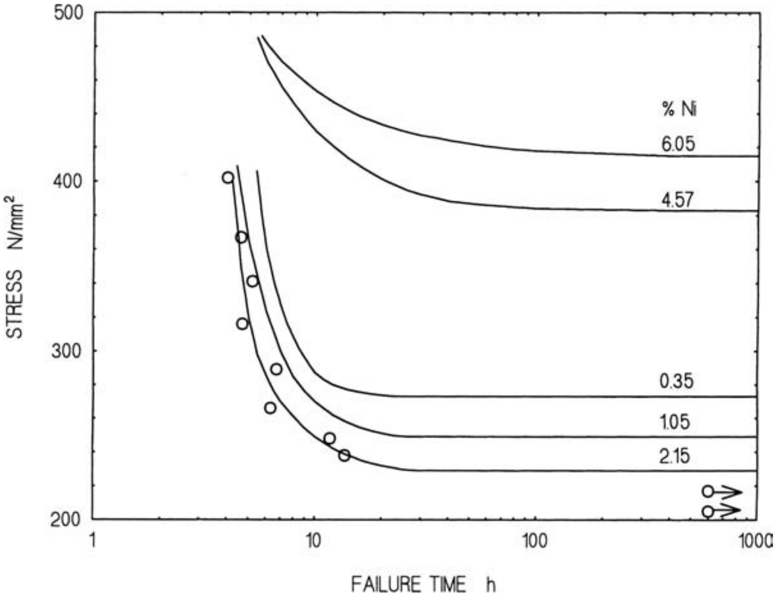

FIGURE 14.7. Initial stress–time to failure curves for ferritic steels with different Ni contents in boiling 4N NH_4NO_3. Data points for only one steel are shown but those give an indication of the scatter for each steel [11].

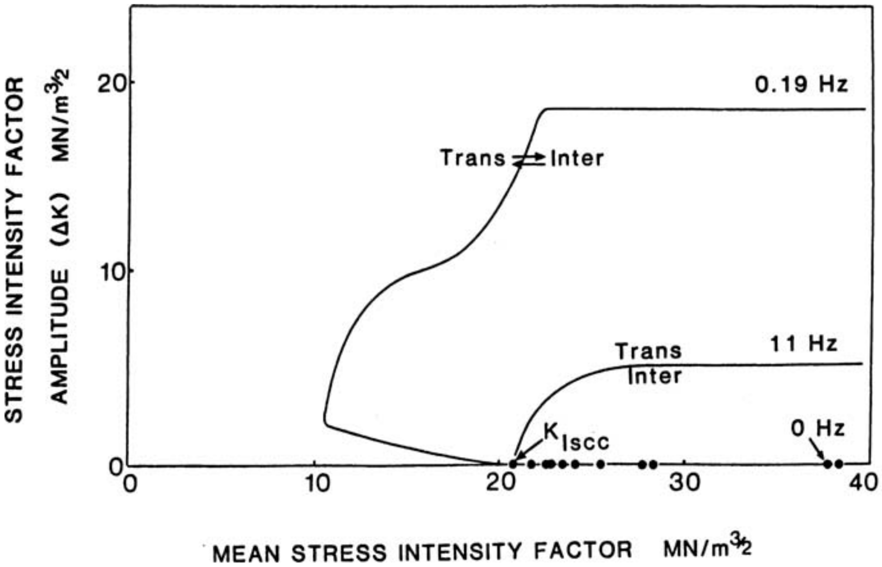

FIGURE 14.8. Modified Goodman diagram indicating loading parameters for which intergranular or transgranular cracking were observed in pipeline steel exposed to carbonate–bicarbonate solution at 75°C and -0.65 *V*(SCE) [13].

threshold, although intergranular cracking extended to ΔK values of ~ 5 MN/m$^{3/2}$ before a transition to transgranular cracking. With reduction of the frequency of load cycling to 0.19 Hz, not only is the purely intergranular cracking observed at higher ΔK values, but the threshold mean stress intensity factor is reduced to ~ 10 MN/m$^{3/2}$ at small values of ΔK. Similar large reductions in threshold stresses have been observed with initially plain specimens when subjected to cyclic loading at low frequencies and stress amplitudes of $\sim 20\%$ of the mean stress.

Of course, it may be argued that with cyclic loading what is being studied is corrosion fatigue, but fractographically the cyclically loaded specimens are indistinguishable from statically loaded samples, providing that the ΔK values are maintained below those levels that promote transgranular cracking. Indeed it may be argued that the latter mode of cracking is more typical of what may be expected in corrosion fatigue in such a system. The distinction here then is not between static and cyclic loading, or SCC and corrosion fatigue, but rather between relatively small stress amplitudes at low frequencies, sometimes referred to as ripple loading, and the much higher stress amplitudes usually involved with fatigue. Such distinctions are inevitably rather arbitrary, but there is another point to be remembered in this context, which relates to environmental influences. The environments that will promote corrosion fatigue in, say, ferritic steels are much more extensive than those that will promote SCC. A possible reason is that, as already mentioned, for SCC the environment needs to have characteristics that assist in the retention of crack geometry by filming of crack sides, but with large amplitude stresses mechanical crack sharpening occurs, so that there are less stringent requirements for the properties of the environment.

D. PREVENTION AND CONTROL OF SCC

Since the incidence of SCC requires a susceptible alloy to be exposed to a specific environment at stresses above some limiting value, it follows that control of the problem may be through manipulation of any or all of these three parameters. Ideally, approaches to prevention should begin with the selection of a resistant alloy, which is the most usual approach, followed by consideration of possible modification of the stress or environment, with variations within these three themes as outlined in Figure 14.9 [14]. However, it sometimes happens that SCC occurs in an existing plant when such had not been anticipated at the design stage or, indeed, that a susceptible material had to be used because of other considerations, in which cases the approaches to prevention are restricted. Whatever approach is pursued, it is likely to depend on experience or laboratory test data, and it is important to realize that alloy susceptibility is not simply a function of alloy composition or structure but also of the environmental conditions. Thus, Figure 14.7 shows the beneficial effects of sufficient Ni additions to a ferritic steel upon resistance to cracking, as measured by the threshold stress, in a nitrate environment. However, if the same steels are exposed to a boiling $MgCl_2$ solution, then the Ni additions have the effect of increasing cracking susceptibility, although much higher ($\approx 50\%$) additions may promote immunity, based upon data for austenitic steels containing some 18–20% Cr [15].

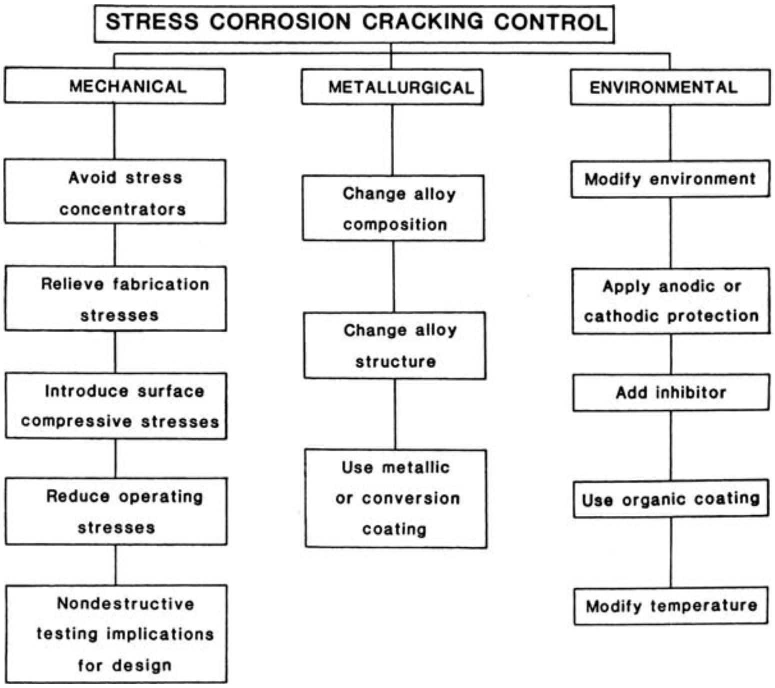

FIGURE 14.9. Approaches to SCC control.

D1. Metallurgical Approaches

There are many published studies of the manipulation of the composition or structure of alloys to control SCC [16]. Where intergranular cracking is due to segregation at the grain boundaries, control of the segregant affords a means of controlling SCC. Thus, restricting the carbon content of stainless steels to a maximum of 0.02%, whereby weld sensitization is avoided, can markedly improve cracking resistance [17]. There are other examples of relatively small changes in alloy composition markedly influencing cracking resistance (e.g., in aluminum alloys [18]), but in many instances, relatively large additions of alloying elements are necessary to achieve significant improvements in resistance. The point may be illustrated by data for additions to ferritic steels in relation to their SCC susceptibility in NO_3 or OH solutions [11]. It has already been mentioned that cracking is a function of potential for a given environment, and determination of that relationship in SSRTs affords a means of comparing the effects of alloying additions. The susceptibility in an SSRT may be expressed in terms of the ratio of the time to failure in the potent solution to that in an inert environment (oil) at the same temperature, a ratio of 1 indicating no susceptibility and increasing departure from 1 indicating increasing susceptibility. A plot of that ratio against potential bounds an area within which SCC occurs, that area being a measure of the stress corrosion index (SCI), and reductions or increases in that area indicate beneficial or deleterious effects, respectively, for alloying additions. Multiple regression analysis of the data resulted in the following equations for the relative effects of various alloying additions upon SCI in NO_3 and OH solutions:

$$\begin{aligned} SCI_{(NO_3)} &= 1777 - 996\%\,C - 390\%\,Ti - 343\% \\ &\quad Al(-132\%Mn) - 111\%\,Cr - 90\%\,Mo \\ &\quad - 62\%\,Ni + 292\%Si \end{aligned}$$

$$\begin{aligned} SCI_{(OH)} &= 105 - 45\%\,C - 40\%\,Mn - 13.7\%\,Ni \\ &\quad - 12.3\%\,Cr - 11\%\,Ti + 2.5\%\,Al \\ &\quad + 87\%\,Si + 413\%\,Mo \end{aligned}$$

The first constant on the right-hand side of those expressions reflects the greater propensity for cracking and the wider potential range involved with NO_3 than OH solutions, while negative coefficients for the various alloying elements indicate beneficial effects and positive coefficients deleterious influences. (Where a coefficient is bracketed, the t ratio, the coefficient/standard error of the coefficient, was <2 and only the remaining elements should be regarded as having significant effects.) The data reflected in these equations underline a point mentioned earlier, that alloying additions that are beneficial in relation to cracking in one environment may not have a similar influence in a different solution. Thus, while Mo additions are beneficial in relation to the cracking of ferritic steels in NO_3, they are markedly deleterious in relation to OH-induced cracking,

largely because they extend the range of potentials for cracking in OH solutions. It is apparent from the coefficients involved that relatively large alloying additions are necessary for large decreases in susceptibility, varying with the environment and element involved, but averaging some 8–9%, neglecting carbon where other considerations usually inhibit its involvement in the prevention of SCC. By the same token, some possible compositions that could be deduced from those equations as rendering a ferritic steel immune, would not produce usable materials.

The structure of an alloy is often determined by strength or ductility considerations rather than SCC resistance, although the latter has been shown to be influenced by structure in many materials. In general, large grain sizes are often associated with relatively low threshold stresses for SCC, reflecting the influence of grain size upon yield strength, but increasing the latter by quenching and tempering treatments, where feasible, or heat-affected zones associated with welds, may result in higher crack growth rates. In relation to intergranular SCC, heat treatments may be effective in redistributing those features at grain boundaries that promote electrochemical heterogeneity. Thus, solution heat treatment of stainless steels to redissolve carbides and eliminate Cr depletion at previously sensitized grain boundaries can be effective in avoiding SCC [17]. There are other examples involving materials as diverse as Al and Ni alloys where cracking can be influenced by appropriate heat treatments. Structural modification associated with cold work may also influence SCC resistance, but it will rarely be the case that this can be used in plant in view of its implications in other directions.

A review [19] of information on the use of metallic coatings applied to Al, Mg, and Ti alloys, together with low alloy and stainless steels, concluded that sacrificial coatings are beneficial on all those materials except low alloy steels. Medium-to-higher strength steels are particularly prone to hydrogen-related cracking, so metallic coatings, especially Zn, that promote low electrode potentials must be used with care, with galvanized high-strength steel bolts being capable of delayed failure when subjected to atmospheric corrosion. Where SCC occurs in potential ranges above those that lead to hydrogen discharge, the use of metallic coatings based on Al, Cr, or Ni can be beneficial, depending on their influence on potential in relation to the range of the latter in which SCC occurs. The same review [19] indicates that conversion coatings applied to Al, Mg, or Ti alloys give little protection against SCC when applied alone, or may even be deleterious, but in conjunction with high-grade paint schemes, they give fair protection.

D2. Environmental Approaches

In relation to control through environmental factors, Figure 14.9 indicates a number of different approaches. Where the offending chemical species can be removed from the environment, there is an obvious action, as has been practiced in cases where small amounts of chloride have caused cracking of stainless steel. Of course, where the offending substance is a reactant or product in a process, that approach is not available and recourse must be to some alternative, of which anodic or cathodic protection looks attractive in light of the restricted ranges of potential in which SCC occurs. Cathodic protection could be applied to preventing SCC in the systems to which Figure 14.6 refers, although as already mentioned, each of those environments can promote hydrogen-related cracking in steels at sufficiently low potentials. Consequently, the potential needs to be carefully controlled below the lowest value for dissolution-related cracking but above the highest potential for hydrogen-induced failure. Anodic protection could be an effective means of control for some of the systems involved with Figure 14.6, although not where cracking is associated with pitting, since the primary requirement for such protection is an environment that allows the formation of stable passivating films at potentials above the cracking domain. For either of these approaches to SCC control it is vital that the current required to change the potential reaches all of the surfaces exposed to the environment This can present some difficulties where narrow crevices are present in the structure or where intermittent wetting or discontinuous liquid films are involved.

Inhibitive additions to environments to control SCC have long been practiced, especially in relation to the caustic cracking of boilers, although other systems may be similarly treated [20, 21]. Oxidizing substances that simply raise the potential above the range for SCC can be effective providing they are maintained at an appropriate concentration. However, some such inhibitors may be unsafe in that they are ineffective if some other agency operates to cause the potential to remain within the cracking range. Thus, while raising the pH of NO_3 solutions to about 7 inhibits intergranular cracking at the open-circuit potential, steels tested at even higher pH values can suffer SCC if the potential is held within the cracking range. Clearly the ideal, or safe, inhibitor is one that prevents cracking even when the potential is within the range that promotes SCC in the absence of the inhibitor. Safe inhibitors have been identified for particular systems and can be effective in preventing the growth of existing cracks as well as avoiding initiation, while substances capable of preventing the ingress of hydrogen to metals are also known. Some of those inhibitors are suitable for incorporation into paints or other organic coatings, preferably within the priming coat as leach primers, in view of the well-established facility of coatings to allow the passage of water and other molecules.

Temperature is an important parameter in most instances of SCC, the conditions for cracking in terms of potential range and crack velocities being typical thermally activated

processes. While temperatures may be dictated by other considerations than SCC control (e.g., in process plant), lower temperatures are less likely to result in cracking in many situations or will be associated with lower crack growth rates.

D3. Stress Control

Many practical instances of SCC result from the presence of residual stresses, so thermal stress relief may be expected to be beneficial. The most usual problems with applying full stress relieving heat treatments to structures is that they are either too large for available furnace capacity or they distort at the relatively high temperatures involved ($\approx$ 650°C for ferritic and $\approx$ 800°C for austenitic steels). However, partial stress relief by heating to lower temperatures can be adequate where the total residual and operating stresses are reduced below the threshold stress. Moreover, these lower temperatures can be achieved with less distortion in furnace annealing and can be achieved with locally applied heating on large structures. The application of local heating to obtain reduction of the peak tensile residual stresses needs to be practiced with care, if the thermal stresses involved in the relieving process are not to simply move the high stresses to other areas. A variation on local heating for redistributing stresses has been applied to the stainless steel cracking problem associated with boiling water reactors. Induction heating of the outside of a pipe to 500–550°C, while maintaining the inside surface at 100°C with cooling water, results in compressive stresses on the inside surface where SCC may otherwise occur [22]. Similar changes in the residual stress distribution may be achieved with last pass heat sink welding, involving the application of a high weld heat input during the last pass while maintaining the inside surface of the pipe at $\sim$ 100°C with flowing water [22]. Compressive stresses at surfaces where SCC would otherwise initiate can be induced by other means, shot peening or grit blasting having been shown to be effective in that respect [14].

While residual stresses probably account for most SCC failures in service, operational stresses may be becoming an increasing contributor to such failures, possibly deriving from the more efficient use of materials by employing higher operating stresses. Operating conditions are largely dictated by considerations other than control of SCC, but it is important to remember that stress cycles in particular may lower the threshold stress for cracking below that associated with static loading. In some service situations, the most damaging stress fluctuations are likely to be associated with start-up and shutdown, a matter that has been considered in some detail in relation to the damage to boiling water reactor components [23]. Otherwise relatively little consideration has been given to whether or not start-up or shutdown procedures for plant may be identified that would minimize SCC risks while remaining realistic from other operations viewpoints. The latter considerations will most often override the former, but there are likely to be some circumstances where operational conditions can be manipulated to minimize the risk associated with stress cycles.

While ideally structures should be designed and fabricated so that SCC is avoided, in practice it is sometimes necessary to live with the problem. This implies an ability to detect and measure the size of cracks before they reach the critical size that may result in catastrophic failure. Such inspection has important implications for plant design, which obviously should allow inspection at appropriate locations. Failures have occurred at locations where inspection was not possible, but could have been avoided by inspection had the problem been anticipated. The most likely locations for cracking, with their implications for inspection, are regions of high residual stress (welded, bolted, or riveted joints) and regions where stress or environment concentration can occur (notches and crevices). A variety of nondestructive test (NDT) techniques are available for monitoring crack growth and provision for such is now being made at the design stage in some cases so that early detection can be achieved. There is one NDT technique that may have widespread use, even though it is not one for monitoring crack growth so much as detection, and which is worthy of special mention in the present context. It involves the use of liquids, such as dye penetrants, which can themselves induce cracking in some materials, especially high-strength steels prone to hydrogen-induced cracking [14].

A. INTRODUCTION

The four main environmental cracking phenomena of concern [1–5] when steels are exposed to wet H_2S environments are

1. Hydrogen blistering: blister formation, originating at nonmetallic inclusions
2. Hydrogen-induced cracking (HIC): also known as stepwise cracking (SWC)
3. Stress-oriented hydrogen-induced cracking (SOHIC)
4. Sulfide stress cracking (SSC): cracking in steels of high strength or high hardness

These four types of hydrogen damage are illustrated in Figure 15.1. For any of these to occur, there must be a corrosive environment and a material that is susceptible to cracking. The stress may be applied (or residual) stress, as in SOHIC and SSC, or internal stress resulting from the internal pressure of hydrogen, as in HIC and hydrogen blistering.

A variation of HIC, called SOHIC, has also caused failures; for example, SOHIC in a hard weld microstructure caused a major explosion of a pressure vessel [1, 6]. Evidence suggested that cracks propagated to the critical size by a HIC mechanism. Hydrogen evolved at the reacting surface can be absorbed by the steel as atomic hydrogen, as shown in Figure 15.2, which can diffuse through the steel and enter hydrogen traps, such as voids around nonmetallic inclusions. There, hydrogen atoms can combine to form molecular hydrogen, which can cause the internal pressure to increase to a level at which cracks initiate and propagate, as shown in Figure 15.3. In SOHIC, the laminations are arranged in parallel arrays perpendicular to the surface. Numerous catastrophic failures have been reported, many of them of steels of high yield strength for tubing and casing, although accidents have also occurred with low alloy steels used in pipelines and pressure vessels [7].

B. HYDROGEN-INDUCED CRACKING

Hydrogen-induced cracking, also known as SWC, can lead to failures of pipelines, tubulars, and pressure vessels exposed to sour environments, such as sour gas, sour crude oil, and other H_2S-containing environments [8–10]. Hydrogen-induced cracking in pipeline steel in the United States was first reported in 1954 [11]. In 1972, an undersea pipeline made of Grade 448 (X-65) steel in the Persian Gulf began to leak after a few weeks of service [12, 13]. The pipe had been made using a low-temperature (690–750°C) controlled

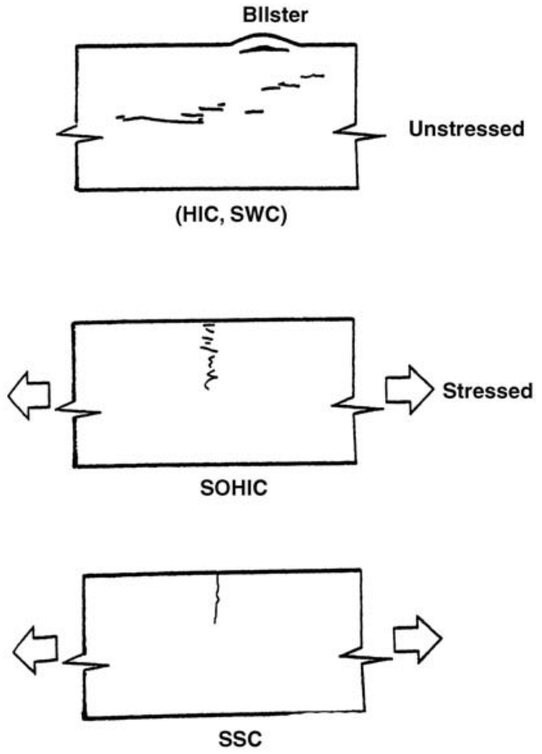

FIGURE 15.1. Schematic presentation of various hydrogen-induced cracks in steel.

rolling process, which was suspected as contributing to the cause of failure. Another major failure occurred in 1974 with a sour-gas pipeline in Saudi Arabia, which occurred within a few weeks of startup and affected a length of about 10 km [14].

Hydrogen-induced cracking occurs in three steps [15]:

1. Formation of hydrogen atoms at the steel surface and adsorption on the surface
2. Diffusion of adsorbed hydrogen atoms into the steel substrate
3. Accumulation of hydrogen atoms at hydrogen traps, such as voids around inclusions in the steel matrix, leading to increased internal pressure and crack initiation and propagation

Cracking requires the production of nascent hydrogen atoms (H^0) at the steel surface, usually by a corrosion reaction in an H_2S-containing, aqueous solution:

$$H_2S + Fe^{2+} \xrightarrow[H_2O]{} FeS + 2H^0$$

The hydrogen atoms produced at the steel surface may combine to form innocuous hydrogen gas molecules (H_2); however, in the presence of sulfide or cyanide, the hydrogen recombination reaction is poisoned, so that the nascent hydrogen atoms (H^0) diffuse into the steel rather than recombining on the metal surface to form hydrogen gas.

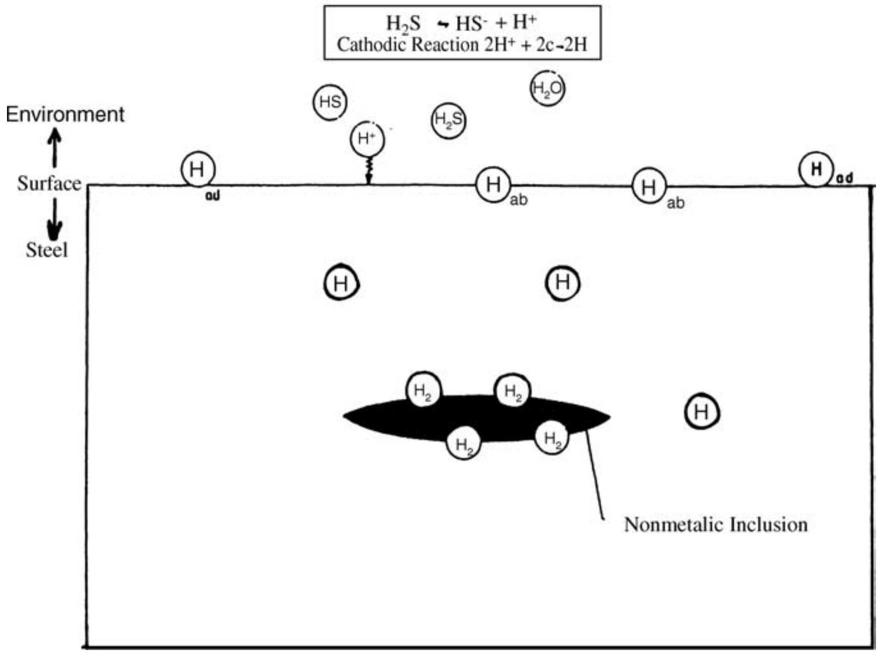

FIGURE 15.2. Mechanism of hydrogen entry.

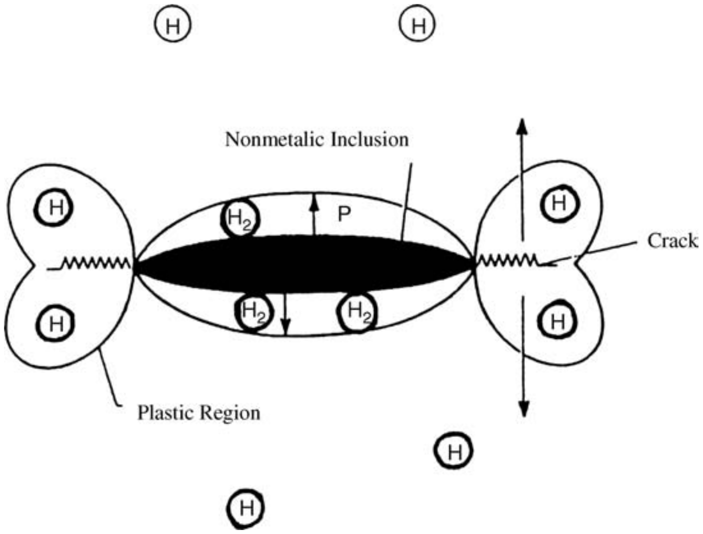

FIGURE 15.3. Schematic illustration of cracking mechanism.

Hydrogen atoms that enter the metallic lattice and permeate through the metal can cause embrittlement and failure of structures in service environments. It is generally observed that, if large amounts of hydrogen are absorbed, there may be a general loss in ductility. Internal blisters may occur if large amounts of hydrogen collect in localized areas [16, 17]. Small amounts of dissolved hydrogen may also react with microstructural features of alloys to produce failures at applied stress far below the yield strength. All these phenomena are referred to as hydrogen embrittlement [18–23].

Chemical species that have been reported to accelerate hydrogen damage include hydrogen sulfide (H_2S), carbon dioxide (CO_2), chloride (Cl^-), cyanide (CN^-), and ammonium ion (NH_4^+).

Some of these species help to produce severe hydrogen charging of steel equipment and may lead to HIC and SOHIC, either of which can cause failure. It is essential to characterize the cracking severity of environments, so that either aggressive environments can be modified and/or materials can be selected with adequate resistance to cracking.

The performance of steels is generally considered to be affected by

Material condition (composition, processing history, microstructure, and mechanical properties)

Fabrication (welding and joining)

Total stress (applied stress plus residual stress)

Environmental effects (corrosion, HIC, SSC, etc.)

Specific chemical agents in service environments may result in degradation, and, additionally, degradation is a function of time, temperature, and other environmental factors. In certain processes, these effects may be complicated since some environmental variables cannot be easily characterized because of the dynamic nature of engineering systems; for example, welded construction in refinery service involves local variations in chemical composition, inhomogeneous microstructure, and residual stresses. These effects are superimposed on influences of environmental factors, which add to the complexity of the situation. Careful assessment of service experience, evaluation of failures in plant tests, and laboratory research are all important and can provide useful information on parameters that are critical to serviceability.

B1. Hydrogen Blistering and HIC

Hydrogen blistering occurs as a result of nascent hydrogen (H^0) atoms diffusing through the steel and accumulating at hydrogen traps, typically voids around inclusions. When hydrogen atoms meet in a trap and combine, they form hydrogen gas (H_2) molecules in the trap. As more gas molecules form, the pressure increases, causing HIC and blister formation. Blisters occur primarily in low-strength steels (<80 ksi or 535 MPa yield strength) and are formed preferentially along elongated nonmetallic inclusions or laminations in the steels used for linepipe [24, 25].

Two types of HIC cracks, centerline cracks and blister cracks, are shown in Figure 15.4. Blister cracks, Figure 15.4(b), are HIC that form near the surface, where hydrogen pressure forms blisters. The formation of blister cracks is related to the type and distribution of nonmetallic inclusions in the steel. Elongated, type II MnS inclusions as well as planar arrays of other inclusions are the predominant initiation sites for cracking. Since inclusions are elongated and/or aligned in the longitudinal (rolling) direction, the cracks propagate in the longitudinal direction.

The steels most susceptible to this form of attack are those with high concentrations of sulfur and manganese, which

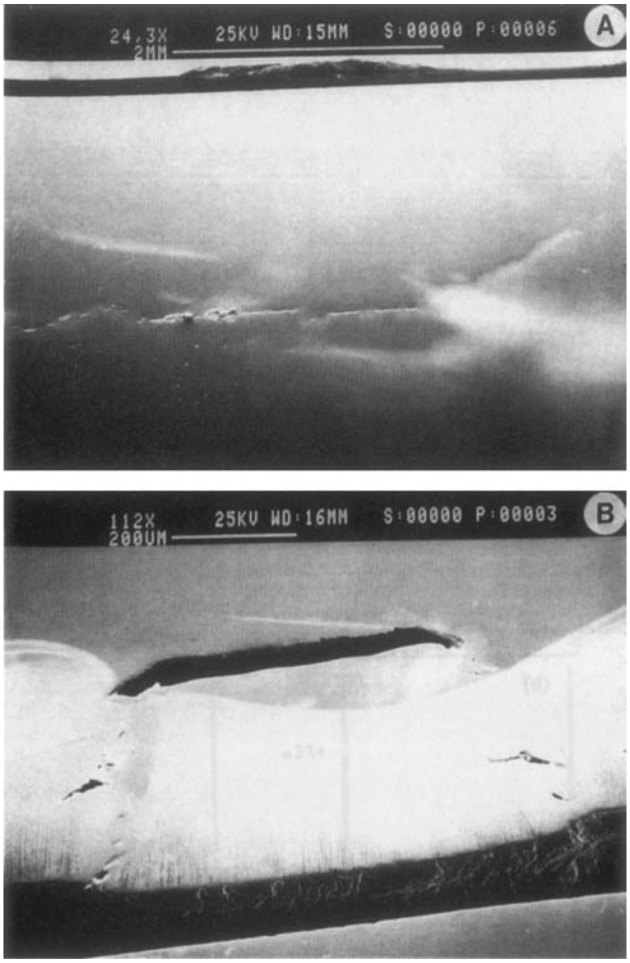

FIGURE 15.4. Two types of HIC. (a) centerline cracks and (b) blister cracks.

combine during melting to form MnS inclusions. Rolling tends to elongate these inclusions (Figure 15.5), increasing the surface area of hydrogen traps. Nevertheless, low-S steels are not necessarily HIC resistant since alloying for inclusion shape control, reduced centerline segregation, and reduction of nitrides and oxides also is necessary [26]. In addition, high-S steels are not necessarily susceptible to HIC. Micro-segregation and inclusion shape are more important than bulk sulfur content [26].

Hydrogen-induced cracking is a form of blistering in which lamination-type fissures parallel to the steel surface link in the through-thickness direction, as shown schematically in Figure 15.6. This type of damage (Figure 15.7), caused by linkage of individual defects, can result in rapid through-wall penetration.

Hydrogen-induced cracking may propagate in a straight or stepwise manner. Straight growth occurs in steels having ferrite-pearlite structures if there are high levels of Mn and P segregation or if there are martensitic or bainitic transformation structures. The Mn level around linear cracks may be twice that in the matrix, whereas the P level may be elevated by a factor of 10 [27–29].

Figure 15.8 shows schematically the stepwise growth of cracks as conceptualized from models based on stress analysis of cracking caused by hydrogen accumulation within voids [30].

1. In case I, two relatively large inclusions are connected.
2. In case II, a small inclusion bridges the gap between two larger ones.
3. In case III, several small inclusions are connected to an adjacent larger one.

An example of crack linkage is shown in Figure 15.9. Linkage of this type has been found to occur if the spacing between inclusions is <0.3 mm.

Like HIC, SOHIC is caused by atomic hydrogen dissolved in steel combining irreversibly to form molecular hydrogen. The molecular hydrogen collects at defects in the metal lattice, as in HIC. However, due to either applied or residual stresses, the trapped molecular hydrogen produces microfissures that align and interconnect in the through-wall direction, as shown in Figure 15.10(a). Although SOHIC can propagate from blisters caused by HIC and SSC, and from prior weld defects [31, 32], neither HIC nor SSC are preconditions for SOHIC [31]. As with HIC, the primary cause of SOHIC is probably atomic hydrogen produced at the steel surface by wet acid gas corrosion [9, 33–35].

Stress-oriented hydrogen-induced cracking tends to occur in the base metal adjacent to hard weldments in pipe and plate steels where cracks may initiate by SSC. The SOHIC is characterized by interlinking microscopic cracks oriented both in the direction perpendicular to the stress and in the plane defined by nonmetallic inclusions, as shown in Figure 15.10(b). The SOHIC is a process by which SSC can propagate in relatively low-strength steels [hardness <22 HRC (Rockwell C hardness)], which would otherwise be considered resistant to SSC.

B2. Factors Influencing HIC

B2.1. Environmental Factors. Figure 15.11 shows the hydrogen uptake in steel as a function of pH. Hydrogen-induced cracking can occur if the hydrogen content exceeds C_{th} (threshold hydrogen concentration, about 0.8 mL/100 g), so it can occur for plain carbon steel at $pH < 5.8$, whereas with Cu-bearing steel, it would occur only at $pH < 4$. Copper alloying improves HIC resistance, particularly in media containing H_2S at pH 4–6. Copper does not improve resistance at $pH < 4$, and thus, effects of Cu are detected in the British Petroleum (BP) test, but not in NACE TM0177 solution, as shown in Figure 15.11.

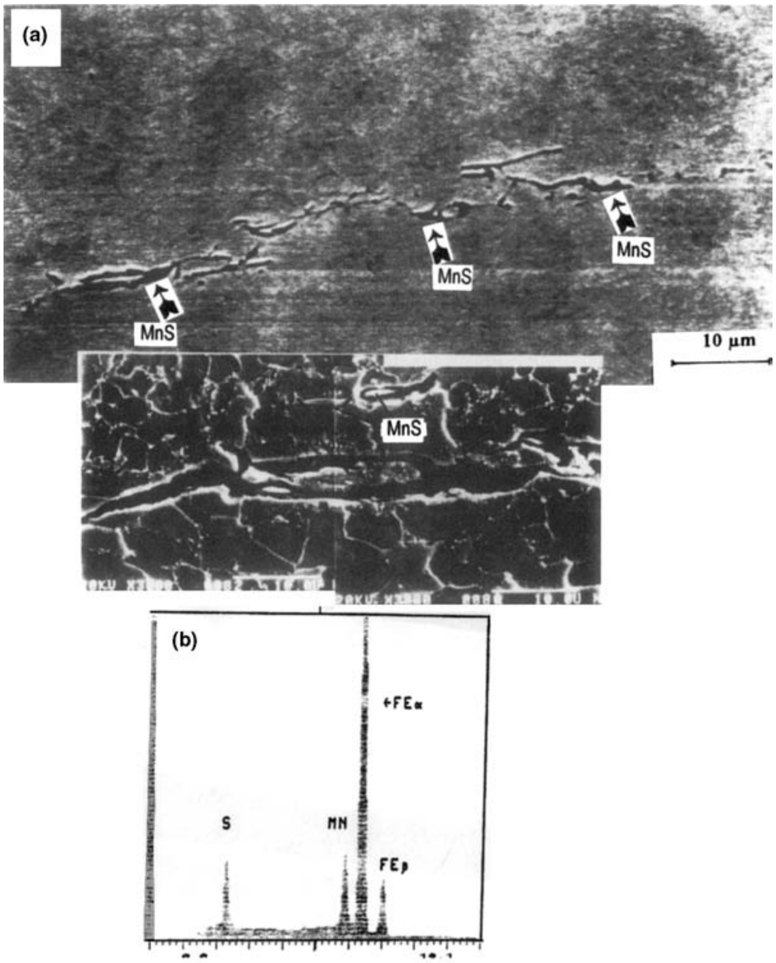

FIGURE 15.5. Scanning electron micrograph of coupons tested in sour environment showing, (a) Massive and elongated nonmetallic inclusion (MnS) and (b) energy-dispersive X-ray (EDX) analysis of the above cracking surface.

Hydrogen penetration decreases as the pH increases and becomes minimal at pH 7.5; at higher pH, hydrogen penetration increases [36]. Hydrogen-induced cracking in alkaline media has been reported [37]; in such cases, NH_3 and CN may accompany the H_2S.

Hydrogen-induced cracking is accelerated when Cl^- accompanies H_2S; mill scale inhibits HIC in media containing H_2S but lacking Cl^-, whereas there is no such effect when the two occur together [38]. Carbon dioxide often accompanies H_2S in a sour well; the combination of H_2S and CO_2 tends to increase the occurrence of HIC and to increase the concentration of hydrogen at the surface, C_0.

Water is almost always present and is essential to HIC since hydrogen from the cathodic corrosion reaction penetrates the steel. When there is no water, corrosion does not occur, so there is no hydrogen evolved to penetrate, and no HIC should occur. At elevated H_2S contents, the medium is generally more corrosive [39].

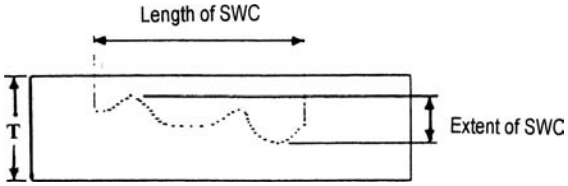

FIGURE 15.6. Schematic illustrating how length and extent of SWC are defined. "T" indicates the through-thickness direction in plate or pipe sample.

B2.2. Material Factors. The HIC-resistant pipeline steels have been developed [40–44]. Figure 15.12 [45] compares susceptibility of various commercial steels based on ingot cores (where susceptibility is highest). The larger the ingot the higher the HIC susceptibility. The susceptibility of the ingot core is ascribed to the high-volume proportion of segregating materials there, whereas the low susceptibility at the rim is caused by the low-volume fraction of segregating materials, as the cooling rate at the surface is high. The upper

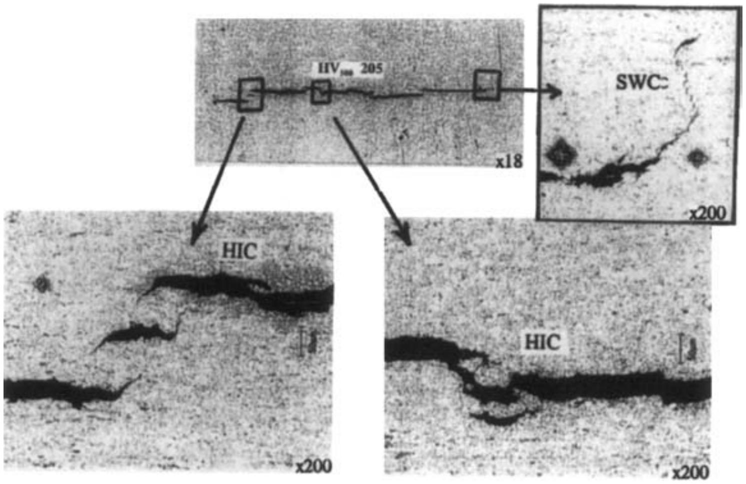

FIGURE 15.7. Typical example of stepwise cracking.

part of the ingot has been described as more susceptible than the bottom part. Because susceptibility depends on nonmetallic inclusions and anomalous structures due to P and Mn segregation, HIC can be reduced either by reducing the proportion of nonmetallic inclusions by lowering the S content or by modifying the morphology of segregation by adding Ca. Tempering is effective in eliminating the low-temperature anomalous structure. Addition of Cu ($> 0.2\%$) is also effective. Hot-strip mill products are more susceptible than plate mill products.

Plate-shaped inclusions provide hydrogen traps and, thus, tend to raise the HIC susceptibility [46]. Figure 15.13 [29] shows the crack length ratio as a function of inclusion length, the two increasing together and not greatly influenced by the finishing temperature. It has also been found [47, 48] that the cracking susceptibility in commercial steel is usually larger at lower rolling temperatures, which may be related to the shape of the MnS inclusions; that is, those inclusions may be elongated by controlled rolling at $\sim$750°C but are not deformed at higher temperatures.

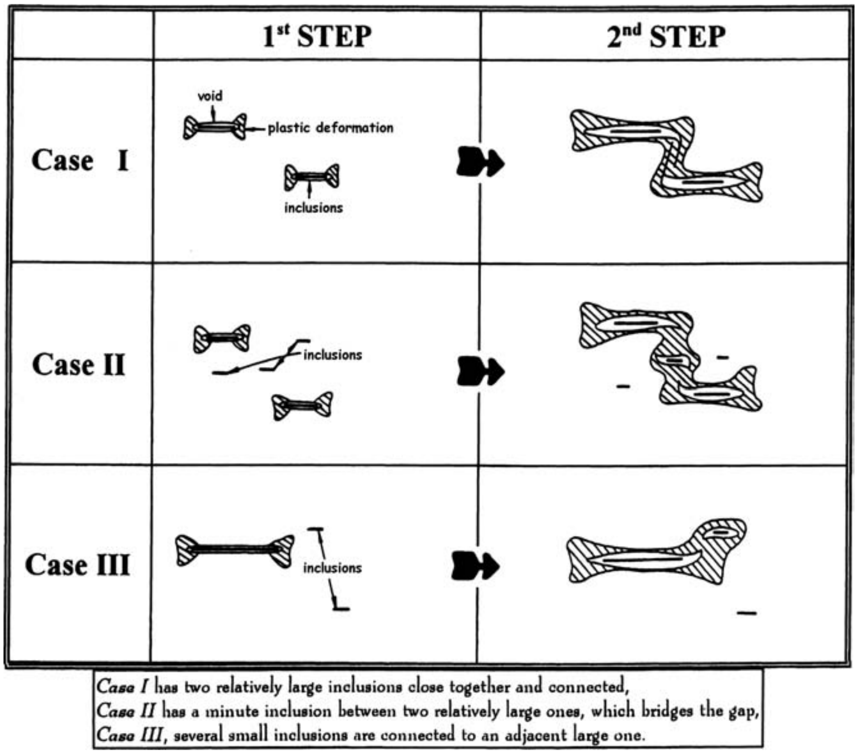

FIGURE 15.8. Stepwise crack growth [30].

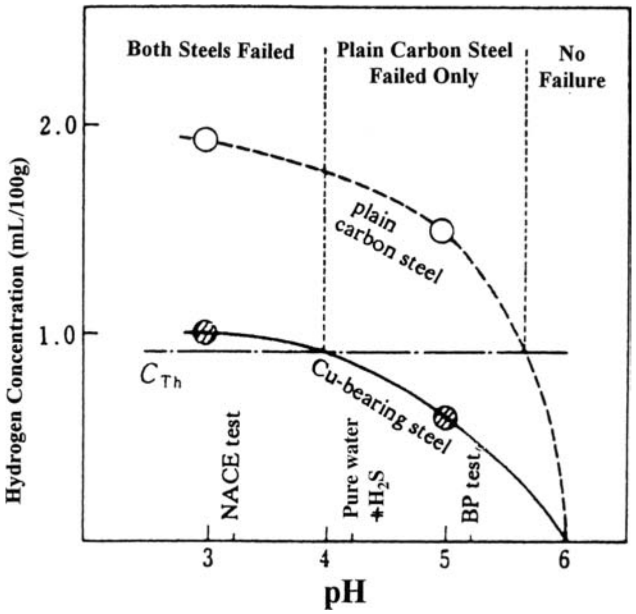

FIGURE 15.11. Relationship between pH and hydrogen uptake for plain and Cu-bearing steels [30].

When S < 0.007, it produces good resistance in the ingot rim of controlled-rolled and hot-strip mill materials regardless of the finishing procedure [44]. The effects of S are not so evident for specimens from the core, where there are numerous inclusions other than MnS. Type II MnS inclusions occur in the core, and specimens taken from cores having average S contents as low as 0.001% can show HIC susceptibility [47, 49]. Calcium is sometimes added for shape control of type II MnS inclusions, but excess Ca results in CaS clusters, so that there is a best Ca/S range that depends on the S concentration [50, 51].

The effects of alloying elements on HIC occur through the effects on strength, microstructure, and segregation. Copper affects hydrogen uptake; above 0.2% Cu, susceptibility is much reduced [29, 52]. Copper reduces C_0, but does not alter C_{th} [41], so that the NACE TM0177 solution shows no HIC inhibition as a result of Cu addition to the steel [53–55], Over 1.0% Mn increases the susceptibility, but *Q* and *T* treatment can remove the detrimental Mn effect [40, 42, 56]. When Co accompanies Cu, the hydrogen uptake is reduced and the HIC susceptibility is lowered [53].

The elements C, Si, Ni, Cr, and V have only minor effects on susceptibility [53, 56], although it is stated [53] that Ni reduces the hydrogen uptake, and it has also been found [53, 57] that Mo and Cu together result in the beneficial effect of Cu being reduced. It has also been reported [55, 58–59] that Cu + W has only slight effects on the sensitivity. It is claimed [59] that Bi, Pd, or Pt improves the resistance by forming surface films, but the use of these expensive metals may not be a practical solution in most applications.

Calcium and rare earth metals, such as La and Ce, spheroidize nonmetallic inclusions, raising C_{th}, (i.e., the resistance); these additions are often used in making steels for severe environments [41–45].

Manufacturing processes and treatments affect the MnS morphology and influence sensitivity; for example, rimmed and Si-killed steels have relatively low susceptibility because type I MnS predominates [60, 61]. If the MnS inclusion content is sufficiently low, even the adverse effects of low-temperature controlled rolling are reduced [29]. Both *Q* and *T* treatments can reduce the susceptibility substantially [50].

B3. Prevention and Control

There are two ways of inhibiting HIC: One is to prevent hydrogen from penetrating the steel and another is to reduce the concentration of hydrogen traps. The HIC can be inhibited by using over 0.2% Cu. In addition, Co, Cu + Co, Cu + W, and Ni are also stated to be effective. Alternatively, an inhibitor can be added to the solution to produce a protective film [60–63], or the pH can be raised. Using a paint or lining to isolate the steel may also inhibit hydrogen penetration and prevent HIC [64–66].

If S is reduced to 0.002–0.005%, the number of nonmetallic inclusions, such as MnS, may be reduced and HIC inhibited. It is claimed that Ca and rare earth metals inhibit HIC susceptibility by modifying the morphology of inclusions [67]. Tempering is also effective in eliminating localized Mn and P segregation if the Mn level is more than 1%; tempering reduces hardness around inclusions, and thus, the HIC susceptibility. Calcium added to steels low in S and Mn for use in sour-gas pipelines improves HIC resistance.

C. SULFIDE STRESS CRACKING

Sulfide stress cracking was first recognized as a serious problem in the early 1950s, when the oil industry experienced failures of tubular steels and well-head equipment [11] constructed from steels with hardness values greater than HRC 22. The NACE International recommendations to prevent SSC were based on an approach that has been reasonably successful in practice; that is, heat treat steels to hardness levels less than HRC 22. Although the base metal of steel pipe normally has hardness levels well below this value, service failures have occurred in regions of high hardness in the weld heat-affected zone. It is, therefore, common to apply the HRC 22 limit (equivalent to Vickers hardness "HV 248") to the weld/HAZ areas in pipeline steels. Test procedures for SSC are reviewed in Chapter 78.

Sulfide stress cracking is a form of hydrogen embrittlement that occurs in high-strength steels [3] and in localized hard zones in weldment [39] of susceptible materials. The graph in Figure 15.14 shows the synergistic effects of high steel strength and high H_2S concentration in the environment to cause SSC [68]. In the heat-affected zones adjacent to welds, there are often very narrow hard zones combined with regions of high residual tensile stress that may become embrittled to such an extent by dissolved atomic hydrogen that they crack, as shown in Figure 15.10(b). Sulfide stress cracking is directly related to the amount of atomic hydrogen dissolved in the metal lattice and usually occurs at temperatures below 90°C (194°F) [32]. Sulfide stress cracking also depends on the composition, microstructure, strength, and

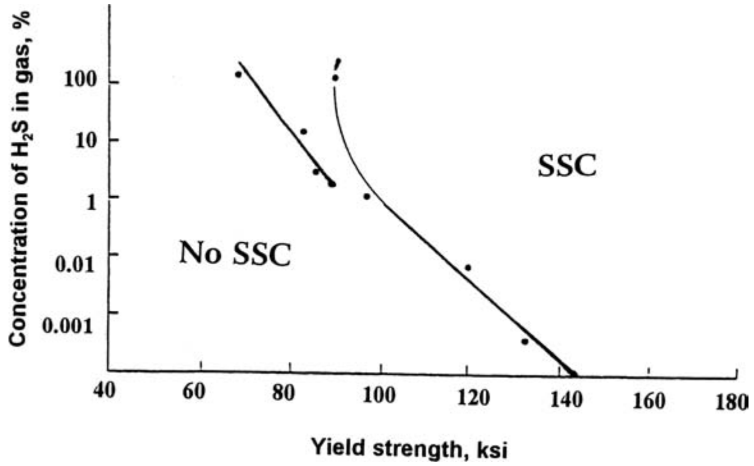

FIGURE 15.14. The maximum H_2S concentration limit for SSC-fiee behavior at 100% of yield strength [68]. (Copyright Materials Properties Council. Reprinted with permission.)

TABLE 15.1. Comparison of Features of HIC and SSC

	Hydrogen-Induced Cracking	Sulfide Stress Cracking
Crack direction	Dependent on microstructure	Perpendicular to stress
Applied stress	No effect	Affects critically
Material strength	Primarily in low-strength steel	Primarily in high-strength steel
Location	Ingot core	Anywhere
Microstructure	Cleanliness and nonmetallic inclusions are critical	Critical effect, Q and T treatment enhances SSC resistance
Environment	Highly corrosive conditions, appreciable hydrogen uptake	Can occur even in mildly corrosive media

the total stress (residual stress plus applied stress) levels of the steel [31].

C1. Comparison of HIC and SSC

Features of HIC and SSC are compared in Table 15.1; the orientation of HIC depends on microstructure and morphology of nonmetallic inclusions, whereas SSC is perpendicular to the stress. Sulfide stress cracking occurs only under certain stress conditions, whereas HIC can occur without external stress. Sulfide stress cracking occurs in high-strength steel, whereas HIC occurs in low-strength steel. The occurrence of HIC depends on nonmetallic inclusions, so that the steelmaking process and the location within the steel ingot are very important. This resistance can be increased by quench and temper heat treatments, although SSC of high-strength steel can occur in mild environments where the steel absorbs only small amounts of hydrogen. On the other hand, HIC occurs in low-strength steel in severe environments, in which appreciable amounts of hydrogen are formed by cathodic reduction on the steel surface and absorbed by the steel.

A. INTRODUCTION

Corrosion fatigue is caused by crack development under the simultaneous action of corrosion and fluctuating, or cyclic, stress. Many instances of environment-assisted cracking are caused by corrosion fatigue because loads on most engineering structures do vary to some extent Corrosion fatigue is a subject of international conferences [1–3], major review papers [4–6], and books [7].

Metal subjected to a fluctuating stress will fail at a stress much lower than is required to cause failure under constant load. The extent of stress fluctuation is defined by the stress ratio, $R =$ minimum stress/maximum stress. The number of cycles to failure, the fatigue life, increases as the maximum stress during cycling decreases until the endurance limit, or fatigue limit, is reached; at or below this stress, the material undergoes an infinite number of cycles without failure. True fatigue limits exist for only a limited number of materials; for the majority of engineering alloys, the fatigue limit refers to the stress level below which failure does not occur within a specified number of cycles, usually 10^7 or 10^8 cycles.

Fatigue crack growth rate, the increment of crack size per load cycle, is important for risk assessment and for predicting remaining life, and is often described by a relationship with stress intensity factor, K, which includes stress and crack sizes.

Both the fatigue life and the fatigue limit can be markedly reduced in the presence of a corrosive environment, and, in many cases, the endurance limit is no longer observed. In addition, corrosive environments can accelerate crack growth. The damage due to corrosion fatigue is almost always much greater than the sum of the damage by corrosion and fatigue acting separately. Figure 16.1 shows an example of the reduction of fatigue life and the elimination of the fatigue limit of high-strength steel in a sodium chloride solution [8]. This figure also shows that cathodic polarization restores the fatigue properties of the steel.

In general, a corrosive environment can decrease the fatigue properties of any engineering alloy, meaning that corrosion fatigue is not material–environment specific. Although fatigue cracks are typically transgranular, corrosion fatigue cracks can be transgranular, intergranular, or a combination of both, depending on the mechanical loading and environmental conditions. Localized corrosion, such as pitting, often produces favorable sites for corrosion fatigue crack initiation, but pits are not the only initiation sites, and pitting is not a necessary precursor to failure. Although multiple cracks can initiate, fatigue failure often results from the propagation of a single crack; whereas crack interaction and coalescence are important in the corrosion fatigue failure process.

Blackwell Science Ltd., Oxford, UK.]

B. MECHANISTIC ASPECTS OF CORROSION FATIGUE

Like stress corrosion cracking, corrosion fatigue depends on interactions among the material, environmental, chemical, and electrochemical parameters and mechanical loading conditions.

Cracking phenomena for ductile alloys involve plastic deformation, and it is the localization of plastic deformation, due to cyclic loading, that causes fatigue failure at a stress level far below the yield stress of the material. There are two main processes associated with corrosion damage, anodic metal dissolution and cathodic reactions (often hydrogen reduction). The reduction of material resistance to fatigue under the influence of a corrosive medium can be regarded as a result of the synergistic enhancements of these processes.

There are two main categories for the mechanisms of corrosion fatigue: anodic slip dissolution and hydrogen embrittlement, as schematically summarized in Figure 16.2 [9]. As shown in Figure 16.2(a), cracks grow by slip dissolution that results from diffusion of the active species (e.g., water molecules or halide anions) to the crack tip; rupture of the protective oxide film at a slip step or in the immediate wake of a crack tip by strain concentration or fretting contact between the crack faces; dissolution of the exposed surface; nucleation and growth of oxide on the bare surface.

For the alternative mechanism of hydrogen embrittlement in aqueous media, the critical steps [Fig. 16.2(b)] involve: diffusion of water molecules or hydrogen ions to the crack tip; reduction to hydrogen atoms adsorbed at the crack tip; surface diffusion of adsorbed atoms to preferential surface locations; absorption and diffusion to critical locations (e.g., grain boundaries, the region of high triaxiality ahead of a crack tip, or a void).

Under cyclic loading, fretting contact between the mating crack faces, pumping of the aqueous environments to the crack tip by the crack walls, and continual blunting and resharpening of the crack tip by the reversing load influence the rate of dissolution. Consequently, both cyclic frequency and stress waveform strongly influence crack development by corrosion fatigue, whereas for fatigue alone these factors are usually less significant.

Fatigue damage can be divided into the following four stages:

1. *Precrack Cyclic Deformation.* Repetitive mechanical damage is accumulated in some local regions; dislocation and other substructures may develop; and persistent slip bands (PSBs, slip bands that develop on the sample surface during cyclic deformation and that reappear at the same locations during further cyclic deformation after polishing the surface), extrusions, and intrusions form.
2. *Crack Initiation and Stage I Growth.* Cracks initiate as a result of deepening of the intrusions; crack growth in this stage is within the planes of high shear stress.
3. *Stage II Crack Propagation.* Well-defined cracks propagate on the planes of high tensile stress in the direction normal to the maximum tensile stress.
4. *Ductile Fracture.* When the crack reaches sufficient length so that the remaining cross section cannot support the applied load, ductile fracture occurs.

The relative proportion of the total cycles to failure that are involved in each stage depends on mechanical loading conditions and on the material. There is considerable ambiguity in deciding when a cracklike surface feature should be called a crack. In general, a larger proportion of the total cycles to failure are involved in propagation of stage II cracks in low-cycle fatigue than in high-cycle fatigue, whereas initiation and stage I crack growth comprise the largest segment for low-stress, high-cycle fatigue. The surface conditions of the material also influence the proportion of each stage in the total fatigue lifetime. Surface discontinuities, such as sharp notches and nonmetallic inclusions, can significantly reduce the number of cycles required for crack initiation and early stages of propagation.

A corrosive environment can influence all the stages of crack development except the last one, in which ductile

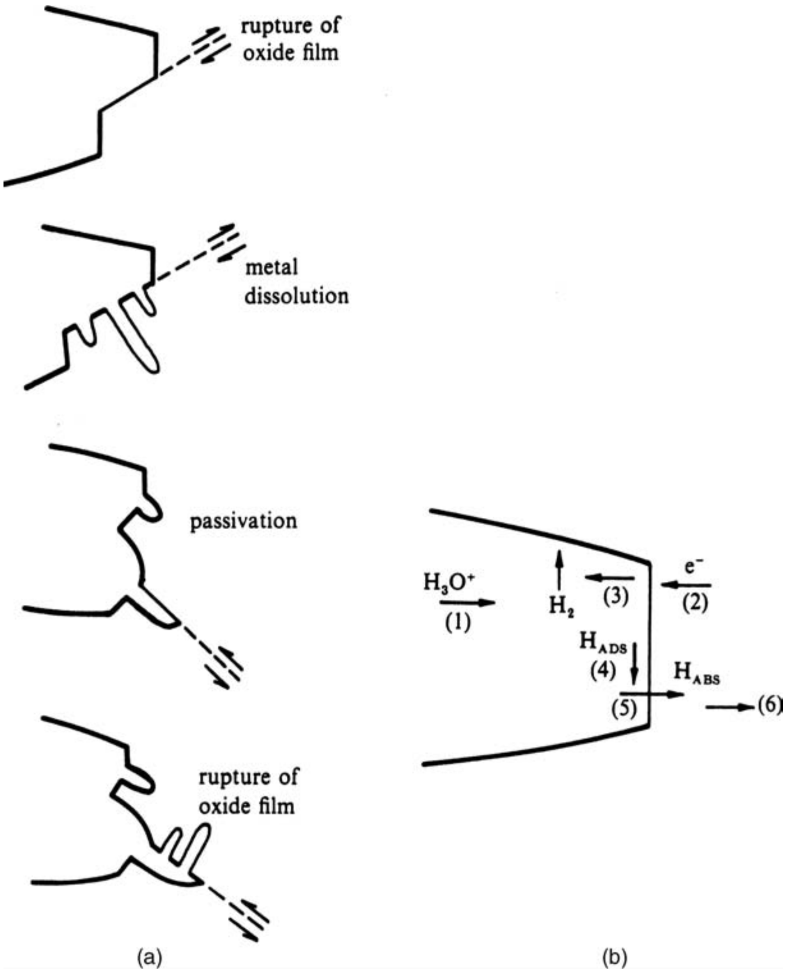

FIGURE 16.2. Schematic of (a) slip dissolution and (b) hydrogen embrittlement in aqueous media; (1) liquid diffusion, (2) discharge and reduction, (3) hydrogen adatom recombination, (4) adatom surface diffusion, (5) hydrogen absorption in metal, and (6) diffusion of absorbed hydrogen. (Reproduced with permission from Subra Suresh, Fatigue of Materials, Cambridge University Press, Cambridge, UK, 1991, p. 363.)

fracture occurs, and can also influence the relative proportion of the total cycles to failure that take place in each stage.

C. CORROSION FATIGUE CRACK INITIATION

C1. Role of Nonmetallic Inclusions

For low-stress, high-cycle fatigue, crack initiation consumes a large portion of the total lifetime. Fatigue crack initiation in commercial alloys occurs on the surface or the subsurface and is usually associated with surface defects, especially nonmetallic inclusions. For an inclusion to be a potential source of fatigue failure, two main criteria must be fulfilled: The inclusion should have a critical size and the inclusion should have a low deformability, related to the expansion coefficient at the temperature during fatigue [10]. For steels, the "dangerous" inclusions include single-phase alumina ($A1_2O_3$), spinels, and calcium-aluminates $> 10\,\mu m$ in size. The most common elongated sulfide inclusions (MnS) appear to be the least harmful. Surface discontinuities can act as stress raisers causing local stress concentration, but it is the enhanced localization of plastic deformation around an inclusion that reduces the fatigue resistance of a material.

Preferential attack by an environment at specific surface locations may provide the most favorable sites for crack initiation when a cyclically loaded engineering component or structure is exposed to a corrosive medium during service. For a high-strength steel exposed to a sodium chloride solution, it was found that sulfide inclusions contribute sites for corrosion pits and subsequent fatigue crack initiation, whereas the angular-shaped calcium-aluminates, which are responsible for fatigue crack initiation in air, did not affect corrosion fatigue [8, 11]. The relative chemical and electrochemical activity of an inclusion determines whether it is preferentially dissolved. Both the stress concentration

associated with a pit and the local environment within the pit, which can be markedly different from the bulk solution, can significantly affect the cracking process. Sulfide inclusions and the immediate area surrounding them are anodic to the steel matrix [12, 13]. Hydrogen sulfide (H_2S) and HS^- ions formed by dissolution of sulfides have the most deleterious effects on development of corrosion pits. The H_2S and HS^- ions produced in solution can catalyze the anodic dissolution of iron from the matrix and poison the cathodic discharge of hydrogen. Local acidification due to hydrolysis of ferrous and ferric ions, in turn, enhances the dissolution of sulfide inclusions, and accumulation of HS^- ions favors continued localized attack, producing micropits. It has also been reported that, under the application of a cyclic stress, corrosion at the inclusion–matrix interfaces develops more rapidly than under stress-free conditions [13].

For high-strength steel, the reduction in fatigue life by sodium chloride solution was found to result primarily from the shorter time for crack initiation to occur, although the crack growth rate was also accelerated. Figure 16.3 shows that, for fatigue in air, >80% of the life was spent in crack initiation and propagation below the length of 100 μm; the corrosive environment reduced the fatigue life and also the proportion of time spent in the crack initiation stage, so that the fatigue life was predominantly crack propagation [8, 11].

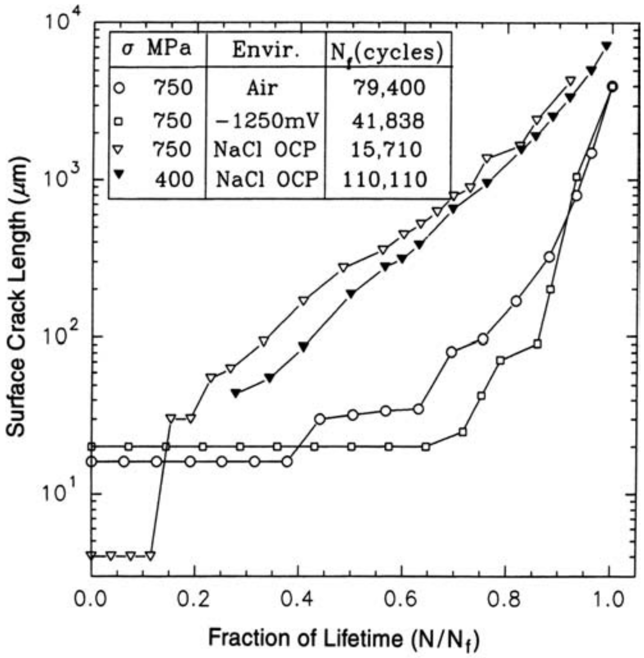

FIGURE 16.3. Surface crack length versus fraction of lifetime for high-strength steel at different conditions. The fatigue life data are shown in Figure 16.1. Number of cycles to failure N_f. Struct. 18(3), 295 (1995). Blackwell Science Ltd., Oxford, UK. and Reproduced with permission from Y.-Z. Wang and U. Akid, Corrosion, 52, 92 (1996)]

C2. Critical Corrosion Rate

In research on steels, Uhlig and co-workers [14, 15] found that the fatigue life of initially smooth specimens in aqueous solution was reduced only when a critical dissolution rate was exceeded. However, fatigue crack propagation in precracked specimens was accelerated by applying cathodic polarization, which suppresses anodic dissolution. Later, it was found that the fatigue life of a high-strength steel was dominated by crack initiation, and the influence of the environment on fatigue life was through the reduction of the initiation time by corrosion pits, which developed by selective dissolution of MnS inclusions [8, 11]. Cathodic polarization suppresses the dissolution rate and prevents pit formation, extending the time required for crack initiation and restoring the fatigue life. The increased crack growth rate of well-defined cracks by cathodic polarization was attributed to hydrogen effects.

The influence of corrosion rate on corrosion fatigue behavior is also related to the mechanical loading conditions. For a Grade 448 (X-65) pipeline steel exposed to a dilute solution simulating the groundwater environment, the number and sizes of cracks were larger at pH 5.6 than at 6.9 when the applied stress ratio was at or below 0.6; at higher stress ratio, 0.8, cracking occurred at pH 6.9, but not at 5.6 [16]. This difference in behavior was attributed to the balance required between corrosion rate and severity of mechanical loading. For this steel–environment system, passivation that would prevent crack lateral dissolution does not occur, and only cyclic loading maintains crack sharpness. High corrosion rate accelerates corrosion fatigue when sufficient cyclic damage is simultaneously induced.

Corrosion fatigue cracks tend to initiate at surface discontinuities, such as notches and pits. Nevertheless, crack initiation is a competitive process, occurring first at the most favorable sites. Eliminating one type of initiation site can extend the fatigue life but may not prevent failure by corrosion fatigue. The beneficial effect of shot peening is attributed to the compressive stress generated at the surface layer that delays corrosion fatigue crack initiation.

C3. Three Corrosion Situations

Duquette [6] divided material and corrosive environments into three groups on the basis of surface conditions:

1. Active dissolution conditions
2. Electrochemically passive conditions
3. Bulk surface films, such as three-dimensional oxides

In the first group, emerging persistent slip bands (PSBs) are preferentially attacked by dissolution. This preferential attack leads to mechanical instability of the free surface and the generation of new and larger PSBs, which localize corrosion attack and lead to crack initiation. Under passive conditions, the relative rates of periodic rupture and reformation of the

passive film control the extent to which corrosion reduces fatigue resistance. When bulk oxide films are present on a surface, rupture of the films by PSBs leads to preferential dissolution of the fresh metal that is produced.

D. CORROSION FATIGUE CRACK PROPAGATION

D1. Fracture Mechanics Characterization

As in stress corrosion cracking (SCC), the propagation behavior of well-defined corrosion fatigue cracks is often described using fracture mechanics, where the average crack extension per cycle (*da*/*dN*) is described as a function of the applied stress intensity factor range ($\Delta K = K_{\max} - K_{\min}$). Under cyclic loading, corrosion fatigue cracks can propagate when the maximum stress intensity factor is considerably below the threshold stress intensity factor for stress corrosion cracking; and in the presence of a corrosive environment the crack growth rate can be markedly increased.

It is convenient to characterize the effects of environment on the rates of fatigue crack growth by considering different combinations of crack growth rates measured under purely mechanical fatigue and under SCC conditions. Figure 16.4(a) schematically illustrates the sigmoidal variation of fatigue crack growth as a function of stress intensity factor range (on a log–log scale) under purely mechanical cyclic loading conditions. The typical variation in crack velocity, *da*/*dt*, as a function of the applied stress intensity factor, *K*, is plotted (on a log–log scale) in Figure 16.4 (b) for growth of cracks in metallic materials under sustained loading in the presence of an environment. As shown in this figure, the environment has no effect on fracture behavior below a static stress intensity factor, $K_{\mathrm{I_{SCC}}}$, the threshold stress intensity factor for the growth of stress corrosion cracks in mode I (tensile opening mode). Above $K_{\mathrm{I_{SCC}}}$ the crack velocity increases precipitously with increasing

stress intensity factor, K (region I). This region is followed by a region of growth (region II) in which the crack increment per unit time is essentially independent of the applied K. As the maximum stress intensity factor approaches the fracture toughness of the material, K_{Ic} (region III), there is a steep increase in crack velocity.

Corrosion fatigue crack growth can be schematically represented in three ways [17]. Figure 16.4(c) illustrates type A true corrosion fatigue growth behavior in which the synergistic interaction between cyclic plastic deformation and environment produces cycle- and time-dependent crack growth rates. True corrosion fatigue influences cyclic fracture even at maximum stress intensity factor $K_{\max}$ in fatigue $< K_{\mathrm{Iscc}}$. The cyclic load form is important. Figure 16.4(d) shows the stress corrosion fatigue process, type B, purely time-dependent corrosion fatigue crack propagation that is a simple superposition of mechanical fatigue [Fig. 16.4(a)] and SCC [Fig. 16.4(b)]. Stress corrosion fatigue occurs only when $K_{\max} > K_{\mathrm{Iscc}}$. In this model, the cyclic character of loading is not important. The combination of true corrosion fatigue and stress corrosion fatigue results in type C, the most general form of corrosion fatigue crack propagation behavior, Figure 16.4(e), which involves cyclic time-dependent acceleration in da/dN below K_{Iscc}, combined with time-dependent cracking (SCC) above the threshold.

Figure 16.5 shows examples of corrosion fatigue crack propagation behavior. Figure 16.5(a) illustrates the behavior of maraging steel exposed to 3% NaCl [18], representing Type A growth, and Figure 16.5(b) shows the behavior of high-strength type 4340 [Unified Numbering System (UNS)

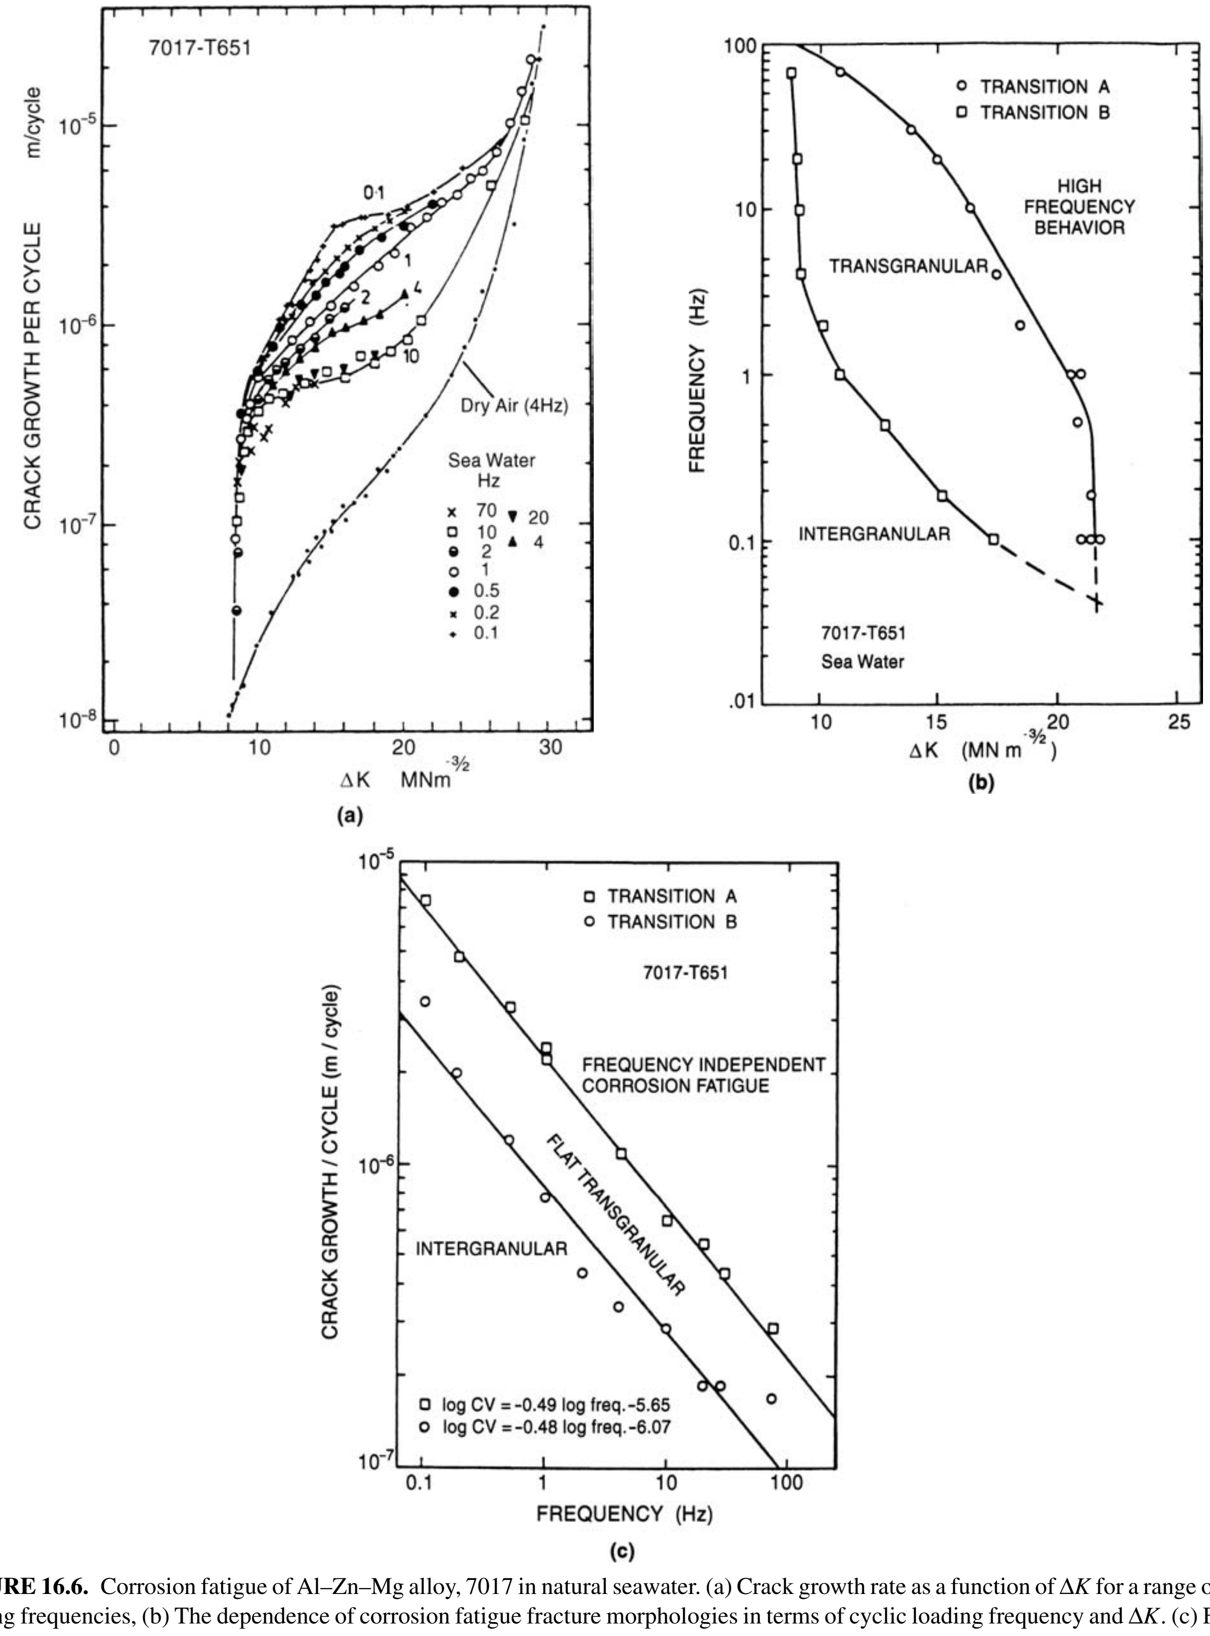

FIGURE 16.6. Corrosion fatigue of Al–Zn–Mg alloy, 7017 in natural seawater. (c) Fracture morphologies in terms of crack growth rate and cyclic loading frequency. [Reprinted from N. J. H. Holroyd and D. Hardie, "Factors Controlling Crack Velocity in 7000 Series Aluminum Alloys during Fatigue in an Aggressive Environment," Corrosion Science, 23, pp. 529, 533, 535 (1983), with permission from Elsevier Science.]

G43400] steel in water vapor and argon [19], representing type B growth. In Figure 16.5(a), there is a substantial corrosion fatigue effect below the static load threshold, but only for those load waveforms that include a slow deformation rate to maximum stress intensity. The solid line in Figure 16.5(b) demonstrates that time-dependent corrosion fatigue crack growth rates are accurately predicted by linear superposition of stress corrosion crack growth rates (*da*/*dt*) integrated over the load–time function for fatigue.

A number of interactive variables influence the relationship between corrosion fatigue crack growth rate and stress intensity. Growth rates are affected by environmental chemical variables (e.g., temperature; gas pressure and impurity content; electrolyte pH, potential, conductivity, and halogen or sulfide ion content); by mechanical variables, such as ΔK, mean stress, frequency, waveform, and overload; and by metallurgical variables, including impurity composition, microstructure, and cyclic deformation mode. Time, or loading frequency, is also critical.

Figure 16.6 shows the effect of loading frequency and stress intensity range on the corrosion fatigue crack growth rate and the cracking morphology of Al–Zn–Mg alloy, 7017, in natural seawater [20]. Although $da/dN - \Delta K$ shows type B growth behavior, a simple superposition model is inappropriate for describing the corrosion fatigue crack growth rate and the effect of load frequency. The cracking morphology, intergranular or transgranular, is influenced by both the load frequency and the stress intensity factor range, and intergranular cracking can occur at a very high load frequency (70 Hz) as long as the ΔK values are sufficiently low. The frequency dependence of the crack velocities associated with the transition from intergranular to transgranular cracking shows a linear relationship with the square root of the loading cycle period, implying that the rate-controlling step is consistent with grain boundary diffusion of hydrogen during the loading cycle.

Corrosion fatigue can be prevented by using high-performance alloys resistant to corrosion fatigue; but for most engineering applications this approach may not be practical because of the availability and cost of these alloys. In general, methods that reduce corrosion rate and/or cyclic damage can be beneficial for eliminating corrosion fatigue damage. While effective coatings and inhibitors can delay the initiation of corrosion fatigue cracks, improving surface conditions is also very useful. Compared with reducing the maximum stress level, it is often more beneficial and more cost effective to reduce the magnitude of the stress fluctuation.

A. INTRODUCTION

The effect of flow on corrosion is complex and varied and is dependent on both the chemistry and physics of a system. The effect of chemistry is typical of most corrosion mechanisms except that flow has a significant effect on the kinetics of the corrosion reactions and the phases participating in the corrosion reaction. These effects are related to the influence of flow on the movement, distribution, and mixing of fluids in the flowing system.

The key variable defining the effect of flow on corrosion is turbulence. High turbulence can result in flow-induced corrosion, erosion–corrosion, or cavitation. Low turbulence can result in corrosion in a separated water phase and allows the occurrence of corrosion under deposits and/or in separated liquid water. The emphasis is on flow in pipes since pipe flow is the location of the vast majority of flow-induced corrosion problems.

"Flow-induced corrosion" is the term used to describe the increase in corrosion resulting from high fluid turbulence due to the flow of a fluid over a surface in a flowing single or multiphase system. "Underdeposit corrosion" is the term used to describe the increased corrosion occurring in a separated water phase beneath deposits of nonmetallic solids on a metal surface resulting from low-flow turbulence.

A clear understanding of the difference between flow-induced corrosion and "erosion–corrosion" aids in the discussion. The two are not the same, as indicated by the definitions of these terms in the Glossary. Flow-induced corrosion is the increase in corrosion resulting from increased fluid turbulence intensity and mass transfer as a result of the flow of a fluid over a surface. Erosion–corrosion is the increased corrosion due to the physical impact on a surface causing mechanical damage. The impact can be from solid particles entrained in a liquid or gas phase or liquid droplets entrained in a gas phase. The effect of erosion on corrosion is covered in Chapter 18, Erosion–Corrosion in Single- and Multiphase Flow.

B. FLOW BASICS RELATED TO CORROSION

Corrosion is a surface phenomenon, and, as such, what goes on at the metal surface has a profound effect on corrosion. Many aspects of fluid dynamics relate to and define the interactions of a fluid with the surface that are important to corrosion.

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie
Copyright © 2011 John Wiley & Sons, Inc.

When a fluid flows over a solid surface, the flow is characterized as either laminar or turbulent. In most situations where the effect of fluid flow on corrosion is important, the flow is turbulent; so the physical structure of turbulent flow is a primary consideration. A number of possibly unfamiliar terms introduced in this chapter are defined in the Glossary. The definitions of symbols used in equations are given in the Nomenclature at the end of this chapter.

B1. Turbulent Boundary Layer

Fully developed turbulent flow consists of a turbulent core where the mean velocity is essentially constant and a boundary layer of varying fluid velocity near the solid–fluid interface. The majority of the changes in fluid stress characteristics, turbulence, mass transfer, and fluid interaction with the wall occur within this boundary layer.

All mean and turbulent velocity components of the flow must go to zero at the wall and must be very small in the immediate vicinity of the wall. Therefore, the components of all turbulent stresses must also go to zero at the wall, leaving only the viscous stresses of laminar flow to act on the wall. This layer near the wall within the boundary layer, where viscous forces dominate over turbulent forces and flow is laminar-like, is termed the viscous sublayer. There is a transfer of turbulent energy from the outer layer to the viscous sublayer and a turbulent diffusion of energy from the laminar sublayer to the outer layer at approximately equal rates for established flow. A diagram of these layers and the transfer processes is shown in Figure 17.1 [1].

The calculated boundary layer thickness generally referred to in the corrosion literature is related to and representative of the physical boundary layer but is actually a defined thickness that is a linear approximation [2]. This approximation for the diffusion boundary layer ($\delta_{\mathbf{d}}$) and the hydrodynamic boundary layer (δ_ν) is shown graphically in Figure 17.2 [3]. The approximation assumes that the flowing fluid can be broken down into two parts: (1) a thin boundary layer near the solid surface and (2) the bulk solution, and that the transition occurs abruptly, defining the boundary layer thickness. The basic assumption is that momentum and mass transport occur by viscous flow and diffusion within the boundary layer, as measured by the mass transfer coefficient (k) and the shear stress (τ), and by turbulent flow and convection outside the boundary layer [2].

The turbulent boundary layer is further resolved into three regions: an outer "logarithmic" region ($30 < y_+ < 100$), an intermediate "buffer" region ($5 < y_+ < 30$), and, very close to the solid wall, a "viscous" region ($y_+ < 5$), where y_+ is the dimensionless viscous length perpendicular to the wall, defined as $\boldsymbol{y}_+ = \boldsymbol{y}\boldsymbol{u}_\tau/\boldsymbol{\nu}$ [4]. A diagram of these layers along with an idealized plot of the normalized turbulent velocity variation is shown in Figure 17.3 [4]. Experimental details of the variation in boundary layer turbulence with distance from the wall are given by Kline et al. in their extensive study into the structure of the turbulent boundary layer [3].

The nature of the turbulent boundary layer dictates that this is where the processes that control corrosion and film formation will occur. The majority of the movement of corroding species to, and of corrosion products from, the wall and chemical reactions with the wall must occur in this region. Therefore, any disturbance in the turbulent boundary layer must be a primary factor affecting the corrosion process.

B2. Boundary Layer Disruption

Disruption of the boundary layer in turbulent flow occurs primarily by the formation of turbulent bursts and sweeps. The turbulent burst is an ejection of fluid from the wall, which also causes fluid to impinge on the wall by the simultaneous formation of sweeps, or movement of fluid toward the wall. Turbulent bursts and sweeps occur through the formation of vortices and the lift-up of wall streaks [5].

One process of vortex formation and evolution into a turbulent burst proposed by Praturi and Brodkey [6] is illustrated in Figure 17.4. The vortex moves with the flow and is increasingly tilted by the mean shear in the viscous

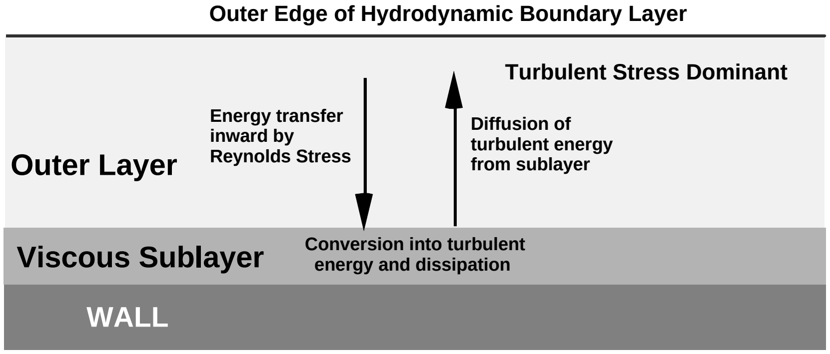

FIGURE 17.1. Basic structure of turbulent boundary layer and associated mechanical energy flow within the boundary layer [1].

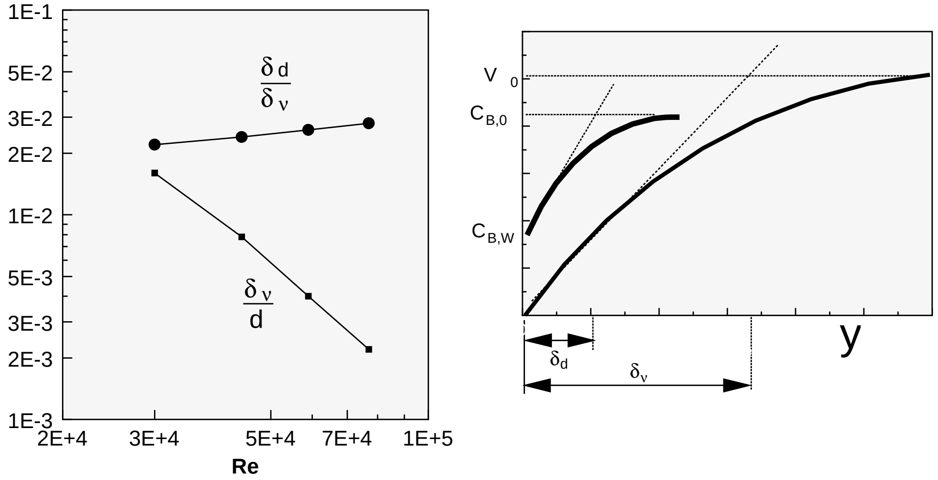

FIGURE 17.2. Relative boundary layer thickness (δ) for concentration (c) and velocity (v) profiles in a turbulent flowing fluid (solid line = true profile; dotted line = linear approximation) [3].

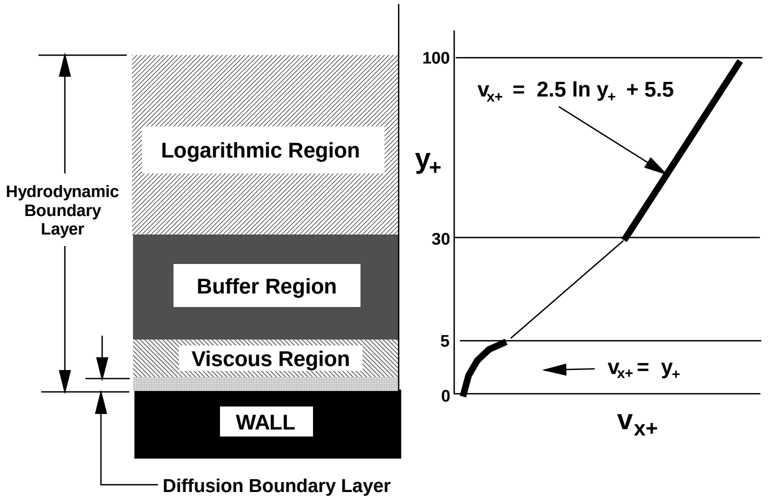

FIGURE 17.3. Structure of the turbulent boundary layer with an idealized plot of the normalized turbulent velocity variation with distance from the wall, expressed as dimensionless viscous length [4].

region (stages 1–4). At some point, the vortex becomes unstable and a strong ejection occurs along with a rapid sweep of fluid into the viscous region (stage 5). It is evident that severe pressure fluctuations must occur with the formation of a turbulent burst and during the rapid ejection of fluid.

A slightly different model of the bursting process is given by Often and Kline, where a description of the complete burst cycle is given [7]. In this model, bursting is associated with wall streaks and stretched and lifted vortices. All of the current theories of wall turbulence agree in the basic structure of the turbulence, that is, the existence and interaction of turbulent bursts, ejections, sweeps, and wall streaks. The differences lie in the mechanisms of formation of these structures and the details of their interaction.

An excellent review of the present understanding of the turbulent boundary layer structure is given by Robinson [8]. As a result of this review, Robinson concluded that coherent motions exist in the viscous region, that they consist of elongated, unsteady regions of high- and low-speed streaks, and that sweep motions dominate the viscous region. The majority of the coherent flow structures occur in the buffer region of the turbulent boundary layer, with only sweeps and ejections penetrating into the viscous layer [8]. Laser Doppler measurements have clearly demonstrated the presence of turbulence in the viscous region near the wall as shown in Figure 17.5 [4].

The relationship of turbulent structures in the boundary layer, specifically near wall bursting activity, and fluctuations

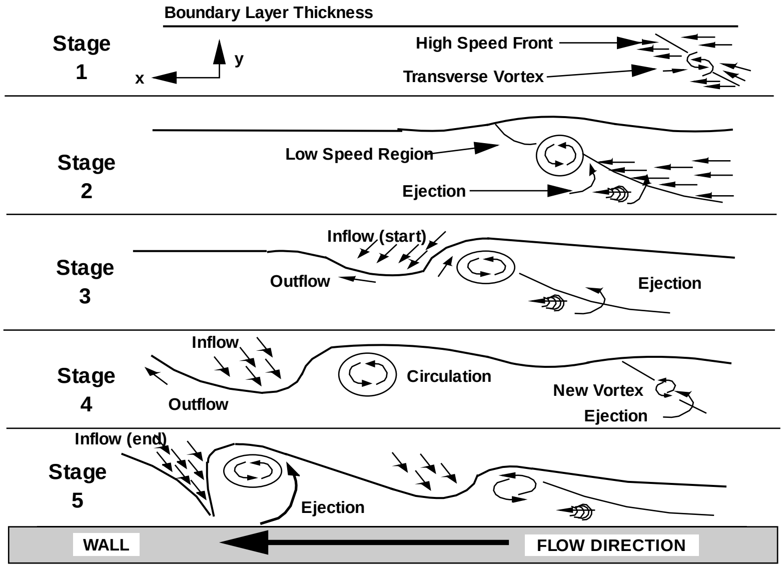

FIGURE 17.4. Progression of near-wall flow illustrating the formation of shear layer vortices and evolution into turbulent bursts [6].

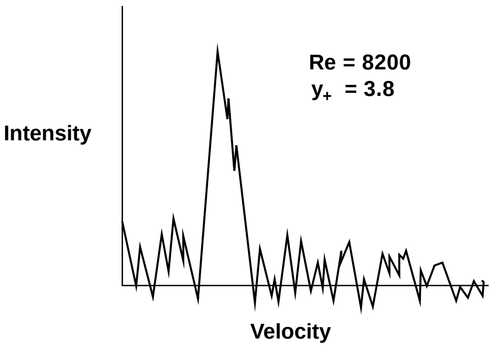

FIGURE 17.5. Laser Doppler measurements at $y_+ = 3.8$, showing turbulence inside viscous region for water flowing in rectangular pipe. The large peak is the main velocity component, and the small peaks represent instantaneous velocity fluctuations [4].

in the wall shear stress and wall pressure were measured by Thomas and Bull [9]. A diagram of their results is given in Figure 17.6. This work provides evidence of significant variations in wall shear stress related to the boundary layer turbulence generation process that could have a major effect on corrosion processes.

B3. Flow Parameters

Fluid flow must be expressed in terms broadly related to flow parameters that are common to all hydrodynamic systems and that effectively define the interaction of the fluid with the metal surface. The parameters that best fit this requirement are wall shear stress (τ**w**) and mass transfer coefficient (k). These parameters are calculated from empirical equations developed to characterize fluid flow.

B3.1. Wall Shear Stress. Wall shear stress is a direct measure of the viscous energy loss within the turbulent boundary layer and is related to the intensity of turbulence in the fluid. It is defined as the isothermal pressure loss in a moving fluid within an incremental length due to fluid friction as a result of contact with a stationary wall. The mathematical definition of wall shear stress, τ_w, is as follows. [2] The total shear stress, τ, in a fluid moving past a fixed wall is the sum of the viscous and turbulent stresses, expressed as

$$\tau = \nu\left(\frac{\partial \bar{U}}{\partial y}\right) - u_x u_y \tag{17.1}$$

where

ν = kinematic viscosity (m^2/s)
U = mean velocity (m/s)
y = direction $\perp$ to the surface (m)
u_x, and u_y = fluctuating velocity component (m/s) in the x and y direction

The Reynolds stresses ($u_x u_y$) go to zero at the wall, leaving only the viscous stress in the fluid. The wall shear stress, τ_w, is defined as this viscous shear stress at the wall ($y = 0$), expressed as

$$\tau_w = \nu\left(\frac{\partial U}{\partial y}\right)_{y=0} \tag{17.2}$$

B3.2. Mass Transfer Coefficient. Mass transfer defines the chemical and electrochemical effects of fluid flow. It relates to the transport of reactive chemical species from the bulk solution to and from the solid surface through the boundary layer. It defines the movement of corrosive species to the metal surface and the movement of corrosion products away

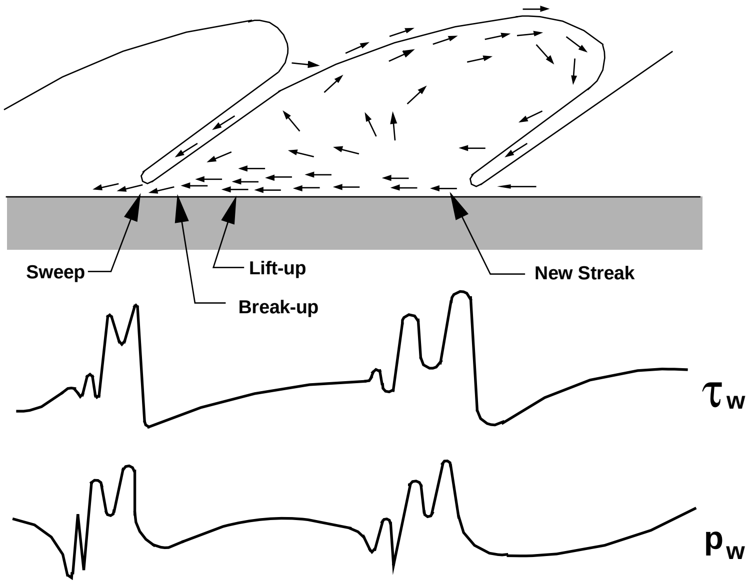

FIGURE 17.6. Wall shear stress and wall pressure fluctuations in relation to location of near-wall bursting activity in turbulent boundary layer [9].

from the metal surface. The diffusion layer, in which the mass transfer occurs, is roughly defined by the diffusion mass flux density ($N_{b,y}$) as expressed in the Nernst diffusion model [10]:

$$N_{j,y} = -D_j\left(\frac{dC_j}{dy}\right)_y = -D_j\frac{C_{j,0} - C_{j,y}}{\delta_d} \tag{17.3}$$

where

$N_{j,y}$ = mass flux density of species j in the y direction (mol/m^2 s)
D_j = diffusion coefficient for species j (m^2/s)
C_j = concentration of species j (mol/L)
δ_d = diffusion boundary layer thickness (m)

The mass transfer coefficient, k_d, is defined as the proportionality between the mass flux density and the concentration gradient, expressed as

$$k_d = \frac{N_{j,y}}{C_{j,0} - C_{j,y}} \tag{17.4}$$

Substituting the definition of the flux density from Eq. (17.3), the mass transfer coefficient is defined as

$$k_d = \frac{D_j}{\delta_d} \tag{17.5}$$

B3.3. Interrelationship of Mass Transfer Coefficient and Wall Shear Stress. Mass transfer is related to wall shear stress in that changes in flow parameters that affect one result in changes in the other. The diffusion coefficient can be related to the wall shear stress by the Chilton–Colburn analogy:

$$k_d \approx \left(\frac{\tau_w}{\rho}\right)^{0.5} \tag{17.6}$$

where ρ is fluid density (kg/m^3). This relationship is more precisely defined as

$$k_d = 17.24\left(\frac{\tau_w}{\rho}\right)^{0.5} Sc^{2/3} \quad \text{for Sc} > 100 \tag{17.7}$$

where Sc is the Schmidt number.

C. FLOW REGIME AND FLOW CORROSION

C1. Single-Phase Flow

Single-phase flow consists of only one phase, gas or liquid. In single-phase aqueous systems there is a flow pattern that consists of a turbulent core and a boundary layer near the solid–fluid interface as described earlier. All of the mass and momentum transfer to the boundary layer occurs through this turbulent core. The equations and relationships discussed in the sections on wall shear stress and mass transfer are directly applicable to the single-phase flow situation.

C2. Multiphase Flow and Flow Regime

For multiphase flow the volume flow rates of the various phases affect the resulting flow pattern, called the "flow regime." The flow regime is a primary consideration in the determination of flow-induced corrosion in multiphase flow. The basic criterion for flow-induced corrosion in multiphase

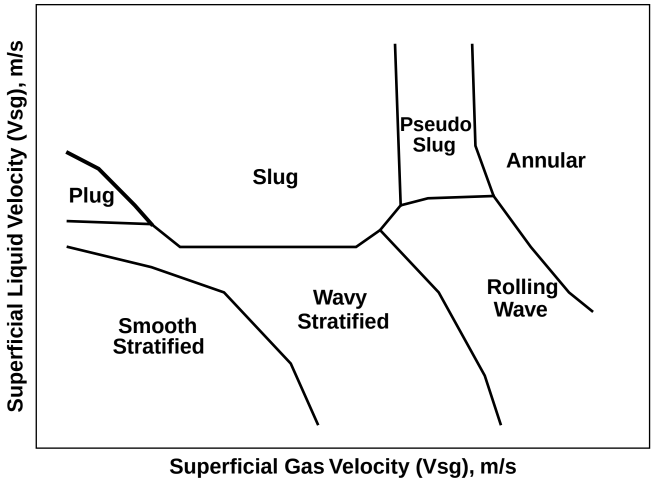

FIGURE 17.7. Typical gas–liquid flow regime map showing boundaries between various regions [11].

flow is that a liquid corrosive phase be present and be in contact with the metal surface. The flow regime affects the turbulence in the liquid phase, the location of the liquid phase in the flowing stream, and whether or not solids can settle out of the flowing stream. An example of a flow regime map showing the flow regimes encountered in multiphase gas–liquid horizontal flow is given in Figure 17.7 [11].

The bubbly flow regime occurs in liquid systems with low gas and high liquid rates. Stratified flow occurs at low liquid rates or when a liquid phase condenses. The liquid in stratified flow is generally stagnant or very low flow, with low turbulence.

Slug flow occurs at higher liquid flow rates and is characterized by very high turbulence, with a corresponding influence on corrosion [10]. This flow regime has the most severe effect on corrosion.

Annular flow occurs at very high gas rates over a wide range of liquid production rates. Turbulence in annular flow with respect to the effects on corrosion is not well characterized.

A diagram of the flow regimes encountered in gas–water horizontal flow is given in Figure 17.8 [11] and hydrocarbon–water flow in Figure 17.9 [12]. When a hydrocarbon phase is present, the significant aspect of the flow regime with respect to corrosion is the separation of the hydrocarbon and water–liquid phases, or the level of turbulence required to eliminate the water phase as a separate entity contacting the metal wall.

A diagram of the flow regimes encountered in gas–hydrocarbon–water horizontal flow and the flow regime map is given in Figure 17.10 [13]. Gas–hydrocarbon–water flow combines the characteristics of the gas–water and hydrocarbon–water flow regimes. The gas phase adds a high degree of turbulence, but the primary corrosion concern is the contact of water with the metal wall.

The flow regime maps shown are for horizontal flow and are significantly altered for inclined flow [14]. The effect of inclination is particularly important for the occurrence and severity of slug flow with upward inclination, where both the frequency and intensity of the slug increases [14]. This is particularly significant due to the effect of slug flow on turbulence and corrosion [13].

A generalized summary of the types of corrosion expected for the various flow regimes, along with the location of free

water and the water turbulence, is outlined in Table 17.1 [15]. The flow regimes where either underdeposit corrosion or flow-induced corrosion is expected are given in this table.

C3. Effect of Disturbed Flow

Flow-induced corrosion failures in many environments occur in areas where fully developed flow patterns are disrupted, termed regions of disturbed flow [15–18]. Examples of these disturbed flow locations are:

- Downstream of weld beads, at pipe joints and upsets
- Downstream of pipe fittings, at preexisting pits
- Downstream of valves, at bends and elbows in piping
- Downstream of orifice plates, at heat exchanger tube inlets

The flow disturbance destroys the fully developed hydrodynamic boundary layer and the diffusion boundary layer. The effect of this boundary layer disruption is the production

TABLE 17.1. Flow Regime Influence on Corrosion Type [15]

Flow Regime	Free Water Location	Water Turbulence	Corrosion Type
Gas/water			
Stratified flow	Bottom	Stagnant to laminar	Underdeposit corrosion Pitting of stainless steels
Slug flow	Mostly bottom, mixed	Very turbulent	Flow-induced corrosion
Annular flow	Circumferential	Turbulent	Flow-induced corrosion
Gas–liquid–water			
Stratified flow	Bottom, separated	Stagnant to laminar	Underdeposit corrosion Pitting of stainless steels
Slug flow	Mostly bottom, mixed	Very turbulent	Flow-induced corrosion
Annular flow	Circumferential	Possibly turbulent	Flow-induced corrosion
Liquid–water			
Segregated flow	Bottom	Stagnant to laminar	Underdeposit corrosion Pitting of stainless steels
Mixed flow	Mostly bottom, mixed	Laminar to turbulent	Underdeposit corrosion
Dispersed flow	Mixed	Turbulent	Flow-induced corrosion[a]

[a]Only if the hydrocarbon water mixed phase is water external, that is, contacts the pipe wall.

of a steady-state condition as opposed to an equilibrium condition. In this case, the normal equilibrium corrosion reactions cannot be maintained, and a steady-state condition is established. The result is increased corrosion at the location of the flow disturbance, although the corrosion rate in the rest of the pipe wall is low. The corrosion pattern appears as large pits or corroded areas, often showing the signs of flow direction. A schematic of the effect of disturbed flow over a weld bead is shown in Figure 17.11 [15].

C4. Low-Turbulence-Flow Corrosion

Low-turbulence-flow corrosion occurs in multiphase flow for a stratified flow regime and in single-phase flow containing solids where the turbulence is insufficient to keep the solids suspended. In low-turbulence conditions where solids are present deposits can accumulate at the bottom of a horizontal or slightly inclined line. A schematic showing the occurrence of corrosion under the accumulation of deposits in the bottom of a pipeline is shown in Figure 17.12. An example of the severe corrosion that can occur in the bottom of a pipeline under deposits is shown in Figure 17.13.

The presence of the solids deposit can also result in crevice corrosion of susceptible alloys, where the deposited solids form a crevice on the metal underneath. This can result in a differential aeration or differential metal ion concentration corrosion cell. This can result in a galvanic interaction between the steel under the deposit and that outside the deposit. The deposit can also allow bacteria to proliferate, resulting in microbiologically induced corrosion (MIC). Colonies of bacteria grow under the deposits and are protected by the deposits.

For passive metals such as stainless steels, the area under the deposit can lose passivity, resulting in an active–passive galvanic couple. The area under the deposit can acidify just as in a traditional crevice, accelerating corrosion in that area. This is particularly severe when the water phase contains chlorides.

Liquid and possibly solids accumulation in gas lines can be present in areas of liquid holdup. This occurs primarily on

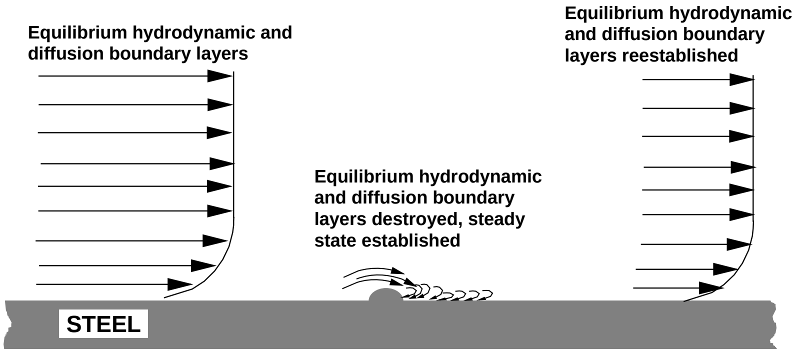

FIGURE 17.11. Effect of disrupted flow over weld bead on boundary layer [15].

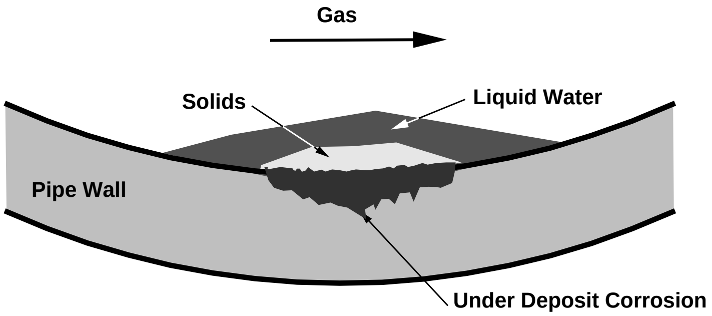

FIGURE 17.12. Occurrence of corrosion under water–solids deposits in bottom of pipeline at locations where liquid holdup occurs.

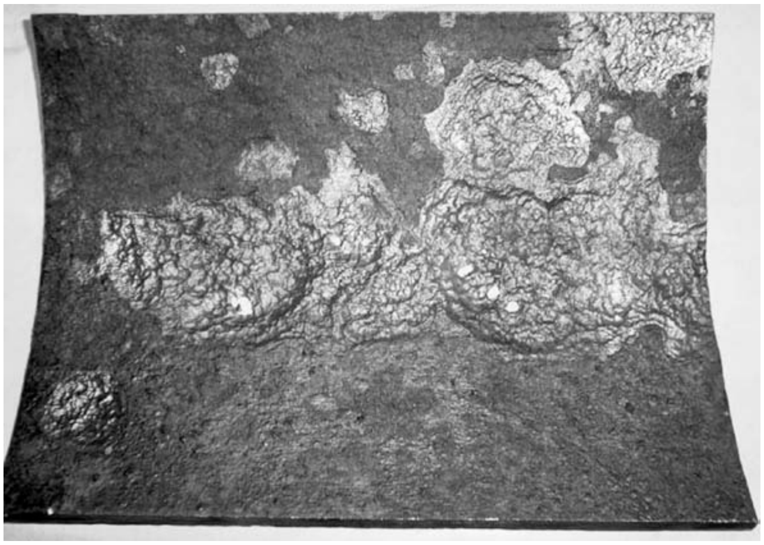

FIGURE 17.13. Corrosion in bottom of pipeline resulting from solids deposits under low-flow conditions.

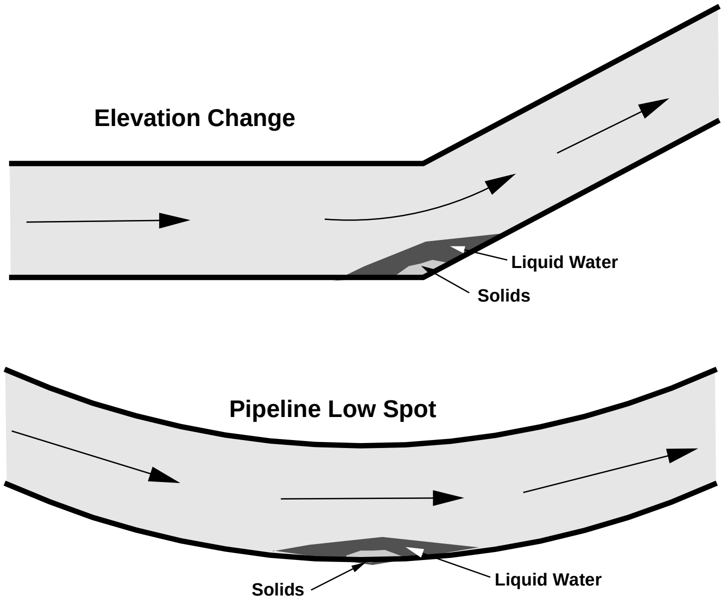

FIGURE 17.14. Locations where liquid holdup and solids deposition can occur.

areas of upward elevation change or at low spots, as shown in Figure 17.14. In these areas, gas moves across the top of the accumulated water, but the actual flow in the water is generally very slow to stagnant. Even with a high gas flow rate through the pipeline, the liquid flow in the areas of liquid holdup is sufficiently low to allow entrained solids to drop out from the liquid stream and settle to the bottom of the pipeline.

NOMENCLATURE

C	Concentration (mol/L)
D	Diffusion coefficient (m^2/s)
d	Diameter, m
e	Roughness factor, m
i	Current density, A/m^2
K	mass transfer coefficient (m/s)
L	Characteristic length, m
N	Mass flux density (mol/m^2s)
P	Pressure, Pa, kg/m s^2
$R_{\mathbf{cor}}$	Corrosion rate, mm/y, mpy
r	Radius or radial distance, m
T	Temperature, °C
t	Time, s
U	Mean velocity, m/s
u	Local velocity fluctuation, m/s
x	Direction parallel to surface, m
y	Direction perpendicular to the surface, m
y_+	Viscous length $= yu\tau/\nu$, dimensionless
z	Direction parallel to the surface but perpendicular to the flow direction, m

Greek Symbols

Δ	Gradient of a property
δ	Boundary layer thickness (m)
ρ	Density (kg/m^3)
μ	Dynamic viscosity (kg/m s)
ν	Kinematic viscosity (m^2/s)
τ	Shear stress (N/m^2)

Subscripts

b	Boundary layer
cor	Corrosion
d	Diffusion
f	Final or ending
i	Initial or beginning
j	Species "*j*"
lim	Limiting
0	Standard or primary
t	Value at time t
w	Wall or electrode surface
x	Direction parallel to surface
y	Direction perpendicular to surface
$+$	Normalized dimensionless form

Dimensionless Groups

f	Friction factor, $\dfrac{(2\tau)}{(\rho U^2)}$
Re	Reynolds number, $\dfrac{(\rho U d)}{\mu}$
Sc	Schmidt number, $\dfrac{\mu}{(\rho d)}$
Sh	Sherwood number, $\dfrac{(kd)}{D}$

A. INTRODUCTION

Erosion–corrosion encompasses a wide range of flow-induced corrosion processes. Flowing fluids can damage protective films on metals resulting in greatly accelerated corrosion. Damage to the films may be the result of mechanical forces or flow-enhanced dissolution and the accelerated corrosion may be accompanied by erosion of the underlying metal. This conjoint action of erosion and corrosion is known as erosion–corrosion [1]. Impingement attack by liquid droplets and solid particles and cavitation attack are also included here under this broad definition of erosion–corrosion. In practice, the relative contributions of *accelerated corrosion* and erosion to the total metal loss vary widely with the type of erosion–corrosion and the hydrodynamic intensity of the flow.

B. FLOW CONDITIONS

Erosion–corrosion normally occurs under *turbulent-flow* conditions. The flowing fluid may be single phase (Fig. 18.1) as in the erosion–corrosion of copper tubing by potable water (Fig. 18.2). Multiphase flows [2–4] (Fig. 18.3) with various combinations of gas, water, oil, and sand can cause severe erosion–corrosion of oil/gas production systems [5–7] as shown in Figures 18.4–18.6

The most severe erosion–corrosion problems occur under conditions of *disturbed* turbulent flow [8, 9] at sudden changes in the flow system geometry, such as bends, heat exchanger tube inlets, orifice plates, valves, fittings, and turbomachinery, including pumps, compressors, turbines, and propellers. Surface defects in the form of small protrusions or depressions such as corrosion pits, deposits, and weld beads can give rise to disturbed flow on a smaller scale but sufficient to initiate erosion–corrosion [10, 11]. The presence of suspended solid particles, gas bubbles, or vapor bubbles in aqueous flow and liquid droplets in high-speed gas flow can be especially damaging.

C. PROTECTIVE FILMS

Most metals and alloys used in industry owe their corrosion resistance to the formation and retention of a protective film. Protective films fall into two categories:

- The relatively thick porous *diffusion barriers* such as those formed on carbon steel (red rust) and copper (cuprous oxide)
- The thin invisible *passive films* such as those on stainless steels, nickel alloys, and other passive metals such as titanium

Diffusion barriers are typically formed by anodic dissolution followed by precipitation whereas passive films are formed by direct oxidation without the metal ions entering the solution. The softer thicker diffusion barriers are more easily damaged and more slowly repaired than the passive films, and passive alloys can withstand much more severe service conditions.

D. EROSION–CORROSION RATE

The effect of film destruction on the corrosion rate is illustrated by the following example. Carbon steel pipe carrying water is usually protected by a film of rust, which slows down the rate of mass transfer of dissolved oxygen to the pipe wall. The resulting corrosion rates are typically <1 mm/a. The removal of the film by a flowing sand slurry gives corrosion rates of the order of 10 mm/a in addition to any erosion of the underlying metal [12]. When corrosion is controlled by the rate of dissolved oxygen mass transfer, the corrosion rate can be calculated by the application of well-established mass transfer correlations of dimensionless groups. In general,

$$\mathrm{Sh} = \alpha\, \mathrm{Re}^{\beta}\, \mathrm{Sc}^{\gamma}$$

where

Re $= l u_b \rho / \mu$, Reynolds number, ratio of inertial forces to viscous forces

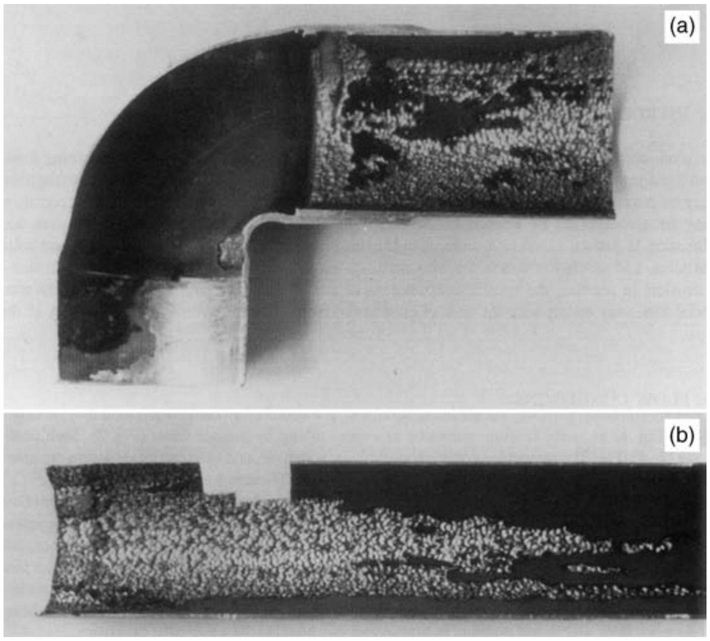

FIGURE 18.2. Erosion–corrosion of 53-mm copper tubing by potable water. (a) The attack started at the step whore the tubing fitted into the elbow.(b) Once started, the attack progressed along the tube as a result of additional disturbed flow created by the erosion–corrosion roughened surface.

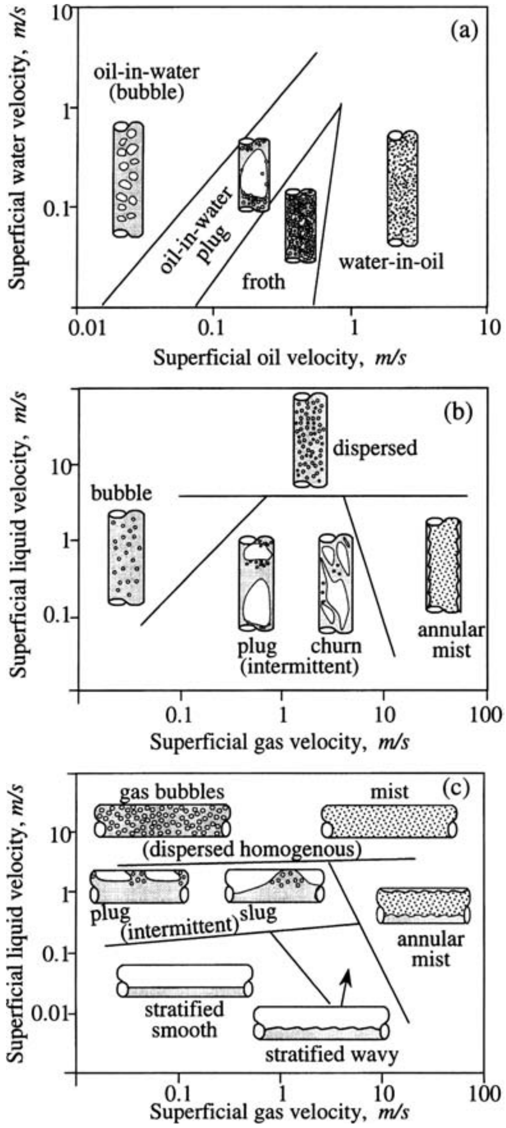

FIGURE 18.3. Qualitative two-phase flow structures in pipes: (a) oil–water in vertical pipe; (b) liquid–gas in vertical pipe; (c) liquid–gas in horizontal pipe. (Adapted from Lotz [2], Weisman [3], and Govier and Aziz [4].)

Sc = $\mu/\rho D$, Schmidt number, ratio of momentum diffusivity to mass diffusivity
Sh = kl/D, Sherwood number, ratio of convective mass transport to diffusive transport
k = mass transfer coefficient, m/s
l = characteristic dimension (e.g. pipe diameter), m
D = diffusion coefficient, m^2/s
u_b = bulk flow velocity, m/s
μ = viscosity, Pa·s
ρ = density, kg/m^3
α,β,γ = experimental constants

The Berger–Hau [13] correlation, one of the most widely accepted mass transfer correlations for fully developed turbulent flow in smooth pipes, gives $\alpha = 0.0165$, $\beta = 0.86$, and $\gamma = 0.33$. Based on the above correlation, a corrosion rate (CR in mm/a) calculated using the rate of mass transfer of dissolved oxygen to a film-free carbon steel pipe wall is given by

$$\mathrm{CR} = 4923 C_b \left(\frac{D_{\mathrm{O}_2}}{d}\right) \mathrm{Re}^{0.86}\, \mathrm{Sc}^{0.33}$$

where
C_b = bulk oxygen concentration, mol/m^3
D_{O_2} = diffusion coefficient for oxygen in water, m^2/s
d = pipe diameter, m

This calculation assumes that two-thirds of the oxygen reaching the wall is used in oxidizing the iron to ferrous ions and that one-third is used in the oxidation of the ferrous ions to ferric ions close to the wall [12]. On this basis, a 100-mm-diameter pipe carrying an aerated aqueous solution with $C_b = 8$ ppm $\equiv 0.25$ mol/m^3 of dissolved oxygen, $D_{O_2} = 2 \times 10^{-9}$ m^2/s flowing at 2 m/s would corrode at 7 mm/a.

The above calculation demonstrates the aggressive nature of erosion–corrosion and gives an indication of the high and unacceptable rates of corrosion whenever a protective film is damaged by erosion. Uniform erosion–corrosion and fully developed mass transfer is assumed. In practice erosion–corrosion often occurs under disturbed flow conditions at localized areas. Consider, for example, iron, where the rust film formed at ambient temperatures is a poor cathode for oxygen reduction. The rate of oxygen mass transfer (and corrosion) at the small surface area where the protective film is removed will be substantially enhanced by:

- The disturbed flow effect [9, 14, 15]
- The mass transfer entrance length effect [16]
- The surface roughness effect [17] shown in Figure 18.7

In addition, the situation may be complicated by the formation of flow-induced macroscopic corrosion cells following localized film disruption with differing behavior observed for copper and iron alloys [18].

E. RELATIVE ROLES OF EROSION AND CORROSION

The *accelerated corrosion*, following damage to the protective film, may be accompanied by *erosion* of the underlying metal. In some cases the erosion of the base metal is not a factor. In other cases erosion is the predominant factor and a wide spectrum of behaviors is observed [19]. The relative roles of corrosion and erosion following damage to the

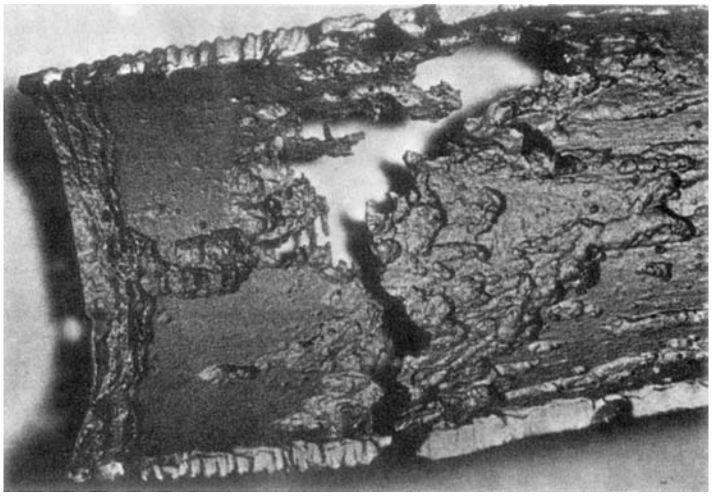

FIGURE 18.4. Erosion–corrosion of 115-mm API L-80 oil well tubing. Environment: Crude oil/CH_4/CO_2 and 1% H_2O in tight emulsion; temperature 200°C; velocity 6.4–7.9 m/s. Corrosion rate >10 mm/y. Temperature: 79°C. Exit velocity from valve 91 m/s. Remedy: replacement with 13 Cr martensitic ss. (From Houghton and Westermark [6]. Reprinted by permission of NACE International.)

protective film can be estimated (Table 18.1) on the basis of the exponent y in the relationship between the metal loss rate and the bulk flow velocity, u_b [2]:

$$\text{erosion} + \text{corrosion} \propto u_b^y$$

The value of y will depend on the relative contributions of corrosion and erosion to the total metal loss. In disturbed flow it is the flow characteristics in the direct vicinity of the wall rather than the bulk flow velocity that are important. In practice, however, the superficial flow velocity is the flow parameter that is readily measured and controlled [2].

F. EROSION–CORROSION MECHANISMS

The sources of the various *mechanical* forces involved in the erosion of protective films and/or the underlying metal at flow system walls (Fig. 18.8) are:

- Turbulent flow, fluctuating shear stresses, and pressure impacts
- Impact of suspended solid particles
- Impact of suspended liquid droplets in high-speed gas flow

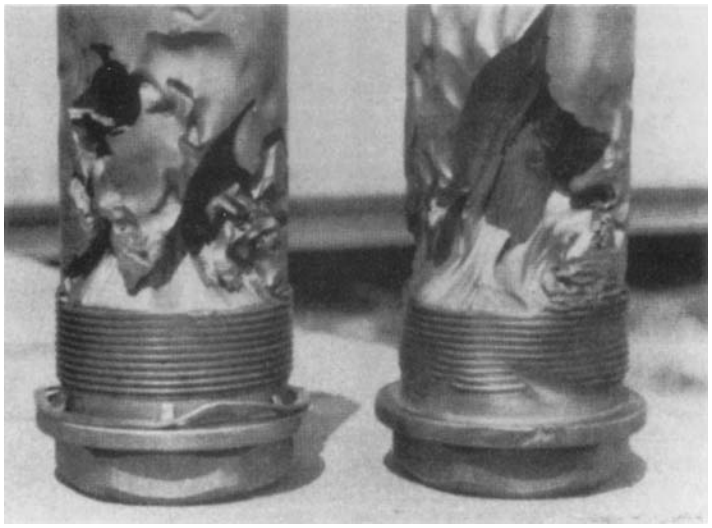

FIGURE 18.6. Erosion of tungsten carbide choke beans inside a steel holder from an oil well with sand production. Note the highly polished, streamlined appearance of the erosion pattern. Subcritical flow occurred in this well and these assemblies lasted between 6 and 9 months. (From Smart [7]. Reprinted by permission of NACE International.)

TABLE 18.1. Flow Velocity as Diagnostic Tool for Erosion–Corrosion Rates Following Damage to Protective Film

Mechanism of Metal Loss	Velocity Exponent, *y*
Corrosion	
Liquid-phase mass transfer control	0.8–1
Charge transfer (activation) control	0
Mixed (charge/mass transfer) control	0–1
Activation/repassivation (passive films)	1
Erosion	
Solid-particle impingement	2–3
Liquid-droplet impingement in high-speed gas flow	5–8
Cavitation attack	5–8

- Impact of suspended gas bubbles in aqueous flow
- Violent collapse of vapor bubbles following cavitation

Flow-enhanced film dissolution and thinning are “chemical” forms of protective film erosion leading to accelerated corrosion of the underlying metal.

F1. Turbulent Flow

Erosion–corrosion occurs in single-phase turbulent pipe flow. The exact mechanism of protective film damage is still in doubt. There is uncertainty regarding the roles of mechanical forces and mass transfer in film disruption [20–22] since both are directly related to the turbulence intensity.

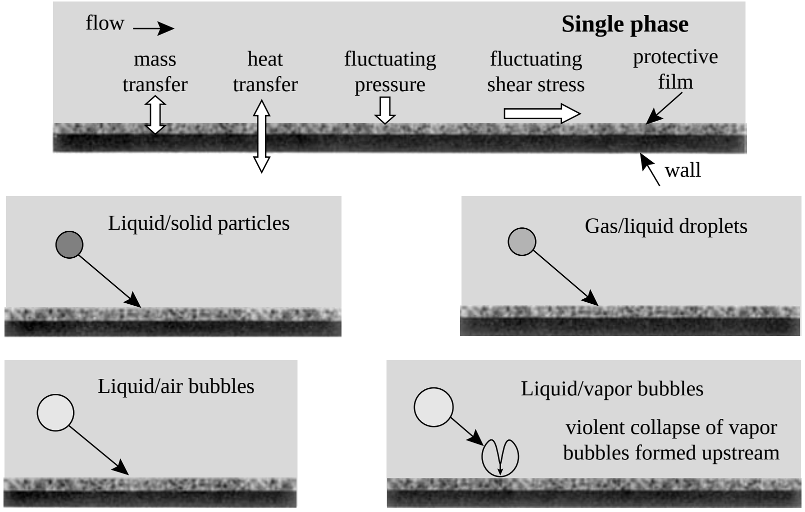

FIGURE 18.8. Interaction of flowing fluid with wall of the flow system leading to erosion–corrosion. (Adapted from Heitz [18].)

Distinct "breakaway" velocities above which damage to normally protective films occurs in copper alloy tubes are observed [20] and this gave rise to the concept of a *critical shear stress* for film disruption.

The wall shear stress τ_w for flow in pipes is given by

$$\tau_w = f(\tfrac{1}{2}\rho\, u_b^2)$$

where f is the Fanning friction factor [23]. In general [24]

$$f = f\left(\text{Re}, \frac{\varepsilon}{d}, \frac{\varepsilon'}{d}, m\right)$$

where ε is a measure of the size of the roughness projections, ε' is a measure of the arrangement of the roughness elements, and m is a form factor that is dependent on the shape of roughness elements.

For flow in smooth pipes

$$f = 0.046\,\text{Re}^{-0.2}$$

is valid to higher Reynolds numbers than the Blasius equation [25]. Values of the Fanning friction factor for both smooth and rough commercial pipes and tubes can be obtained from a Moody* chart [23]. For fully rough† pipe flow, f is independent of Re, and $\tau_w \propto u_b^2$.

* The Fanning friction factor should not be confused with the Darcy friction factor, which is four times greater and is used on some Moody charts.

† In flow through rough pipes, the roughness elements penetrate the boundary layer into the main fluid stream at high Re resulting in form drag, and, under fully rough conditions, the viscous forces become negligible.

Early attempts [26] to correlate film damage with the wall shear stresses in pipe flow based on the bulk flow velocity resulted in shear stress values (Table 18.2) that seem too low [20] to strip a corrosion product film unless it is very loosely adhering. The "breakaway" velocities u_{cr} shown in Table 18.2 were calculated from critical shear stress values. Design velocities for heat exchanger tubing should not be based on critical shear stress values for fully developed *non disturbed* tube flow since the flow is both developing and disturbed at the tube inlets. In fact, disturbed flow must be allowed for in most industrial systems. The values calculated from $0.5u_{cr}$ are also shown and can be compared to the "maximum recommended design velocities" [27]. The design velocity must clearly be chosen with care with previous experience in similar systems being the best guide.

In turbulent flow there are fluctuating shear stresses and pressures at the wall. The largest values are obtained during quasi-cyclic bursting events close to the wall which are said to be responsible for most of the turbulent energy production in the entire wall-bounded shear flow [28, 29]. This is true of both nondisturbed and disturbed pipe flows. In practice, film removal in single-phase aqueous flow is invariably associated with the vortices created under disturbed flow conditions produced by sudden macro- or microscale changes in the flow geometry. It is quite difficult to avoid microscale geometric imperfections in a flow system during experimental studies to determine critical shear stress values.

The films on passive alloys, such as stainless steels, are not usually damaged by single-phase aqueous flow [18, 30]. Rust films on carbon steel at ambient temperature are more mechanically stable than the protective films formed on copper. The compactness and protectiveness of rust films (FeOOH) increase with velocity [31]. The magnetite films formed in high-temperature water and sulfide films formed

on carbon steel have a high mechanical stability in single-phase aqueous flow [18]. Thus the velocity limit, around 1 m/s, suggested for copper tubing [32, 33] is lower than the velocities tolerated by carbon steel and low-alloy piping at ambient temperatures and much lower than the allowable velocities at elevated temperatures.

In *slug flow* [Fig. 18.3(c)] large but short-lived shear stress fluctuations are observed [2]. The slugs of liquid travel at much higher velocities than is encountered in single-phase liquid flows and have been suspected to be the cause of severe erosion–corrosion problems in oil/gas production systems.

F2. Solid-Particle Impingement

Solid-particle impacts can damage both types of protective films (thick diffusion barriers and thin passive films) leading to erosion–corrosion. The particles may also erode the underlying metal, adding to the overall metal loss.

As might be expected, the erosion rate ER is a function of the kinetic energy of the particles (proportional to u_p^2) and the frequency of impacts (proportional to u_p), and to a first approximation [2],

$$\mathrm{ER} \propto u_p^3$$

The kinetic energy of the particle normal to the wall will be determined by the *impact velocity* and *impact angle* along with the particle *density* and *size*. The impacts of small particles in aqueous slurries may be damped by the presence of a thick boundary layer at the wall [36]. In practice, hard abrasive slurries are often transported through mild-steel pipes with the particles finely ground. The erosion is reduced because of the smaller particle size and the lower flow velocity required to maintain the solids in suspension [37].

Both the impact velocity and the impact angle will be strongly affected by disturbed flow and this is where the most severe erosion is found in practice. Impact angles in non-disturbed turbulent pipe flow are $<5°$ whereas a wide range of angles will be encountered in disturbed flow [38]. Thus carbon–steel pipe can transport sand slurries with an *erosion* rate of $<$ 1 mm/a under nondisturbed flow conditions [12, 36] (Fig. 18.9). Similar sand slurry flows caused the erosive failure of a reducer located immediately downstream of a T-junction and pinch valve in eight days, illustrating [Fig. 18.9(c)] the very severe erosion that can occur under disturbed flow conditions [36].

In dilute slurries $<$5 vol % solids, the impact frequency and erosion rate are proportional to the *solids concentration* [8]. At higher concentrations particle–particle interference reduces this dependency [37, 39].

The *shape* of the particle [34] and the *microroughness* of the particle surface [40] influence the effective forces generated at the wall by the impact. Thus rounded sand particles, which were apparently smooth, resulted in erosion rates [39] two orders of magnitude greater than the erosion by glass beads in the same system. The difference in behavior was related to the micro-roughness of the sand particles, which could be seen at high magnification under an electron microscope.

The damage done will be strongly related to the *relative hardness* (Fig. 18.10) of the impinging particles and the flow system walls. Erosion drops dramatically [35, 37, 41] when the impacting particles are softer than the wall. For example, the Mohs hardness of coal is ~2, iron ore 6, and sand 7. Carbon steel pipe API 5LX or similar used for long-distance slurry transportation [42] has a Brinell hardness of ~120 (Mohs hardness ~3). Thus it might be expected that whereas coal slurries could possibly damage rust films and cause accelerated corrosion, there would be no erosion of the underlying metal. Sand, iron ore, and other hard minerals

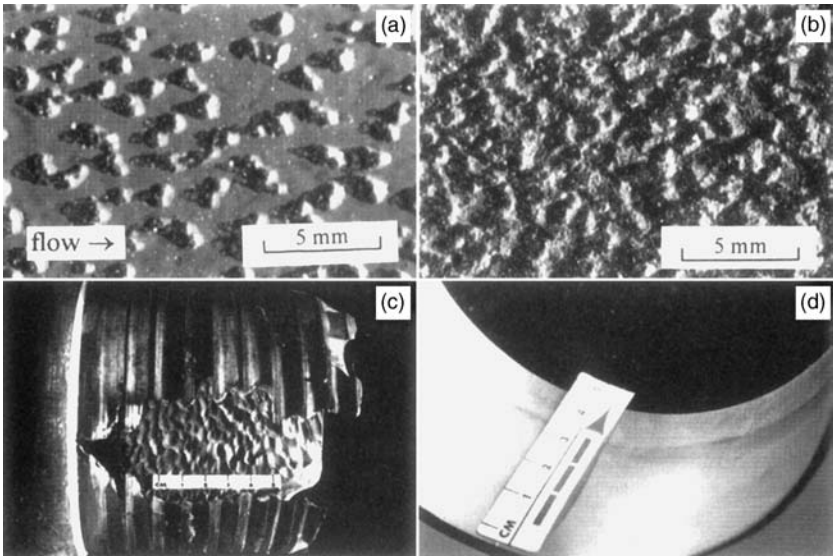

FIGURE 18.9. Variations in erosion–corrosion wear patterns in a 100-mm-diameter pipe carrying an abrasive sand slurry. (a) Developing erosion–corrosion wear pattern in nondisturbed flow showing individual pits. (b) Fully developed erosion–corrosion wear pattern with roughened surface. (c) Effect of disturbed flow, with failure of reducer placed downstream of T-junction and pinch valve in 8 days. [36]. Reprinted by permission of NACE International.)

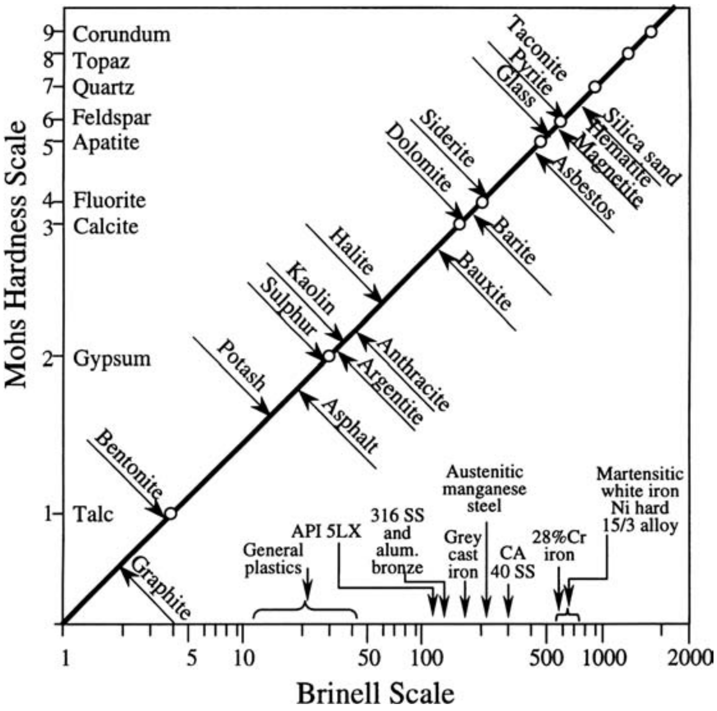

FIGURE 18.10. Approximate comparison of hardness values of various common minerals and metals. (Adapted from Wilson [55].)

could cause both accelerated corrosion and erosion. A complicating factor sometimes found with coal and other slurries is the presence of small amounts of silica and other hard minerals.

The ability of impacting particles to damage or interfere with the development of protective films is difficult to quantify in the absence of information regarding the mechanical properties of the in situ films [18] and in the case of passive films the damage and healing characteristics. In general, impacting particles will often damage protective films even under circumstances where they cannot erode the base metal. Lotz [2] has proposed that solid-particle damage to passive films with subsequent rapid repassivation will result in a corrosion rate directly proportional to the particle concentration and flow velocity. Any erosion of the underlying metal will increase the exponent on the velocity. Metal loss measurements [43] with dilute slurries in fully developed turbulent pipe flow resulted in values of the velocity exponent up to 3 for corrosion-resistant materials and values down to 1.4 for less corrosion resistant materials. Measurements [12] with sand slurries in carbon steel pipes gave an exponent close to 1 with erosion playing a minor role at the velocities involved. These two sets of results indicate the utility of using the velocity as a diagnostic tool to determine the relative roles of accelerated corrosion and erosion of the underlying metal discussed above.

Sand particles can play a major role in the erosion–corrosion of oil/gas production systems [5]. At low velocities accelerated corrosion is the major factor, whereas at the high velocities found in chokes erosion can lead to the rapid destruction of the component [7], as shown in Figure 18.6.

F3. Liquid-Droplet Impingement

Erosion by impinging liquid droplets carried in high-speed vapor or gas flows is usually called liquid impingement attack. The attack involves the exposure of the solid to repeated discrete impacts by liquid droplets which generate impulsive and destructive contact pressures far higher than those produced by steady flows [44]. Impingement erosion has been a problem with low-pressure steam turbine blades operating with wet steam and rain erosion of aircraft and helicopter rotors. Liquid-droplet impingement attack has much in common with cavitation attack [45] in terms of both the mechanism, which is largely one of deformation erosion, and the morphology of the attack, with continued deepening of discrete sharp-edged pits, which coalesce to a honeycomb-like appearance [46] (Fig. 18.11). Corrosion, as with cavitation attack, usually plays a secondary role, which varies with the hydrodynamic intensity.

F4. Air Bubble Impingement

The erosion–corrosion of copper alloy heat exchanger tube inlets has been linked [10] to the local damage of protective films by impinging air bubbles which have a substantial radial velocity component immediately downstream from the tubesheet inlets. Nitrogen bubbles [20] have a similar effect, and it seems clear that the damage to the film is hydromechanical. The attack, which initially takes the form of isolated "horse-shoes," spreads to a general roughening characteristic of erosion–corrosion. Similar horseshoe patterns were produced by small-scale turbulence at grain boundaries on dissolving solid benzoic acid [10] illustrating the role of hydrodynamics in the erosion–corrosion pattern produced on copper tubing.

F5. Cavitation

Cavitation attack takes the form of steep-sided pits, as shown in Figure 18.12 [33], which sometimes coalesce to form a honeycomb-like structure [45]. The attack is the result of the violent collapse of *vapor cavities*, or bubbles, <1 mm diameter [47, 48] that are formed in a flowing liquid when the hydrostatic pressure drops below the vapor pressure of the fluid. The cavities are carried downstream to higher pressure regions where collapse occurs. The *dynamic forces* associated with the collapse of the cavities at the walls of the system lead to high-frequency fatigue-stress damage. The shock waves from spherical collapse and microjets from asymmetrical collapse have both been suggested as the cause of the damage. The inconsistencies with previous theories are now considered to be explained by the concept of the collapse of clusters of cavities in concert [47]. Cavitation attack often involves an induction period, especially for ductile materials, following which the erosion rate is nonlinear [49]. The time

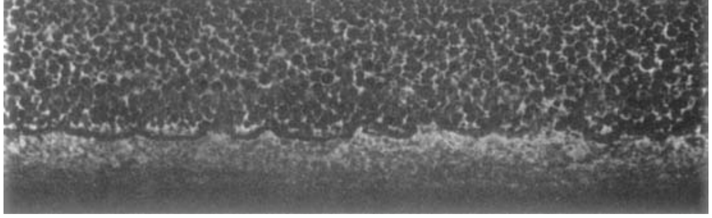

FIGURE 18.11. Impingement attack of outside of cupro nickel tube by wet steam. (From Century Brass [46].)

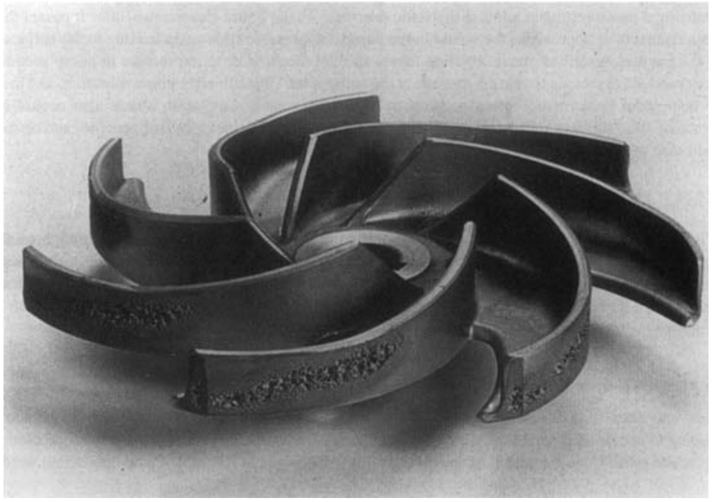

FIGURE 18.12. Gavitation attack of a stainless steel (AISI 316) pump impeller. Environment: skimmed milk at 70°C. Remedy: Replace impeller by one made of Teflon PFA (perfluoroalkoxy). (From [33]. During, Corrosion Atlas: A Collection of Illustrated Case Histories, Vol. 2: Stainless Steels and Nonferrous Materials, Copyright © 1988, with permission from Elsevier Science.)

dependency is similar to that observed in the related phenomenon of liquid-droplet impingement [44].

The cavitation resistance of metals and alloys spans a range of at least two orders of magnitude [44, 48], far greater than the conventional strength properties. The velocity exponent varies widely with values usually given in the range 5–8 [48]. With such a high-velocity exponent, a small change in operating conditions could lead to serious problems. The effects of velocity should not be considered independently of pressure, since the cavitation number σ, which is a measure of the intensity of cavitation, is a function of both parameters [49]:

$$\sigma = \frac{p - p_{\mathrm{v}}}{0.5\,\rho\,u^2}$$

where p and p_{v} are the absolute static pressure and the liquid vapor pressure, respectively, and u the free-stream velocity. When $\sigma = 0$, the pressure is reduced to the vapor pressure and cavitation will occur.

The role of corrosion, which varies with the hydrodynamic intensity, is difficult to predict [49]. Under some circumstances it is claimed that hydrogen bubbles liberated by the application of cathodic protection provide a mechanical cushion reducing the cavitation damage [45] in addition to the normal cathodic protection effect. In other cases corrosion may contribute to the overall attack directly, following damage to protective films. In the latter case, the velocity exponent for a given system might be expected to be reduced as the corrosion component increases, as is the case with erosion–corrosion by solid particles discussed above.

Cavitation is a problem with ship propellers, hydraulic pumps and turbines, valves, orifice plates, and all places where the static pressure varies very abruptly on the basis of the Bernoulli* principle:

$$gz + \frac{u^2}{2} + \frac{p}{\rho} = \text{const}$$

where z is the elevation. Strictly speaking, the Bernoulli equation applies to flow along a streamline†; however, in turbulent disturbed flow it can be used qualitatively. Thus the increase in the velocity as the liquid is accelerated through an orifice plate or over the curved impeller of a centrifugal pump results in a fall in the static pressure. As the liquid slows down, after it passes the vena contracta or approaches the volute in the pump, the pressure rises again, leading to the collapse of the cavities described above. Friction losses and the resulting drop in pressure in pump suction lines can lead to serious cavitation damage at the pump inlet. Objectionable noise, vibration, and loss of equipment performance often accompany cavitation attack.

Cavitation attack also occurs at vibrating solid surfaces such as the cooling-water side of diesel engine cylinder liners [49] and on the shell side of heat exchanger tubing [50].

* The engineering form of the Bernoulli equation includes terms for shaft work and friction losses [23].

† The use of the term streamline in turbulent flow is confusing to some who might think the term applies only to laminar (viscous) flow. A streamline is a continuous line drawn through a fluid so that it has the direction of the velocity vector at every point. There can be no flow across a streamline. When very small solid particles are used to study the flow pattern, by the use of laser Doppler anemometry, the particles follow the streamlines [24].

FIGURE 18.13. Wire drawing in a bronze cam ring for a hydraulic pump. (From Glaeser [51]. Reprinted, by permission of NACE International.)

F6. Wire Drawing

Wire drawing is a form of erosion–corrosion found in very high velocity fluid flow through small gaps. This type of attack, which is difficult to classify, takes the form of single or multiple clean smooth grooves, as shown in Figure 18.13 [51]. The attack could involve liquid-droplet impingement attack when it occurs at valve seats with escaping steam and cavitation attack when it occurs with a single-phase fluid system [44]. The fluid may be aqueous or nonaqueous.

F7. Flow-Enhanced Film Dissolution

Flow-enhanced film dissolution (with thinning) is a "chemical" form of protective film erosion leading to accelerated corrosion. This type of erosion–corrosion has caused some serious problems in carbon steel lines (protected by magnetite films) carrying hot (100–250°C) deoxygenated water or wet steam in fossil-fueled and nuclear power plants.* The problem occurs at locations with high mass transfer rates, corresponding to highly turbulent flow conditions found at bends and downstream of pumps, valves, and orifice plates. At these locations the film is dissolved more rapidly, and a higher anodic current is needed to replenish the protective film. The resulting steady state involves a thinner and less protective film and a much higher corrosion rate, leading to rapid localized thinning of the equipment walls.

* The term flow-accelerated corrosion (FAC) has been used to describe this specific problem [54]. However, the term erosion–corrosion is normally used in the literature and is the preferred term. The term FAC could relate to a whole range of flow-dependent corrosion processes in addition to its application to flow-enhanced film thinning.

At high velocities in wet steam, convective dissolution of magnetite films is said to be supplemented by oxide fatigue by liquid-droplet impacts. At the outside of bends, liquid droplets under the influence of secondary flow and centrifugal acceleration impinge on the magnetite, fatiguing it and causing it to erode away, exposing new metal to the steam. On the inside of the bend, where an inward flowing stagnation point occurs with a very high mass transfer coefficient, convective dissolution is the major mode of oxide damage [52]. Giralt and Trass [53] have suggested that the contribution of dissolution can be additive to film erosion and sometimes acts in a synergistic way by loosening the crystal grains of the film, making them more prone to erosion.

The effect of velocity on flow-enhanced film dissolution is complex and, although much has been learned with respect to the identification and control of this problem, much more work is required on the fundamentals of the processes involved [54].

A. INTRODUCTION

Aqueous carbon dioxide (CO_2) corrosion is usually associated with mild steel. It becomes a serious issue when, in oil and gas production and transportation, significant amounts of CO_2 and water are present. CO_2 is very soluble in water, where it forms carbonic acid (H_2CO_3), which attacks mild steel. This has been known for many decades, yet aqueous CO_2 corrosion of mild steel remains a significant problem for the oil and gas industry [1] (see Fig. 19.1). Despite thousands of papers published on CO_2 corrosion in the open literature, one cannot easily piece together a picture of CO_2 corrosion, since much of the useful information is scattered. The text below is a compilation of the current understanding we have on this subject, with a focus on the basic processes and mechanisms.

It should be noted at the outset that corrosion-resistant alloys (CRAs) exist which are able to withstand CO_2 corrosion, such as many stainless steels and other iron- or nickel-based alloys. Nevertheless, due to cost, mild steel is almost exclusively used as a construction material for large facilities such as pipelines. The cost of pipeline failure due to internal CO_2 corrosion can be enormous, including repair/replacement costs, lost production, environmental impact, and losses in the downstream industries such as refineries.

B. THEORY OF UNIFORM CO_2 CORROSION OF MILD STEEL IN AQUEOUS SOLUTIONS

For the case of mild steel, one can write the overall CO_2 corrosion reaction as

$$Fe + CO_2 + H_2O \Rightarrow Fe^{2+} + CO_3^{2-} + H_2 \qquad (19.1)$$

As iron (Fe) from the steel is oxidized to ferrous ions (Fe^{2+}) in the presence of CO_2 and water (H_2O), hydrogen gas (H_2) is evolved due to reduction of hydrogen ions present in water. It is also common to show the overall corrosion reaction in a

FIGURE 19.1. Section of corroded pipe showing localized CO_2 attack. (With permission from ConocoPhillips.)

more compact form:

$$Fe + H_2CO_3 \Rightarrow FeCO_3 + H_2 \qquad (19.2)$$

To understand aqueous CO_2 corrosion of mild steel, one first needs to define the species present in a CO_2-saturated aqueous solution before looking into the reduction/oxidation processes at the steel surface, which are behind corrosion. The former is best described by *homogeneous aqueous chemistry*, while the latter is the subject of *heterogeneous (electro)chemical analysis*. The state of the solution at the metal surface and that in the bulk are related, as species move back and forth due to concentration gradients; this can be accounted for by proper *mass transfer analysis*. Therefore, the text below is structured to first cover homogeneous chemical reactions in a CO_2 saturated aqueous solution, followed by the description of the heterogeneous (electro) chemical processes occurring at the steel surface and finally a mass transfer analysis which links the two. Means of quantifying the various physicochemical processes involved are provided whenever they are known.

B1. Homogeneous Reactions in CO_2-Saturated Aqueous Solutions

The CO_2 gas is rather soluble in water. In terms of volumetric molar concentrations, almost as much CO_2 can be found in the aqueous phase as in the gas phase. Only a rather small fraction (0.2%) of the dissolved CO_2 molecules is hydrated to form a "weak" carbonic acid, H_2CO_3. The term "weak" refers to the fact that H_2CO_3 does not fully dissociate. This reaction and all the other important homogeneous chemical reactions occurring in an aqueous CO_2 solution are listed in Table 19.1, along with the corresponding equilibrium expressions. The equilibrium "constants" typically depend on temperature and in some cases pressure and ionic strength of the solution, as listed in Table 19.2.

One can use the equilibrium equations listed in Tables 19.1 and 19.2 to calculate the bulk concentrations of all the species in an aqueous CO_2 solution, including the concentration of protons, c_{H^+}, which yields the bulk pH. To achieve this, one

TABLE 19.1. Key Chemical Reactions Occurring in Aqueous CO_2 Solution and Corresponding Equilibrium Expressions

Name	Reaction	Equilibrium Expression	
Dissolution of carbon dioxide	$CO_{2(g)} \overset{K_{sol}}{\Leftrightarrow} CO_2$	$H_{sol(CO_2)} = \frac{1}{K_{sol}} = \frac{p_{CO_2}}{c_{CO_2}}$	(19.3)
Carbon dioxide hydration	$CO_2 + H_2O \overset{K_{hyd}}{\Leftrightarrow} H_2CO_3$	$K_{hyd} = \frac{c_{H_2CO_3}}{c_{H_2O}\, c_{CO_2}}$	(19.4)
Carbonic acid dissociation	$H_2CO_3 \overset{K_{ca}}{\Leftrightarrow} H^+ + HCO_3^-$	$K_{ca} = \frac{c_{H^+} c_{HCO_3^-}}{c_{H_2CO_3}}$	(19.5)
Bicarbonate anion dissociation	$HCO_3^- \overset{K_{bi}}{\Leftrightarrow} H^+ + CO_3^{2-}$	$K_{bi} = \frac{c_{H^+} c_{CO_3^{2-}}}{c_{HCO_3^-}}$	(19.6)
Water dissociation	$H_2O \overset{K_{wa}}{\Leftrightarrow} H^+ + OH^-$	$K_{wa} = \frac{c_{H^+} c_{OH^-}}{c_{H_2O}}$	(19.7)

Note: Means for calculating equilibrium constants are given in Table 19.2 below.

TABLE 19.2. Equilibrium Constant for Homogeneous Reactions Listed in Table 19.1 as Function of Temperature, Pressure, and Ionic Strength

Equilibrium Constant For	Source	
Dissolution of carbon dioxide: $K_{sol} = 14.463 \times 10^{-(2.27+5.65\times10^{-3}\times T_f - 8.06\times10^{-6}\times T_f^2 + 0.075\times I)}$	Oddo and Tomson [2]	(19.8)
Carbon dioxide hydration: $K_{hy} = 2.58 \times 10^{-3}$	Palmer and van Eldik [3]	(19.9)
Carbonic acid dissociation: $K_{ca} = 387.6 \times 10^{-(6.41 - 1.594\times10^{-3}\times T_f + 8.52\times10^{-6}\times T_f^2 - 3.07\times10^{-5}\times p - 0.4772\times I^{0.5} + 0.118\times I)}$	Oddo and Tomson [2]	(19.10)
Bicarbonate anion dissociation: $K_{bi} = 10^{-(10.61 - 4.97\times10^{-3}\times T_f + 1.331\times10^{-5}\times T_f^2 - 2.624\times10^{-5}\times p - 1.166\times I^{0.5} + 0.3466\times I)}$	Oddo and Tomson [2]	(19.11)
Water dissociation: $K_{wa} = 10^{-(29.3868 - 0.0737549\times T_k + 7.47881\times10^{-5}\times T_k^2)}$	Kharaka et al. [4]	(19.12)

Note: T_f is temperature in degrees Fahrenheit, T_k is absolute temperature in Kelvin, $I = (c_1 z_1^2 + c_2 z_2^2 + \cdots)/2$ is ionic strength in molar, and p is the pressure in psi.

more equation is needed to find a unique mathematical solution: a constraint that describes charge conservation, that is, electroneutrality of the solution.

Clearly, chemical reactions shown in Table 19.1, which involve ions, always remain balanced with respect to charge and therefore one can write

$$c_{H^+} = c_{HCO_3^-} + 2c_{CO_3^{2-}} + c_{OH^-} \quad (19.13)$$

This simple method of solution speciation is valid only for a pure ideal CO_2-saturated aqueous solution. If the aqueous solution contains other ions, such as, for example, Fe^{2+} produced by corrosion of steel or Na^+ or Cl^-etc., then Eq. (19.13) needs to be extended to include these species. Likewise, if other homogeneous reactions occur (in addition to those listed in Table 19.1), they need to be included in the analysis and the corresponding equilibrium expressions accounted for by adding them to the list in Table 19.2.

An example of calculated carbonic species distribution in a CO_2-saturated aqueous solution as a function of pH is given in Figure 19.2 for a system where the partial pressure of the CO_2 gas, $p_{CO_2} = 1$ bar, and temperature, $T = 25°C$, are kept constant. The conditions chosen for this plot are not uncommon; for example, the p_{CO_2} of mild steel pipelines typically varies from a fraction of a bar to a few bars. The temperature range is anywhere from 1 to 100°C, and the corresponding pH is slightly below pH 4 for pure (condensed) water and up to pH 7 for buffered (formation) water—often referred to as "brine." The concentration of various salts can be rather high, typically a few weight percent, even if for some "heavy" brines it may exceed 20 wt %.

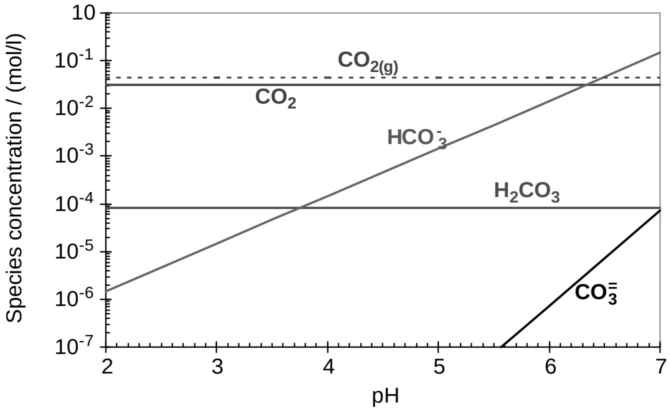

FIGURE 19.2. Calculated carbonic species concentrations as function of pH for a CO_2-saturated aqueous solution; $p_{CO_2} = 1$ bar, 25°C, 1 wt % NaCl.

It should be noted that in Figure 19.2, due to constant p_{CO_2}, the concentration of carbonic acid, $c_{H_2CO_3}$, is also constant across the whole pH range, while the concentrations of the bicarbonate ion, $c_{HCO_3^-}$, and the carbonate ion, $c_{CO_3^{2-}}$, increase with pH.

Some reactions listed in Table 19.1, such as, for example, the dissociation of carbonic acid, are very fast compared to all other processes occurring simultaneously; thus it is reasonable to assume that they are in chemical equilibrium. Other reactions, such as the CO_2 dissolution in water and the hydration of dissolved CO_2, are much slower. In that case, other faster processes occurring simultaneously can lead to local nonequilibrium in the solution. More importantly, when being a part of the overall corrosion process, slow reactions can become the rate-determining step and limit the corrosion rate, as explained further below.

B2. Heterogeneous Reactions in Corrosion of Mild Steel in CO_2-Saturated Aqueous Solutions

The most important reactions which are "behind" the CO_2 corrosion of mild steel are the heterogeneous reduction/oxidation reactions occurring at the steel surface, that is, the electrochemical reactions. The key ones are listed in Table 19.3.

B2.1. Anodic Reaction. The electrochemical dissolution of iron from the steel, reaction 19.14 in Table 19.3, is the main reaction behind aqueous CO_2 corrosion of mild steel. Note that this reversible electrochemical reaction is written as if it occurs only in one direction, that is, as an oxidation or anodic step. The reverse-reduction reaction—the cathodic iron deposition step—has been ignored here. This is because in a corrosion situation reaction (19.14) is not in equilibrium, and there is a net dissolution (oxidation) of iron. In other words, at the corrosion potential, the reverse cathodic partial reaction (iron deposition) can be assumed to proceed much slower than the anodic partial (iron dissolution) and hence does not need to be taken into account. For this to be a sustainable situation, other reduction (cathodic) reaction(s) must be occurring simultaneously to balance the overall corrosion process electrically, as discussed below.

In reality, the anodic iron dissolution reaction is more complicated than it appears in reaction (19.14). For example, the two electrons are not "released" in one step; rather a sequence of steps occurs, which all add up to the overall reaction. These and many other details on the mechanism of the iron dissolution reaction can be found in the open literature, both for general acidic corrosion [5, 6] and more specifically for CO_2 corrosion [7].

The rate of the active dissolution of iron, reaction (19.14) in Table 19.3, is independent of flow and mass transfer and is not a strong function of pH, or of p_{CO_2}, but does depend on temperature. Electrochemically, there can be some variation in the behavior from one type of mild steel to another; however, the corresponding corrosion rate does not vary much, as it is typically controlled by the cathodic reaction, described below. At more positive (anodic) potentials and at high pH often seen in the presence of ferrous carbonate layers, reversible (pseudo)passivation of mild steel may occur, leading to very low corrosion rates.

B2.2. Cathodic Reactions. Mild steel does not corrode significantly in slightly acidic or near-neutral water ($4 < pH < 6$) but does so vigorously when CO_2 is present. The presence of CO_2 increases the corrosion rate primarily by making it easier for hydrogen to evolve from water. How this happens is explained in the paragraphs below.

It is well known that in *strong* mineral acids, which are almost fully dissociated, hydrogen evolution occurs by reduction of the dissociated (free) hydrogen ions, H^+, according to the overall reaction (19.15), given in Table 19.3. Note that the reverse partial reaction (oxidation of dissolved hydrogen gas, H_2) is ignored here for the same reasons as listed above for iron dissolution; at the corrosion potential the oxidation of dissolved hydrogen gas proceeds so slowly that it can be neglected. The rate of hydrogen evolution reac-

TABLE 19.3. Possible Electrochemical Reactions Behind Mild Steel Corrosion in Aqueous CO_2 Solutions

Name	Reaction	
Anodic dissolution (oxidation) of iron	$Fe \rightarrow Fe^{2+} + 2e^-$	(19.14)
Cathodic hydrogen evolution by reduction of dissociated (free) hydrogen ions	$2H^+ + 2e^- \rightarrow H_2$	(19.15)
Cathodic hydrogen evolution by reduction of water	$2H_2O + 2e^- \rightarrow H_2 + 2OH^-$	(19.16)
Cathodic hydrogen evolution by reduction of carbonic acid	$2H_2CO_3 + 2e^- \rightarrow H_2 + 2HCO_3^-$	(19.17)
Cathodic hydrogen evolution by reduction of bicarbonate ion	$2HCO_3^- + 2e^- \rightarrow H_2 + 2CO_3^{2-}$	(19.18)

tion (19.15) depends on the concentration of H^+ ions, making it a strong function of pH. However, in the case of mild steel corrosion in strong acids, the rate of this electrochemical reaction would be extremely high if it were not limited by the rate at which the main reactant, H^+ ions, can be transported from the bulk solution to the steel surface by mass transfer (often referred to as *diffusion*, hence the term *diffusion limitation*). This makes the reaction rate "flow sensitive," which really refers to the fact that turbulent flow can increase the mass transfer rate of H^+ ions and indirectly the rate of the hydrogen evolution reaction and corrosion.

For the pH range seen in typical CO_2-saturated aqueous solutions ($4 < \text{pH} < 6$), this limiting diffusion rate is rather small due to a low concentration of H^+ ions in the bulk. The corresponding corrosion rate should be small as well; however, this is not the case. Therefore, other cathodic reactions must be involved.

The so-called direct reduction of water is one obvious possibility, amounting to the reduction of H^+ ions from the water molecules adsorbed on the steel surface [reaction (19.16) in Table 19.3]. This reaction is thermodynamically equivalent to the hydrogen evolution reaction (19.15), which can be easily shown by combining it with the water dissociation reaction given in Table 19.1. However, the "direct reduction of water" pathway for hydrogen evolution is comparatively slow (kinetically hindered) and cannot be used to explain the high corrosion rates seen in CO_2-saturated aqueous solutions [8, 9]. Therefore it need not be considered in further analysis.

It is the presence of the *weak* H_2CO_3 which enables hydrogen evolution and corrosion at a much higher rate in CO_2-saturated aqueous solutions. Actually, the presence of CO_2 leads to a much higher corrosion rate than would be found in an aqueous solution of a *strong* acid at the same pH.

This apparent paradox can be readily explained by considering that in an aqueous solution the homogeneous dissociation of H_2CO_3 (see Table 19.1) provides additional H^+ ions, which can readily be reduced at the steel surface according to reaction (19.15) [1]. A different pathway is also possible where the H^+ ions are "directly" reduced from the H_2CO_3 molecules adsorbed on the steel surface, much in the same way as happens for adsorbed water molecules; see reaction (19.17) in Table 19.3. This is often referred to as "direct reduction of H_2CO_3" [10–12]. Clearly, this hydrogen evolution reaction also amounts to reduction of H^+ ions, this time from the adsorbed H_2CO_3 molecules, and is thermodynamically equivalent to the other two hydrogen evolution reactions (19.15) and (19.16). This point can be easily proven by combining the various hydrogen evolution reactions [(19.15)–(19.17)] with the homogeneous chemical reactions listed in Table 19.1. For the three cases the distinction is only in the pathway and consequently in the kinetics.

The rate of hydrogen evolution from H_2CO_3 [reaction (19.17)] is much faster than that from water [reaction (19.16)]. Due to the abundance of water and dissolved CO_2, there is a sufficiently large "reservoir" of H_2CO_3 and ultimately H^+ ions in a CO_2-saturated aqueous solution. This would lead to some very high corrosion rates, were it not for the slow CO_2 hydration step (seen in Table 19.1), which gives rise to chemical reaction limiting rates for this cathodic reaction [12, 13], as described below.

In CO_2-saturated aqueous solutions, when the pH increases, so does the concentration of the bicarbonate ions, $c_{HCO_3^-}$ (see Fig. 19.2). Since, HCO_3^- is another weak acid (it only partially dissociates to give CO_3^{2-}; see Table 19.1), then by analogy with H_2CO_3 one can assume that "direct reduction of HCO_3^-" is yet another pathway for hydrogen evolution [14], according to reaction (19.18) in Table 19.3. Again this reaction is thermodynamically equivalent to the previous three pathways for hydrogen evolution, and the distinction is in the kinetics.

Experimental evidence suggests that this pathway for hydrogen evolution is slower than direct reduction of H_2CO_3. However, in neutral and alkaline conditions, the concentration of HCO_3^- is much higher than that of H_2CO_3 (see Fig. 19.2), and it is likely that an accelerated rate of reaction (19.18) can make it the dominant cathodic reaction in CO_2-saturated aqueous solutions. However, in the practical range of interest considered here ($4 < \text{pH} < 6$), the two concentrations are in the similar range, and due to kinetic hindrance, the direct reduction of HCO_3^- can be ignored in further analysis.

This leaves only two significant possibilities for hydrogen evolution in CO_2-saturated aqueous solutions: reduction of the dissociated (free) H^+ ions [reaction (19.15)] and direct reduction of H_2CO_3 molecules adsorbed on the steel surface [reaction (19.17)]. The former is a strong function of pH, while the latter is a function of H_2CO_3 concentration, which is a linear function of CO_2 partial pressure in the gas phase; see Table 19.1. Both are kinetically limited, reaction (19.15) by diffusion of H^+ ions from the bulk to the steel surface and reaction (19.17) by the slow CO_2 hydration step (see Table 19.1), as described in more detail below. The overall CO_2 corrosion process outlined above is shown in the simplified schematic given in Figure 19.3.

B2.3. Calculating the Charge Transfer Rate. A corrosion process proceeds so that the rate of the main anodic process (iron dissolution) is electrically balanced by the rate of the cathodic (hydrogen evolution) reaction(s), as there can be no charge (electron) accumulation in the steel. Means of calculating the rates of the various processes involved are presented below.

A rate $\Re$ [in kmol/(m^2 s)], for any of the cathodic or anodic reactions described above can be readily expressed in terms of current density i (in A/m^2) since the two are directly related

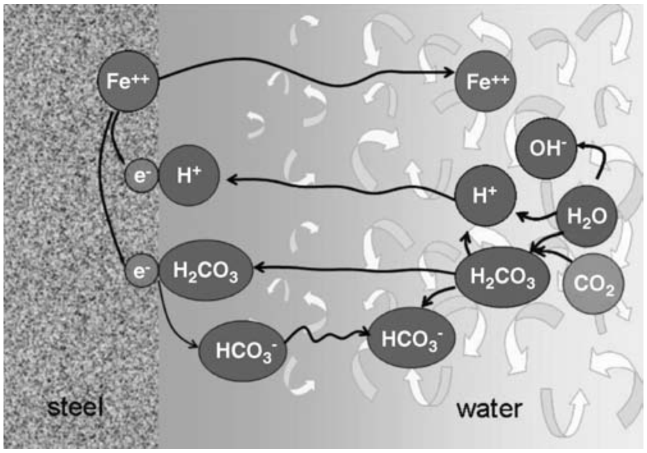

FIGURE 19.3. Simplified schematic representing key reactions occurring during CO_2 corrosion of mild steel.

via Faraday's law:

$$\Re = \frac{i}{nF} \tag{19.19}$$

When the rate of the overall corrosion process is limited by the rate of an electrochemical step in the overall sequence, this is often referred to as "charge transfer"–controlled corrosion rate. Generally, the rate of any electrochemical reaction at the steel surface depends on the concentration of all the reacting species involved in that reaction and temperature. Since electrons are one of the key "reactants" in the electrochemical reactions (19.14)–(19.18), their influence is expressed via the electrical potential at the steel surface using a simplified version of the Butler–Volmer equation:

$$i_\alpha = \pm i_0 \times 10^{\pm (E - E_{\text{rev}})/b} \tag{19.20}$$

In this formalism, the effect of all the other aqueous reactants on the kinetics is captured via the function i_0 as explained below. The plus sign in Eq. (19.20) applies for the anodic (oxidation) reactions, in this case the dissolution-of-iron reaction (19.14), while the minus sign applies for the cathodic (reduction) reactions, such as the various pathways for hydrogen evolution [reactions (19.15)–(19.18)].

It should be noted that in Eq. (19.20), according to standard textbook practice, i_0 is the exchange current density, E_{rev} is the reversible potential, while b is the Tafel slope, all characteristic for a particular reversible electrochemical reaction. However, in order to keep calculations simple, we need to avoid accounting for the reverse partials of the electrochemical reactions (19.14), (19.15), and (19.17), which are deemed negligible. To achieve this, it is easiest not to treat i_0 and E_{rev} in a strict theoretical sense. It is sufficient to quantify i_0, E_{rev}, and b for one important partial of the reversible electrochemical reaction and define the influence of various parameters (temperature, pH, etc.) on that partial without worrying what happens to the reverse partial of the same reaction.

The i_0 for all the important partial electrochemical reactions [(19.14), (19.15), and (19.17)] is a function of temperature, which is best expressed in terms of an Arrhenius-type equation:

$$i_0 = i_0^{\text{ref}} e^{-\Delta H/R\left(1/T_{\text{k}} - 1/T_{\text{k},ref}\right)} \tag{19.21}$$

The parameters for this function are defined in Table 19.4 below for the three key electrochemical reactions.

For cathodic reactions, the i_0 is also a function of the surface concentration of the dissolved species. In the case of the H^+ ion reduction reaction (19.15), $i_{0(H^+)}$ is a function of pH:

$$\frac{\partial \log i_{0(H^+)}}{\partial \text{pH}} = -0.5 \tag{19.22}$$

while for the H_2CO_3 reduction reaction (19.17), the $i_{0(H_2CO_3)}$ depends on H_2CO_3 concentration:

$$\frac{\partial \log i_{0(H_2CO_3)}}{\partial \log c_{H_2CO_3}} = 1 \tag{19.23}$$

The Tafel slope in Eq. (19.20) is defined as

$$b = \frac{2.303 R T_{\text{k}}}{\alpha F} \tag{19.24}$$

TABLE 19.4. Parameters for Key Electrochemical Reactions in Aqueous CO_2 Corrosion of Mild Steel with Reference to Equations (19.21) and (19.24)

Parameter	Iron Oxidation, $Fe \rightarrow Fe^{2+} + 2e^-$	Hydrogen Ion Reduction $2H^+ + 2e^- \rightarrow H_2$	Carbonic Acid Reduction $2H_2CO_3 + 2e^- \rightarrow H_2 + 2HCO_3^-$	Unit
i_0^{ref}	1	0.03	0.06	A/m^2
$T_{\text{k,ref}}$	300	300	300	K
ΔH	50	30	57.5	kJ/mol
α	1.5	0.5	0.5	

The theoretical value of the apparent transfer coefficient factor α is given in Table 19.4 for the three key electrochemical reactions [(19.14), (19.15), and (19.17)], resulting in Tafel slopes in the range of 40–50 mV for the iron dissolution reaction (19.14) and approximately 120–140 mV for the hydrogen evolution reactions (19.15) and (19.17).

B2.4. Calculating the Limiting Rate. Frequently, due to a high rate of the electrochemical reactions, the cathodic reactants at the steel surface are consumed rapidly and their concentration at the steel surface can be much lower than that in the bulk. In that case, the rate of the overall reaction is given by the rate at which these reactants can be replenished. This leads to the concept of limiting current densities, i_{lim}, which are independent from the electrical potential. The overall current density can be written for that case as

$$i = \frac{1}{1/i_\alpha + 1/i_{\text{lim}}} \tag{19.25}$$

When the limiting current/rate is very large (such as in the case of iron dissolution from steel when we can assume the supply of Fe is "unlimited"), we can write $i_{\text{lim}} \gg i_\alpha$ and the overall rate of the reaction is limited by the rate of the charge transfer process; that is from (19.25) we obtain $i = i_\alpha$. When the limiting current is very small, as in the case the hydrogen evolution reactions (19.15) and (19.17), we can assume that $i_{\text{lim}} \ll i_\alpha$, and from (19.25) we obtain $i = i_{\text{lim}}$; that is, the rate of the overall reaction is limited by how fast the cathodic reactants can be replenished at the steel surface.

For the case of the H^+ ion reduction reaction (19.15), the limiting current density is related to the rate of transport (diffusion) of H^+ ions from the bulk of the solution through the boundary layer to the steel surface:

$$i^d_{\text{lim}(H^+)} = k_{m(H^+)} F c_{H^+} \tag{19.26}$$

In turbulent flow, the mass transfer coefficient $k_{m(H^+)}$ can be calculated from a correlation of the Sherwood, Reynolds, and Schmidt numbers, such as the straight pipe correlation of Berger and Hau [15]:

$$\text{Sh}_p = \frac{k_m d_p}{D} = 0.0165 \times \text{Re}^{0.86} \times \text{Sc}^{0.33} \tag{19.27}$$

or the rotating cylinder correlation of Eisenberg et al. [16]:

$$\text{Sh}_r = \frac{k_m d_c}{D} = 0.0791 \times \text{Re}^{0.7} \times \text{Sc}^{0.356} \tag{19.28}$$

This type of correlation is limited to fully developed, steady-state, single-phase flow situations and is valid only for a specific flow geometry such as the two listed above, which are typical for corrosion. For other flow geometries, transient situations, developing and/or multiphase flow, and so on, different correlations must be found which apply to the given condition.

In the case of H_2CO_3 reduction reaction (19.17), the limiting current is due to a slow CO_2 hydration step preceding it [12, 13] (see Table 19.1). The limiting current density can be calculated from the CO_2 hydration rate constant [17] k^f_{hyd} as

$$i^r_{\text{lim}(H_2CO_3)} = F c_{CO_2} f_{H_2CO_3} \sqrt{D_{H_2CO_3} K_{\text{hyd}} k^f_{\text{hyd}}} \tag{19.29}$$

where k^f_{hyd} is a function of temperature:

$$k^f_{\text{hyd}} = 10^{169.2 - 53.0 \times \log(T_k) - 11715/T_k} \tag{19.30}$$

The equilibrium constant for this reaction (listed in Tables 19.1 and 19.2) is by definition $K_{\text{hyd}} = k^f_{\text{hyd}}/k^b_{\text{hyd}}$.

The flow factor $f_{H_2CO_3}$ captures the small effect that turbulent mixing has on this limiting current density [34]:

$$f_{H_2CO_3} = \coth(\zeta_{H_2CO_3}) \tag{19.31}$$

where

$$\zeta_{H_2CO_3} = \frac{\delta_{m(H_2CO_3)}}{\delta_{r(H_2CO_3)}} \tag{19.32}$$

and

$$\delta_{m(H_2CO_3)} = \frac{D_{H_2CO_3}}{k_{m(H_2CO_3)}} \tag{19.33}$$

$$\delta_{r(H_2CO_3)} = \sqrt{\frac{D_{H_2CO_3}}{k^b_{\text{hyd}}}} \tag{19.34}$$

The carbonic acid mass transfer coefficient $k_{m(H_2CO_3)}$ is calculated in the same way as the one described above for H^+ ions, via the Sherwood number correlations.

The diffusion coefficient of either species is a function of temperature according to the Einstein's relation:

$$D = D_{\text{ref}} \left(\frac{T_k}{T_{k,\text{ref}}}\right) \left(\frac{\mu_{H_2O,\text{ref}}}{\mu_{H_2O}}\right) \tag{19.35}$$

B2.5. Calculating the Balance. The rate of mild steel corrosion can now be calculated. The unknown corrosion

potential E_{corr} in Eq. (19.20) can be found from the electrical current (charge) balance equation at the steel surface:

$$i_{(H^+)} + i_{(H_2CO_3)} = i_{(Fe)} \tag{19.36}$$

When the calculated value of E_{corr} is returned to Eq. (19.20) written out for iron dissolution, the corrosion current can be calculated:

$$i_{corr} = i_{(Fe)} \tag{19.37}$$

and the CO_2 corrosion rate is obtained by using Faraday's law:

$$CR = \frac{i_{corr} M_{Fe}}{\rho_{Fe} 2F} \tag{19.38}$$

It happens that, for iron in steel, when i_{corr} is expressed in amperes per meters squared, CR in millimeters per year takes on almost the same numerical value, more precisely, $CR = 1.155 \times i_{corr}$.

B2.6. Ferrous Carbonate Precipitation. Under certain conditions, a ferrous carbonate ($FeCO_3$), layer can form in the CO_2 corrosion of mild steel by precipitation and can reduce the corrosion rate [17]. The causes for the precipitation of $FeCO_3$ are the high local concentrations of Fe^{2+} and CO_3^{2-} species in the aqueous solution. Most of the Fe^{2+} ions are provided by corrosion [see reaction (19.14) in Table 19.3], while the CO_3^{2-} ions come from dissolved CO_2 [see reaction (19.11) in Table 19.1]. When the product of their concentrations exceeds the so-called solubility limit, they form solid ferrous carbonate according to

$$Fe^{2+} + CO_3^{2-} \overset{K_{sp(FeCO_3)}}{\Leftrightarrow} FeCO_{3(s)} \tag{19.39}$$

where the solubility product constant is a function of temperature and ionic strength [18]:

$$K_{sp(FeCO_3)} = 10^{(-59.3498 - 0.041377 \times T_k - 2.1963/T_k + 24.5724 \times \log T_k + 2.518 \times I^{0.5} - 0.657 \times I)} \tag{19.40}$$

Due to corrosion, the product of concentrations of Fe^{2+} and CO_3^{2-} ions in the aqueous solution is frequently much higher than the solubility limit. This is the case particularly at the steel surface where the Fe^{2+} ions are generated and the concentration can be very high. The solubility limit is also easily exceeded at high pH, when the concentration CO_3^{2-} ions is high (see Fig. 19.2). In those cases, reaction (19.39) is not in equilibrium and there is a net rate from left to right amounting to a formation of solid $FeCO_{3(s)}$. This nonequilibrium situation is termed *supersaturation*, defined as

$$SS_{(FeCO_3)} = \frac{c_{Fe^{2+}} c_{CO_3^{2-}}}{K_{sp(FeCO_3)}} \tag{19.41}$$

The higher the supersaturation is, the faster precipitation happens, since the imbalance in reaction (19.39) is larger, driving the process. In simple words, one can say that the $FeCO_3$ precipitation process is the "return" of the solution toward equilibrium. The higher the temperature, the faster this process will happen.

The $FeCO_3$ precipitation starts by heterogeneous nucleation, a process which happens relatively fast due to the many imperfections on the surface of the steel, which serve as good nucleation sites. Nucleation is followed by crystalline $FeCO_3$ layer growth. The rate of precipitation ($\Re_{FeCO_3}$) on the steel surface is therefore limited by the rate of crystal growth, which can be expressed as a function of supersaturation, surface area, and temperature:

$$\Re_{FeCO_3} = k_{r(FeCO_3)} \frac{A}{V} K_{sp(FeCO_3)} \left(SS_{(FeCO_3)} - 1 \right) \tag{19.42}$$

where $k_{r(FeCO_3)}$ is a kinetic constant which is a function of temperature, best expressed using an Arrhenius-type equation [19]:

$$k_{r(FeCO_3)} = e^{A_{(FeCO_3)} - \frac{B_{(FeCO_3)}}{RT_k}} \tag{19.43}$$

where $A_{(FeCO_3)} = 28.2$ and $B_{(FeCO_3)} = 64{,}851$ J/mol. Rapid formation of $FeCO_3$ layers happens only at higher temperature (typically above 50°C) and at high pH (typically at pH > 5). Rapid $FeCO_3$ layer formation is a precondition for its protectiveness, as discussed below.

Scanning electron microscopy (SEM) images of a crystalline ferrous carbonate layer formed on a mild steel substrate are shown in Figures 19.4 and 19.5. When dense, the $FeCO_3$ layer can slow down the corrosion process by being a transport barrier for the corrosive species. Protection from corrosion is also achieved by the so-called coverage of the surface; that is, in places where the $FeCO_3$ crystals adhere to the steel, there is little or no corrosion. This is clearly shown in the TEM image in Figure 19.5, where the attack on the steel seems to proceed only in the area "between" the $FeCO_3$ crystals. In the presence of dense $FeCO_3$ layers, the conditions at the steel surface are different compared to those in the bulk. The pH is much higher, which may lead to formation of other solids such as oxides and hydroxides. Small amounts of magnetite (Fe_3O_4) were detected underneath the $FeCO_3$

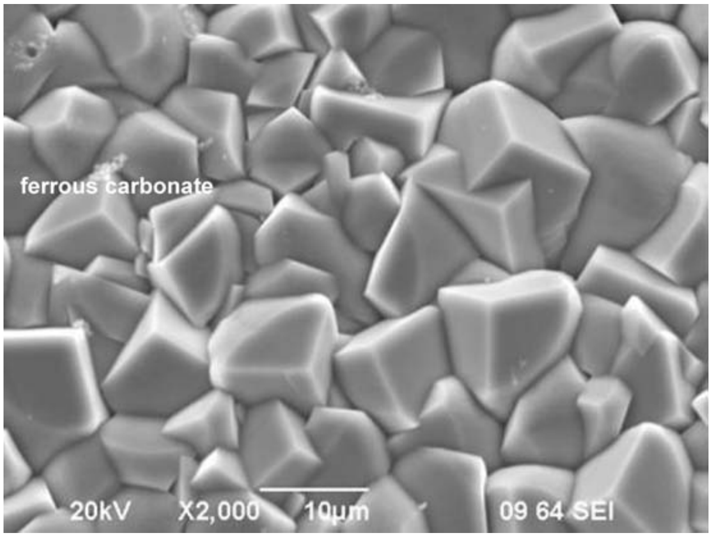

FIGURE 19.4. SEM image showing top view of ferrous carbonate layer formed on mild steel: 80°C, pH 6.6, $p_{CO_2} = 0.5$ bar, stagnant conditions.

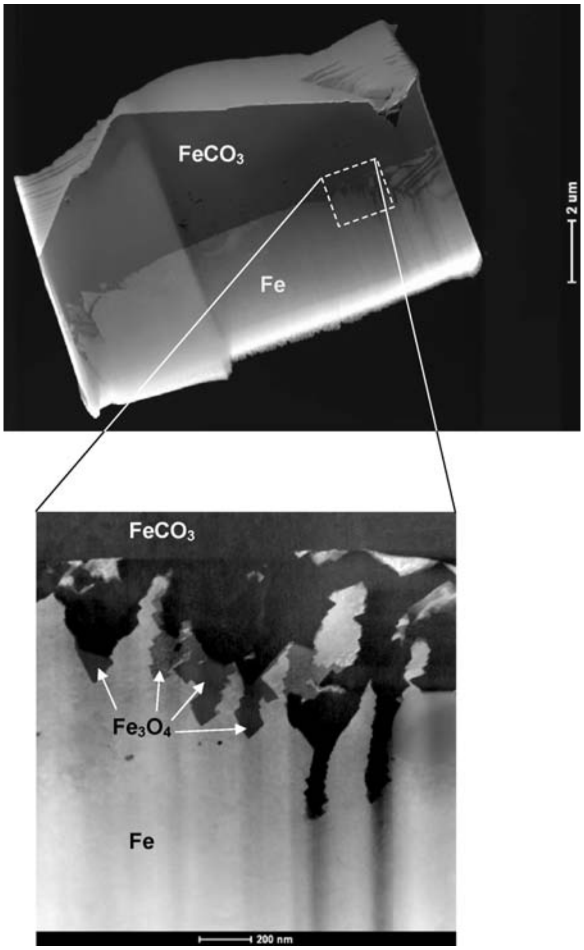

FIGURE 19.5. TEM of ferrous carbonate crystal formed on mild steel: 80°C, pH 6.6, $p_{CO2} = 0.5$ bar, stagnant conditions.

layer, as shown in Figure 19.5, which led to an even better protection from CO_2 corrosion by passivation.

C. FACTORS AFFECTING AQUEOUS CO_2 CORROSION OF MILD STEEL

The primary factors which affect the aqueous CO_2 corrosion of mild steel are discussed below. In many instances it is impossible to fully separate one effect from the other, and there is no perfect way of presenting the overall situation. In the discussion below, the effects of primary factors on CO_2 corrosion are put into the context of the theory described above. The most common range of conditions is considered for each primary parameter, and when it is justifiable, the key secondary parameter is introduced on the same graph.

C1. Effect of pH

The pH is probably one of the most influential parameters in acidic corrosion of steel and CO_2 corrosion is no exception. Even in the limited range of pH ($4 < \text{pH} < 6$), lowering the pH leads to higher corrosion rates and vice versa, as shown in Figure 19.6. If we recall that reduction of free H^+ ions [reaction (19.15)], is one of the two important cathodic reactions in CO_2 corrosion, this effect of pH is to be expected. However, the effect of pH seems to be exaggerated at higher temperature, as shown in Figure 19.6. This is because pH promotes the formation of $FeCO_3$ layers, and the kinetics of this process is highly temperature dependent. There are other more complicated effects of pH, some of which are discussed below.

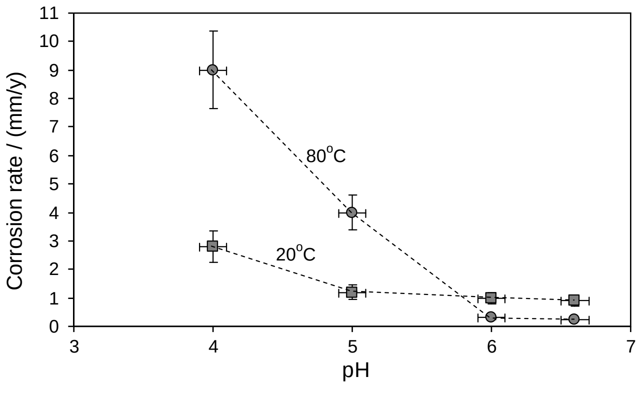

FIGURE 19.6. Effect of pH on CO_2 corrosion rate of mild steel measured at 20°C ($p_{CO_2} = 1$ bar) and 80°C ($p_{CO_2} = 0.5$ bar), 3 wt % NaCl, using rotating cylinder flow with outer diameter (OD) of 10 mm at 1000 rpm. The error bars represent typical variations seen in the experiments. The dotted lines are added to indicate trends.

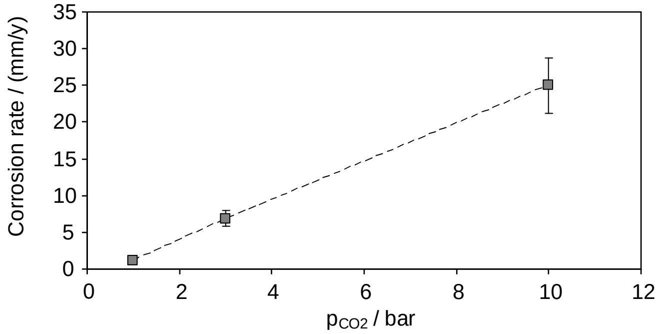

FIGURE 19.7. Effect of p_{CO_2} on CO_2 corrosion rate of mild steel measured at 60°C, pH 5, in single-phase pipe flow, internal diameter (ID) 100 mm, at 1 m/s, 1 wt % NaCl. The error bars represent typical variations seen in the experiments. The dotted line is added to indicate the trend.

C2. Effect of CO_2 Partial Pressure

It has been known for a while that p_{CO_2} leads to an increase in the corrosion rate, even at constant pH and with all other parameters unchanged. Based on the theory laid out above, one can see that with increasing p_{CO_2}, the concentration of H_2CO_3 increases, accelerating the other significant cathodic reaction (19.17) and ultimately the corrosion rate. This effect of p_{CO_2} at a constant pH is illustrated in Figure 19.7. As partial pressures of CO_2 exceed 10 bars, the corrosion rate does not increase as much. It is thought that this is related to formation of protective $FeCO_3$ layers, which is aided at very high p_{CO_2} [20].

C3. Effect of Temperature

Increased temperature accelerates all the processes involved in corrosion. It would then appear that the corrosion rate should steadily increase with temperature. This happens at low pH, when $FeCO_3$ layers do not form, as shown in Figure 19.8. The opposite happens when solubility of $FeCO_3$ is exceeded and a protective layer forms, typically when $\text{pH} > 5$. In that case, increasing temperature accelerates the kinetics of precipitation of $FeCO_3$ and leads to formation of a more protective layer, as shown in Figure 19.8. It should be noted that at low temperature the two curves do not differ much as the corrosion rate is not a function of pH and even at very high pH an unprotective $FeCO_3$ layer forms due to slow kinetics.

C4. Effect of Flow

Theoretically there are two main ways in which flow may affect CO_2 corrosion of mild steel: through *mass transfer* or via *mechanical means*. Turbulent flow enhances mass transport of species to and away from the steel surface by affecting transport through the boundary layer [21]. On the other hand,

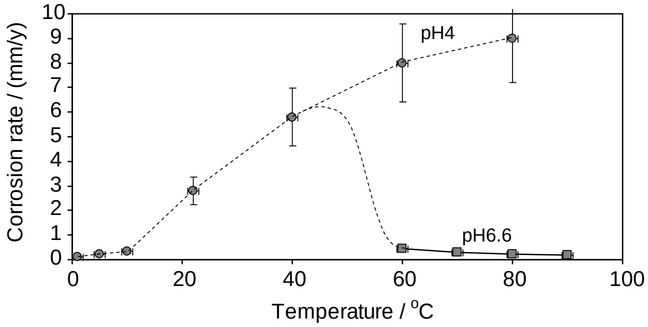

FIGURE 19.8. The effect of temperature on CO_2 corrosion rate of mild steel measured at pH 4 and pH 6.6, 1 wt % NaCl, using rotating cylinder flow with an OD of 10 mm at 1000 rpm. *Note*: In these atmospheric experiments p_{CO_2} decreased with temperature; e.g., at 20°C it was almost 1 bar while at 80°C it was approximately 0.5 bar. The error bars represent typical variations seen in the experiments. The dotted lines are added to indicate trends.

intense flow could theoretically lead to mechanical damage of protective $FeCO_3$ layers or inhibitor films. Both these mechanisms are aggravated by flow disturbances such as valves, constrictions, expansions, and bends, where a local increase of near-wall turbulence is seen. The same is true for gas–liquid flow and particularly in a slug flow regime, where very high short-lived fluctuations of both mass transfer and wall shear stress are measured.

However, very little hard evidence exists that either of these two flow-affected mechanisms is of great significance in CO_2 corrosion. Mass transfer plays a secondary role, as the CO_2 corrosion rate is usually controlled by charge transfer and/or a slow chemical reaction (see Section B above). Wall shear stress varies from a few Pascals seen in single-phase liquid flow to a few hundred or even thousands of pascals for high peaks in slug flow, yet it seems stresses of the order of megapascals are needed to detach a protective $FeCO_3$ layer or an inhibitor film. Therefore it seems both flow effects play only a secondary role in CO_2 corrosion of mild steel; that is, they become important only when the conditions are "at the margin." For example, if water chemistry is such that a protective $FeCO_3$ layer may dissolve, flow may accelerate the process locally and even enhance it by mechanical means. Similarly, flow may interfere locally with protective $FeCO_3$ layer buildup when the driving force for precipitation is not very strong (e.g., low supersaturation and/or low temperature), which can lead to localized corrosion.

Somewhat counterintuitively, flow seems to create more problems in CO_2 corrosion of mild steel when the flow rate is low rather than high. For example, in oil/water flow in pipelines the two liquids can flow stratified or mixed, usually with the oil phase being continuous and the water phase dispersed. In the stratified case, which is typical for low flow rates, corrosion of the bottom of the line is seen, while in the dispersed case, characteristic for high flow rates, no corrosion occurs. Another example is the problem of settling of solids at low flow rates, which leads to the so-called underdeposit attack. The steel under the deposit is hard to protect with conventional corrosion inhibitors, while in some cases galvanic cells or even bacterial attack can aggravate the problem.

C5. Effect of Hydrogen Sulfide

In many field cases, in addition to CO_2, varying amounts of hydrogen sulfide (H_2S) gas are present, from a fraction of a millibar to tens of bars partial pressure. Corrosion issues related to H_2S still represent a significant problem for the oil and gas industry [22–28]. Mild steel corrosion in the presence of H_2S almost inevitably leads to formation of ferrous sulfide layers, which are a dominant factor governing the overall corrosion rate. This brief section will only cover cases where very small amounts of H_2S are present in CO_2 corrosion yet H_2S produces a big impact on the corrosion rate.

Dissolved H_2S is another weak acid, so it can be seen as an additional reservoir of H^+ ions and we must allow possibility of "direct H_2S reduction," in a similar way as was done above for H_2CO_3, both pathways causing an increase in the rate of the hydrogen evolution reaction. The overall corrosion reaction due to H_2S can be written as

$$Fe_{(s)} + H_2S \rightarrow FeS_{(s)} + H_2 \tag{19.44}$$

However, what is even more important is that this reaction almost always results in the formation of a solid ferrous sulfide ($FeS_{(s)}$), layer, usually in the form of a nonstoichiometric sulfur-deficient mackinawite ($Fe_{1+x}S$), which can be found on the corroding steel surface even in the presence of very small amounts of H_2S and even below its thermodynamic solubility limit.

The tightly adherent mackinawite film is very thin ($\ll$1 μm) but apparently rather dense, since it acts as an effective solid-state diffusion barrier for all the species involved in the corrosion reaction. Therefore this thin mackinawite film is one of the most important factors governing the corrosion rate in CO_2/H_2S corrosion. Experiments show that CO_2 corrosion rates are affected even if very small amounts of H_2S are present in the gas phase (as little as 10^{-5} bar). In CO_2 corrosion of mild steel in the presence of significant amounts H_2S, there is usually an outer carbonate/sulfide layer which thickens over time (typically $\gg$1 μm) and forms an additional diffusion barrier. However, this outer layer is more porous and rather loosely attached to the steel surface, so that it rather easily cracks, peels, and spalls, which are accelerated by turbulent flow.

Mackinawite will transform over time into other forms of less soluble and more stable ferrous sulfide: pyrrhotite and troilite. At very high H_2S concentrations, pyrite and elemental sulfur appear. However, there is no clearly defined relationship between the type of the sulfide layer and the nature or

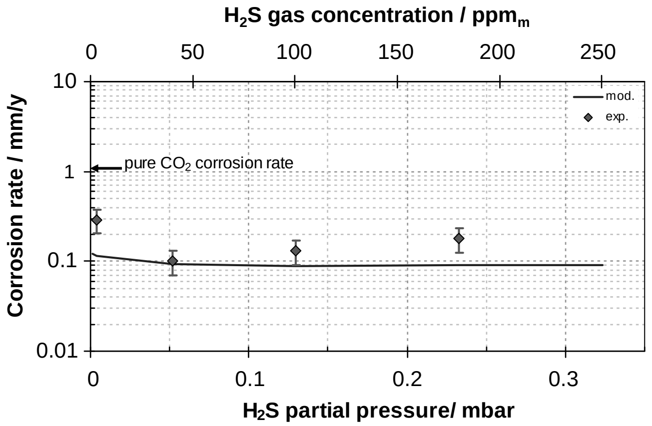

FIGURE 19.9. Effect of H_2S on CO_2 corrosion rate of mild steel measured at $p_{H_2S} = 0.0013–0.32$ mbar, $p_{CO_2} = 1$ bar, 20°C, pH 5, 1 wt % NaCl, using rotating cylinder flow with an OD of 10 mm at 1000 rpm. The error bars represent typical variations seen in the experiments. The dotted lines are added to indicate trends.

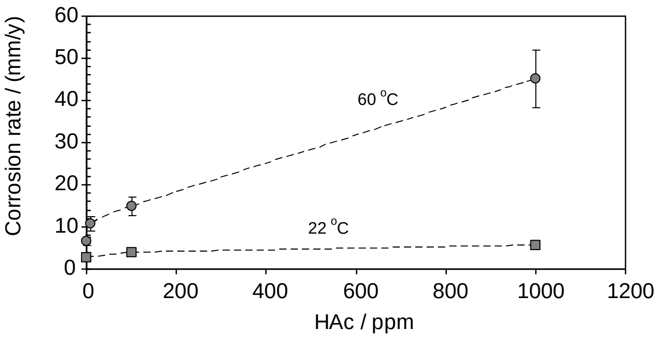

FIGURE 19.10. Effect of organic acid concentration on CO_2 corrosion rate of mild steel at different temperature measured at pH 4, 3 wt % NaCl, using rotating cylinder flow with an OD of 10 mm at 1000 rpm. The error bars represent typical variations seen in the experiments. The dotted lines are added to indicate trends.

intensity of the corrosion process. It is generally thought that all types of ferrous sulfide layers offer some degree of corrosion protection for mild steel.

An example of the effect of very small amounts of H_2S on CO_2 corrosion is seen in Figure 19.9, where, for $p_{CO_2} = 1$ bar, the p_{H_2S} ranges from 0.0013 to 0.32 mbar, corresponding to 1–250 ppm_m in the gas phase; that is, H_2S is present in "traces." Clearly this is a CO_2-dominated corrosion scenario (p_{CO_2}/p_{H_2S} ratio is in the range 10^3–10^6); however, the presence of H_2S and the thin mackinawite layer greatly affects the corrosion rate. Even when present in such small amounts, H_2S reduces the pure CO_2 (H_2S-free) corrosion rate by a factor of 3–10.

C6. Effect of Organic Acids

In many fields, organic acids are found in the fluid stream. The low-molecular-weight acids are primarily soluble in water while the high-molecular-weight acids are oil soluble and are termed *naphthenic acids*. The former can lead to corrosion of upstream mild steel facilities (tubing, pipelines, separators, etc.) while the latter are a problem in refineries at high temperatures. From the low-molecular-weight organic acid found in brines, the acetic acid CH_3COOH (shorthand: HAc) is most prevalent, with varying amounts of other acids, such as propionic, formic, present. Their corrosiveness is very similar to HAc when present in the same concentration. Therefore the HAc is often used to represent all the organic acids found in the brine.

HAc is another weak acid, and many of the electrochemical arguments made above for H_2CO_3 hold for HAc. The presence of HAc can lead to a significant acceleration of the hydrogen evolution reaction, particularly at high temperature (>50°C) and lower pH (<5) when much of the acid is present in undissociated form [29], as seen in Figure 19.10. The overall corrosion reaction due to HAc can be written as

$$Fe_{(s)} + 2HAc \rightarrow Fe^{2+} + 2Ac^- + H_2 \qquad (19.45)$$

Since iron acetate solubility is much higher than that of ferrous carbonate, all corrosion products are soluble. There are some indications that the presence of organic acids impairs the protectiveness of ferrous carbonate layers; however, the mechanism is still not clear.

C7. Effect of Crude Oil

Crude oil affects internal CO_2 corrosion of mild steel pipelines in one of two ways:

- Inhibitive effect—by providing naturally occurring chemicals which act as corrosion inhibitors
- Wettability effect—by sweeping the water away from the internal pipe walls and entraining it in the stream

Adding corrosion inhibitors to fluid stream in the form of large organic surface-active organic compounds is one of the main methods of CO_2 corrosion mitigation. However, in many cases the crude oil contains compounds which can adsorb onto the steel surface by either direct wetting or by first partitioning into the water phase. The most common surface-active organic compounds found in crude oil which have mitigating effects are those containing oxygen, sulfur, and nitrogen in their molecular structure. Furthermore, both asphaltenes and waxes have shown some positive inhibitive effects on corrosion. However, our present understanding of these phenomena is at best qualitative, making it virtually impossible to make any reliable predictions.

Wettability was already briefly discussed in the context of flow effects on corrosion. Low velocities lead to stratification of water and oil and continuous water wetting of the pipe bottom, resulting in corrosion. If the amount of water is relatively small (<10%), a fast-moving oil phase can entrain the water, which may lead to intermittent oil/water wetting or continuous oil wetting of the pipe walls. In the former case the corrosion rate is much reduced while in the latter case there is no corrosion. Various crude oils have widely varying capacities to entrain water. Typically it takes much higher flow rates for light oils to entrain water ($v > 1.5$ m/s) due to their lower density and viscosity. Some heavier oils are able to do the same at velocities as low as 0.5 m/s. However, chemical properties of crude oils and particularly the content of surface-active substances are just as important for wettability as are their physical properties. Again our present understanding of these effects is fairly qualitative and predictions are difficult.

C8. Effect of Glycol/Methanol

Glycol and methanol are often injected into pipeline streams to prevent hydrates from forming at low temperatures. It is not unusual to have them comprise more than 50% of the total liquid phase. It appears that some retardation of corrosion seen in the field is primarily related to dilution of the water phase by glycol/methanol; that is, it is due to the decreased activity of water. However, our current understanding of this effect is rudimentary.

C9. Effect of Condensation in Wet-Gas Flow

In long pipelines, cooling of a wet-gas stream leads to condensation of water vapor and light hydrocarbons on the internal pipe walls. The condensed water is very pure and contains dissolved CO_2, making it corrosive. This leads to the so-called *top-of-the-line corrosion* (TLC) scenario. Condensation rate is an important factor in TLC as high condensation rates (e.g., 1 mL/m^2/s or higher) are related to very high corrosion rates, and vice versa; low condensation rates (<0.1 mL/m^2/s) lead to formation of protective ferrous carbonate layers and low corrosion rates. Incidents of localized attack in TLC were reported, causes of which are presently not well understood [30]. Other important factors are co-condensation of hydrocarbons, temperature, and CO_2 content in the gas. TLC is difficult to inhibit as it is not easy for corrosion inhibitors (which are typically high-molecular-weight liquids) to reach the upper portions of the internal pipe wall. TLC is complicated to predict because, besides water chemistry and surface electrochemistry, considerations must include hydrodynamics as well as heat and mass transfer, which all play a very important role. A full description of TLC exceeds the scope of this text, and the reader is directed to some of the more recent articles on this topic [30, 31].

C10. Effect of Nonideal Solutions and Gases

The infinite dilution theory which is at the core of the chemical expressions used above does not often hold and corrections are needed. A simple way to do this is to utilize the concept of ionic strength, which was already introduced into the various equilibrium expressions in Table 19.2. A more accurate way is to use activity coefficients [32]; however, this path is significantly more complicated. The effect of nonideal solutions on electrochemical reactions behind CO_2 corrosion (given in Table 19.3) is not known and cannot be accounted for presently. Some simple studies have indicated that corrosion is mitigated in very concentrated brines (>10 wt % salt); however, causes of this effect are not well understood.

At very high pressures, the simple assumptions about the ideality of the gas phase as well as its solubility in water, break down. One can make corrections based on the fugacity coefficient [33] and use more accurate equations of state; however, these are complicated and their description exceeds the scope of this text. Cases in which the critical point for CO_2 is exceeded are even more different and much of what was discussed above needs to be reevaluated for liquid and supercritical CO_2 solutions. These topics are beyond the aims of this review.

D. LOCALIZED CO_2 CORROSION OF MILD STEEL IN AQUEOUS SOLUTIONS

When compared to uniform CO_2 corrosion of mild steel, not nearly as much is known about localized CO_2 corrosion. The reason is probably that there are many rather different primary causes of localized CO_2 corrosion, and for each of them there is usually more than one secondary factor which complicates the situation. In addition, the term *localized corrosion* is very broadly defined and used because it only implies that corrosion attack occurs in certain locations while it does not happen elsewhere. Given this definition, one can encounter very different scales of localized corrosion. One example of localized corrosion on a macroscopic scale is shown in Figure 19.1, where the severely attacked area is of the order of centimeters or even meters and is still fairly "localized" when compared to the overall length of the pipeline, which typically measures in kilometers. The specific morphology seen in Figure 19.1 with large, flat receded areas free of corrosion products which have corroded severely, sharply divided from surrounding protected areas covered with corrosion products, is termed *mesa attack*, a name borrowed from geological literature. On the other extreme is the very small scale localized attack measured on the micrometer or millimeter scale, which is often called *pitting*. An example of localized corrosion on this microscopic scale is shown in Figure 19.11, which

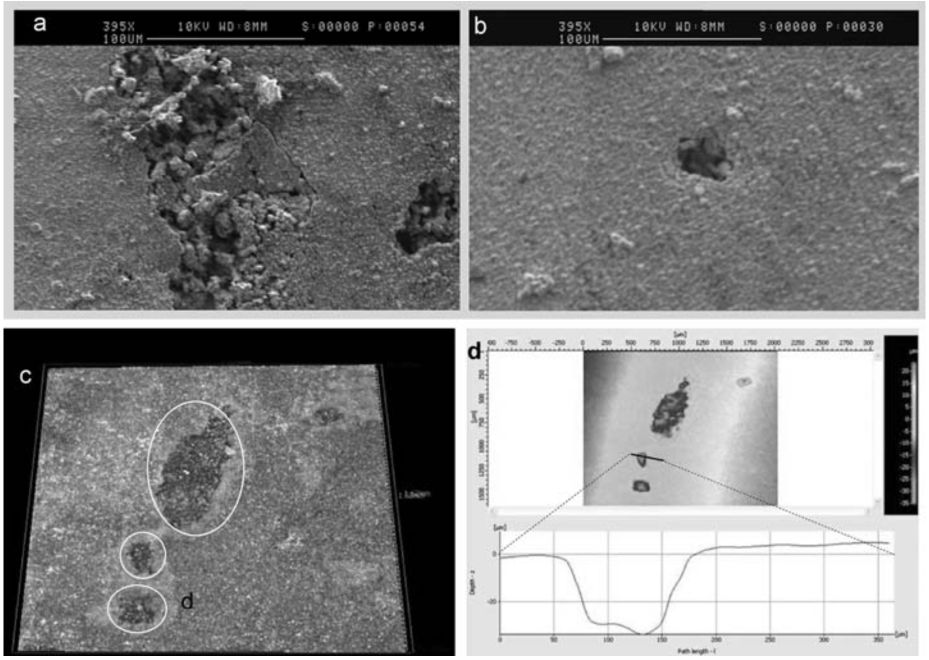

FIGURE 19.11 Isolated pitting on a mild steel surface following partial failure by dissolution of a protective ferrous carbonate layer. Conditions: 80°C, $p_{CO_2} = 0.5$ bar, 10 wt % NaCl, 10 days exposure, pH 6.3 (during 4 days of layer formation), pH 5.0 (during 6 days of layer dissolution). (a and b) SEM images of ferrous carbonate layer surface covering the steel. (c) Corresponding IFM image approximately 1.5×1.5 mm in size of bare steel surface after ferrous carbonate layer removal. (d) Corresponding bare steel surface elevation map and a depth profile across a characteristic pit.

shows localized attack following a partial failure of a $FeCO_3$ layer by chemical dissolution. This type of attack can be isolated or so widespread over a steel surface that it becomes the dominant mode of corrosion (see Fig. 19.12). In some cases the numerous pits merge to give a mesalike morphology.

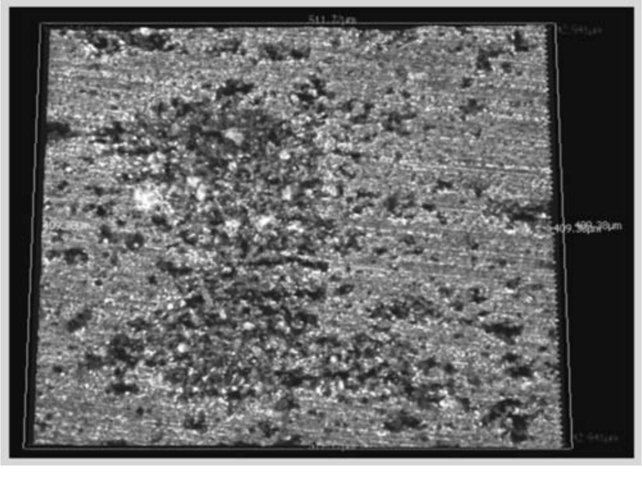

FIGURE 19.12. Image of a mild steel surface approximately 0.5×0.5 mm in size showing widespread pitting following partial dissolution of a protective ferrous carbonate layer, 80°C, $p_{CO_2} = 0.5$ bar, pH 6.3 (during layer formation), pH 5.0 (during layer dissolution), 20 wt % NaCl, 10 days exposure.

The causes of localized CO_2 corrosion defined in this broad sense are many, and they can be divided into those that lead to localized corrosion on a *macroscopic* scale and those that lead to a localized corrosion on a *microscopic* scale. The first group includes:

- Poor or incomplete inhibition
- Water and/or solids separation in multiphase flow
- Flow disturbances and extreme multiphase flow conditions
- Localized condensation in wet-gas flow
- Preferential corrosion of welds
- Ingress of oxygen
- Presence of organic acids
- Presence of H_2S and elemental sulfur

While some of these factors were already discussed above, a more detailed explanation of all the different mechanisms exceeds the scope of the present review. It should be noted that many of them appear simultaneously; for example, precipitation of solids at low flow rates may lead to poor inhibition and a galvanic effect which can be complicated by

an underdeposit bacterial attack. Another example is a flow disturbance which can lead to localized separation of water in oil/water flow or localized condensation of water in wet-gas flow, resulting in partial removal of a protective scale and aggravated galvanic attack.

The localized CO_2 corrosion rate due any combination of these macroscopic factors can be as high as the corresponding uniform CO_2 corrosion rate of unprotected ("bare") steel, which can be anywhere from high to catastrophic, depending on the conditions (e.g., see Fig. 19.6–19.10). However, in some instances the localized CO_2 corrosion rate is even much higher than the corresponding unmitigated uniform corrosion rate. The reason for this is a different mechanism of CO_2 corrosion which evolves on a microscopic scale. In many instances localized CO_2 corrosion on a microscopic scale is caused by one of these two factors:

- Galvanic attack
- Bacteria

Both effects, which are rather complicated and still not properly understood, are the subject of ongoing investigations.

NOMENCLATURE

A	Surface area of steel, m^2
A/V	Surface-to-volume ratio, m^{-1}
$A_{(FeCO_3)}$	Constant in Arrhenius-type equation for $k_{r(FeCO_3)}$
$B_{(FeCO_3)}$	Constant in Arrhenius-type equation for $k_{r(FeCO_3)}$, kJ/kmol
c_{CO_2}	Bulk aqueous concentration of CO_2, $kmol/m^3$
$c_{CO_3^{2-}}$	Bulk aqueous concentration of CO_3^{2-} ions, $kmol/m^3$
$c_{Fe^{2+}}$	Bulk aqueous concentration of Fe^{2+} ions, $kmol/m^3$
c_{H^+}	Bulk aqueous concentration of H^+ ions, $kmol/m^3$
$c_{s(H^+)}$	"Near-zero" concentration of H^+ underneath mackinawite film at steel surface, set to 1.0×10^{-7} $kmol/m^3$
$c_{HCO_3^-}$	Bulk aqueous concentration of HCO_3^- ions, $kmol/m^3$
$c_{H_2CO_3}$	Bulk aqueous concentration of H_2CO_3, $kmol/m^3$
c_i	Bulk aqueous concentration of given aqueous species, $kmol/m^3$
$c_{s(CO_2)}$	Aqueous concentration of CO_2 underneath mackinawite film at steel surface
CR	Corrosion rate, mm/y
d	Characteristic dimension for given flow geometry, m
d_p	Diameter of pipe, m
d_c	Diameter of rotating cylinder, m
D	Diffusion coefficient of given species, m^2/s
$D_{H_2CO_3}$	Aqueous diffusion coefficient of H_2CO_3, m^2/s
$D_{ref(H_2CO_3)}$	Reference aqueous diffusion coefficient of H_2CO_3, $D_{ref,H_2CO_3} = 1.3 \times 10^{-9}$ m^2/s at 25°C
D_{H^+}	Aqueous diffusion coefficient for H^+
$D_{ref(H^+)}$	Reference aqueous diffusion coefficient for H^+, $D_{ref(H^+)} = 2.80 \times 10^{-8}$ m^2/s at 25°C
D_{CO_2}	Aqueous diffusion coefficient for dissolved CO_2, $D_{CO_2} = 1.96 \times 10^{-9}$ m^2/s
E	Potential, V
E_{corr}	Corrosion (open circuit) potential, V
E_{rev}	Reversible potential
$f_{H_2CO_3}$	Flow factor for chemical reaction boundary layer
F	Faraday constant, $F = 96{,}485$ C/mol
$H_{sol(CO_2)}$	Henry's constant for dissolution of CO_2, bar/($kmol/m^3$)
ΔH_{Fe}	Activation enthalpy for Feoxidation, $\Delta H_{Fe} = 50$ kJ/mol
$\Delta H_{(H^+)}$	Activation enthalpy for H^+ ion reduction, $\Delta H_{(H^+)} = 30$ kJ/mol
$\Delta H_{(H_2CO_3)}$	Activation enthalpy for H_2CO_3 reduction, $\Delta H_{(H_2CO_3)} = 57.5$ kJ/mol
i	Current density, A/m^2
i_{corr}	Corrosion current density, A/m^2
i_a	Anodic current density, A/m^2
i_c	Cathodic current density, A/m^2
$i_{c(H^+)}$	Cathodic current density for H^+ ion reduction, A/m^2
$i_{c(H_2CO_3)}$	Cathodic current density for H_2CO_3 reduction, A/m^2
$i^d_{lim(H^+)}$	Mass transfer (diffusion) limiting current density for H^+ ion reduction, A/m^2
$i^r_{lim(H_2CO_3)}$	Chemical reaction limiting current density for H_2CO_3 reduction, A/m^2
$i_{0(Fe)}$	Exchange current density of iron oxidation, A/m^2
$i_{0(H^+)}$	Exchange current density for H^+ ion reduction, A/m^2
$i_{0(H_2CO_3)}$	Exchange current density for H_2CO_3 reduction, A/m^2
$i^{ref}_{0(Fe)}$	Reference exchange current density of Feoxidation, $i^{ref}_{0(Fe)} = 1$ A/m^2
$i^{ref}_{0(H^+)}$	Reference exchange current density of H^+ oxidation, $i^{ref}_{0(H^+)} = 0.03$ A/m^2 at $T_{c,ref} = 25$°C and pH 4
$i^{ref}_{0(H_2CO_3)}$	Reference exchange current density for H_2CO_3 reduction, $i^{ref}_{0(H_2CO_3)} = 0.06$ A/m^2 at $T_{c,ref} = 25$ °C, pH 5, and $c_{H_2CO_3,ref} = 10^{-4}$ $kmol/m^3$
$i_{\alpha(H^+)}$	Charge transfer current density for H^+ ion reduction, A/m^2
$i_{\alpha(H_2CO_3)}$	Charge transfer current density for H_2CO_3 reduction, A/m^2

I	Ionic strength, $kmol/m^3$
k^b_{hyd}	Backward reaction rate of H_2CO_3 dehydration reaction, s^{-1}, $k^b_{hyd} = k^f_{hyd}/K_{hyd}$
k^f_{hyd}	Forward reaction rate for CO_2 hydration reaction, s^{-1}
$k_{m(H^+)}$	Aqueous mass transfer coefficient for H^+, m/s
$k_{m(H_2CO_3)}$	Aqueous mass transfer coefficient for H_2CO_3, m/s
$k_{m(CO_2)}$	Aqueous mass transfer coefficient for CO_2, m/s
$k_{r(FeCO_3)}$	Kinetic constant in ferrous carbonate precipitation rate equation $mol^{-1} s^{-1}$
K_{hyd}	Equilibrium hydration constant for CO_2, $K_{hyd} = k^f_{hyd}/k^b_{hyd} = 2.58 \times 10^{-3}$
K_{bi}	Equilibrium constant for dissociation of HCO_3^-, $kmol/m^3$
K_{bs}	Equilibrium constant for dissociation HS^-, $kmol/m^3$
K_{ca}	Equilibrium constant for dissociation of H_2CO_3, $kmol/m^3$
$K_{sol(CO_2)}$	Solubility constant for dissolution of CO_2, $kmol/m^3/bar$
$K_{sp(FeCO_3)}$	Solubility product constant for ferrous carbonate, $(kmol/m^3)^2$
M_{Fe}	Molecular mass of iron, kg/kmol
n	Number of electrons used in reducing or oxidizing given species, kmol/kmol
p_{CO_2}	Partial pressure of CO_2, bars
p_{H_2S}	Partial pressure of H_2S, bars
$\Re$	Electrochemical reaction rate, $kmol/(m^2 s)$
$\Re_{FeCO_3}$	Precipitation rate for iron carbonate, $kmol/(m^3 s)$
R	Universal gas constant, $R = 8.314$ J/(mol K)
Re	Reynolds number, $Re = v\rho_{H_2O}d/\mu_{H_2O}$
Sc	Schmidt number of a given species, $Sc = \mu_{H_2O}/(\rho_{H_2O}D)$
Sh_p	Sherwood number of a given species for a straight pipe flow geometry, $Sh_p = k_m d_p/D$
Sh_r	Sherwood number of a given species for a rotating cylinder flow geometry, $Sh_r = k_m d_c/D$
$SS_{(FeCO_3)}$	Supersaturation of iron carbonate
T_c	Temperature, °C
$T_{c,ref}$	Reference temperature, $T_{c,ref} = 25°C$
T_f	Temperature, °F
T_k	Temperature, K
v	Water characteristic velocity, m/s
z_i	Species charge of various aqueous species

Greek Characters

$\delta_{m(H_2CO_3)}$	Thickness of mass transfer layer for H_2CO_3, m
$\delta_{r(H_2CO_3)}$	Thickness of chemical reaction layer for H_2CO_3, m
μ_{H_2O}	Water dynamic viscosity, Pa · s
$\mu_{H_2O,ref}$	Reference water dynamic viscosity, at reference temperature, Pa · s, $\mu_{H_2O,ref} = 1.002 \times 10^{-4}$ Pa · s at 20°C
$\zeta_{H_2CO_3}$	Ratio of mass transfer layer and chemical reaction thicknesses for H_2CO_3
ρ_{H_2O}	Density of water, kg/m^3
ρ_{Fe}	Density of iron, kg/m^3

ACKNOWLEDGMENTS

The author is indebted to the many individuals who contributed to the evolution of this review. The list includes fellow scientists and researchers, corrosion engineers from the industry, and graduate students. Many are already mentioned in the list of references. Others, who are too numerous to be listed by name here, are mainly past and present staff and students at the Institute for Corrosion and Multiphase Technology, Ohio University. Also, my gratitude goes to the many companies who have been supporting research efforts in CO_2 corrosion for a sustained period of time by providing continued guidance and funding.

A. INTRODUCTION

A1. Historical Perspective

Oxidation is an important high-temperature corrosion phenomenon. Metals or alloys are oxidized when heated to elevated temperatures in air or in highly oxidizing environments, such as combustion atmospheres with excess air or oxygen. Many metallic components are subject to oxidation in engineering applications.

The first paper that expressly addressed high-temperature oxidation was written by Gustav Tammann in 1920. He articulated the "parabolic law," that is, the rate of oxidation of metal decreases as oxide layer thickness increases. In 1922 he established the logarithmic law of oxidation of metals. However, the first paper that laid out the basics of the problem as we know it was that by N. B. Pilling and R. E. Bedworth in 1923. They defined "high temperature" as that at which the transport of the reactive components through the protective layer was the principal determinant of the reaction rate (as opposed to the situation in aqueous corrosion processes at close to ambient temperatures). They showed that under these circumstances it could be expected that the rate of reaction would diminish as the protective scale thickened, leading to a "parabolic rate law." They also highlighted the problems associated with forming an adherent crack-free protective oxide layer on the oxidizing surface because of the volume changes associated with the oxidation process.

*Editor's Note: In his forthcoming book, *High Temperature Corrosion: Fundamentals and Engineering*, in the Wiley Series in Corrosion, C. A. C. Sequeira discusses the subject of high-temperature oxidation in more detail than is possible in this overview chapter.

The discussion to this seminal paper shows that others were thinking along similar lines at the time. Six years later, Leonard B. Pfeil introduced the concept of movement of metal outward rather than oxygen inward into the oxide layer, and in 1934 Portevin, Prétet, and Jolivet carried out extensive studies on the oxidation of iron and its alloys. At the same time, the discovery that oxides contained lattice defects and that the transport processes within them are determined by the motion of these defects allowed a more quantitative approach. This was recognized by Carl Wagner, who produced an important body of work over the course of the next 20 years largely defining how we now look at the basic theory of the bulk transport processes in oxides. Of significance was the derivation of Wagner's equation by Hoar and Price in 1938. In recent years, however, the recognition that in many cases the transport processes involve short-circuit paths, such as grain boundaries, has introduced further complications into this elegant picture.

The problem of the integrity of the protective oxide was not part of Wagner's contribution, and its practical solution for the high-temperature alloys that were developed for applications mentioned above was discovered essentially by accident in the early 1940s. It was found that very small amounts of what are now called "reactive elements" added to the alloys introduced a remarkable improvement in the apparent integrity of the protective oxide, particularly in its resistance to thermal cycling. The reasons for this effect are still a matter of considerable debate.

Other important contributions in the 1939–1948 period were those of Cabrera and Mott postulating that oxide film growth is controlled by ions jumping from site to site over intervening energy barriers. Mott's theory was then highly criticized by Karl Hauffe, who studied the oxidation of alloys. During the 1920–1940 period, other relevant studies on oxidation at high temperature deserve reference: the interference method of obtaining thickness of oxide films (Tammann, 1920–1926), the spectroscopic method to obtain thickness of oxide film (Constable, 1927), and the X-ray and electron diffraction methods to study oxide films (Finch Quarrell, 1933).

The earliest treatments of oxidation problems considered simple systems, with a single oxidant (usually oxygen) and a pure metal, although in practice high-temperature-resistant materials were always alloys. More recently, approaches such as in multicomponent diffusion theory have been applied, and the growth of oxides on polyphase materials have been analyzed. These approaches have been greatly assisted by the development of modern characterization techniques.

A2. Purpose of This Chapter

The oxidation of metals is usually a reaction between a gas and a solid which produces a solid reaction product. At a first glance, this would seem to be a very simple process but, actually, it is considerably more complex. The metal is usually not pure but contains, in addition to metallic impurities, O, N, H, C, S, and so on. The gas atmosphere is also usually complex, containing (in addition to O_2), N_2, H_2, CO_2, H_2O, and so on. One would think that the reaction product, that is, the scale that formed on the metal, acts as a physical barrier between the reactants, and thus the reaction should cease after the barrier is established. We know that this is not the case, because transport of matter through the scale causes the reaction to continue. We also know that the scale may not be dense and adherent to the substrate, but it may be cracked, partially spalled, partially detached (wrinkled), or even very porous. In some extreme cases, the scale may be a liquid which simply drips from the surface or it may volatilize at very high temperatures. Indeed, the reaction between a gas and a metal is very complicated.

Our interest in this multidisciplinary field of physical chemistry, solid-state chemistry, metallurgy, materials science, and engineering arises from the fact that the chemical activity of a metal in various environments is an important factor in the winning, processing, and use of the metal. Demands are pressing from aerospace/gas turbine, chemical processing, refining and petrochemical, fossil-fired power generation, coal gasification, waste-to-energy industry, pulp and paper, heat treating, mineral and metallurgical processing, nuclear power, space exploration, molecular electronics, and other sides for better metals and alloys for high-temperature service in special reactive atmospheres and for metals with special physical properties.

The science of gas–solid reactions, oxidation referred to in the generic sense, can involve reactions with, for example, sulfur, nitrogen, carbon dioxide, and water vapor and has greatly evolved in the past 50 years. Numerous symposia and colloquia [1–7] have been held on the subject and have been widely attended by researchers from all over the world. One of the many factors enabling advancement of our understanding of the field is the creation and evolution of new, sophisticated instruments and techniques which allow a much better analysis of scale compositions and structures. Details regarding this subject have led to thousands of publications and the writing of several books. Of the more recent books on oxidation, those indicated in references [8–17] have been very useful.

The present chapter summarizes the main factors for determining the nature and extent of gas–metal reactions, which are of paramount importance to understand the subject.

B. THERMODYNAMIC CONSIDERATIONS

An important tool in the analysis of oxidation problems is equilibrium thermodynamics which, although not predictive of kinetics, allows one to ascertain which reaction products

are possible, whether or not significant evaporation or condensation of a given species is possible, the conditions under which a given reaction product can react with a condensed deposit, and so on. The complexity of the oxidation phenomena usually dictates that the thermodynamic analysis be represented in graphical form. The types of thermodynamic diagrams most often used in oxidation research are:

1. Gibbs free energy versus composition diagrams and activity versus composition diagrams, which are used for describing thermodynamics of solutions [18–22]
2. Standard free energy of formation versus temperature diagrams which allow the thermodynamic data for a given class of compounds, oxides, sulfides, carbides, and so on, to be represented in a compact form [23–29]
3. Vapor species diagrams, which allow the vapor pressures of compounds to be presented as a function of convenient variables such as partial pressure of a gaseous component [30–33]
4. Two-dimensional, isothermal stability diagrams, which map the stable phases in systems involving one metallic and two reactive, nonmetallic components [34–37]
5. Two-dimensional, isothermal stability diagrams, which map the stable phases in systems involving two metallic components and one reactive, nonmetallic component [38, 39]
6. Two-dimensional, isothermal stability diagrams, which map the stable phases in systems involving two metallic and two reactive, nonmetallic components [40]

The basic concepts pertinent to the construction and analysis of those thermodynamic diagrams are partial Gibbs free energy, chemical potential, free energy of mixing, Gibbs–Duhem equation, activity, Raoult's law, Henry's law, equilibrium state, variance (number of degrees of freedom of a system), pressure dependence of activity in the case of equilibrium between a condensed solution and a gas phase, and types of solution (ideal, dilute, concentrated). These concepts are described in numerous thermodynamics books [19, 41–43].

Determination of the conditions under which a given corrosion product is likely to form is often required, for example, in selective oxidation of alloys. In this regard, Ellingham diagrams, that is, plots of the standard free energy of formation (ΔG°) versus temperature for the compounds of a type (e.g., oxides, sulfides, carbides) are useful in that they allow comparison of the relative stabilities of each compound. In the next section these free-energy/temperature diagrams will be discussed, and then our considerations on the thermodynamics of high-temperature oxidation will finish with a brief reference to the volatility of oxides.

B1. Ellingham Diagrams

The Ellingham plot is a graphical representation of the standard free energies of oxidation of pure metals versus temperature. The most useful form of representation is to express the quantities in terms of 1 mol of the oxidising species:

$$M + O_2 = MO_2 \qquad (20.1)$$

At a given temperature T, the standard free energy ΔG_T° of the reaction is

$$\Delta G_T^\circ = \Delta H_T^\circ - T\,\Delta S_T^\circ \qquad (20.2)$$

where ΔH_T° and ΔS_T° are, respectively, the standard enthalpy and entropy of the reaction. At equilibrium, we can write

$$\Delta G_T^\circ = -RT \ln \mathrm{K} = -RT \ln\left(\frac{a_{\mathrm{HO}_2}}{a_{\mathrm{M}}} \cdot p_{\mathrm{O}_2}^{-1}\right) \qquad (20.3)$$

Assuming that the oxide MO_2 is stoichiometric and that there is no miscibility between metal and oxide, the activities of M and MO_2 are taken as unity. Thus

$$\Delta G_T^\circ = RT \ln p_{\mathrm{O}_2} \qquad (20.4)$$

The oxygen partial pressure at which the metal and oxide coexist is the dissociation pressure of the oxide. In Ellingham diagrams, ΔG_T°(or $RT \ln p_{\mathrm{O}_2}$) is plotted versus temperature for the compounds of a given type (e.g., oxides, sulfides, chlorides, carbides). The standard enthalpy and entropy of formation of the compounds are also considered to be independent of temperature over large temperature ranges (the "Ellingham approximation"). For these conditions

$$\Delta G_T^\circ = \Delta H_{298}^\circ - T\,\Delta S_{298}^\circ \qquad (20.5)$$

Accordingly, the ΔG_T° values fall on straight lines in the diagram although changes in the slope of the lines occur in the diagram corresponding to phase changes of the metal or the compound. Figure 20.1 is such a plot for many simple oxides. The values of ΔG_T° are expressed as kilojoules per mole of O_2 so the stabilities of various oxides may be compared directly; that is, the lower the position of the line on the diagram, the more stable the oxide.

The values of p_{O_2} may be obtained directly from the oxygen monograph on the diagram by drawing a straight line from the origin marked O through the free energy line at the temperature of interest and reading the oxygen partial pressure from its intersection with the scale at the right side labeled p_{O_2}. Values for the pressure ratio H_2/H_2O for equilibrium between a given metal and oxide may be obtained by drawing a similar line from the point marked H to the scale

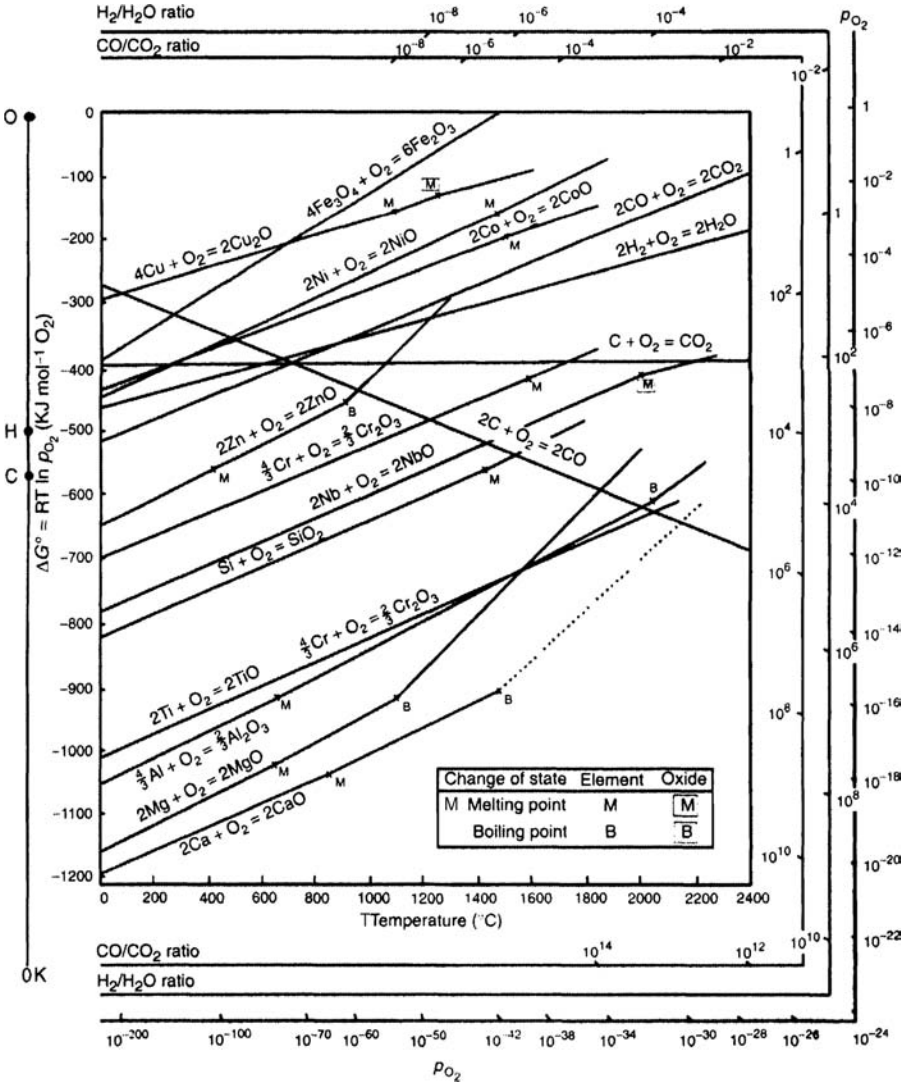

FIGURE 20.1. Standard free energy of formation of selected oxides as function of temperature [12].

labelled H_2/H_2O ratio and values for the equilibrium CO/CO_2 ratio may be obtained by drawing a line from point C to the scale CO/CO_2 ratio. Thus, it is possible to obtain the oxygen potential of the environment in terms of $p_{O_2}, p_{H_2}/p_{H_2O}, p_{CO}/p_{CO_2}$ and the oxygen partial pressure in equilibrium with the oxide of interest from Figure 20.1 to determine whether or not the oxide is likely to form thermodynamically.

Figure 20.1 also illustrates the relative stability of various oxides. The most stable oxides have the largest negative values of ΔG_T°, or the lowest values of p_{O_2}, or the highest values of $p_{H_2}\,/\,p_{H_2O}$ and p_{CO}/p_{CO_2}.

It is clear from Figure 20.1 that oxides of iron, nickel, and cobalt, which are the alloy bases for the majority of engineering alloys, are significantly less stable than the oxides of some solutes (e.g., chromium, aluminum, silicon) in engineering alloys. When one of these solute elements is added to iron, nickel, or cobalt, internal oxidation of the solute is expected to occur if the concentration of the solute is relatively low. As the solute concentration increases to a sufficiently high level, oxidation of the solute will be changed from internal oxidation to external oxidation, resulting in an oxide scale that protects the alloy from rapid oxidation. This process is known as "selective oxidation." The majority of iron-, nickel-, and cobalt-based alloys rely on selective oxidation of chromium to form a Cr_2O_3 scale for oxidation resistance. Some high-temperature alloys use aluminum to form an Al_2O_3 scale for oxidation resistance.

Most oxides exhibit high melting points and remain in a solid state for the temperature range in which the alloys are used. Oxides of molybdenum (MoO_3) and vanadium (V_2O_5), however, exhibit very low melting points. Vanadium (V), which is a strong carbide former, is often used in alloy steels for increasing the strength of the material. However, the

amount used typically is quite small and is not likely to form V_2O_5. Molybednum (Mo) is also a strong carbide former and is used in a small amount to strengthen low-alloy steels (e.g., Cr–Mo steels). It is unlikely that these steels will be affected by MoO_3 oxidation problems.

Industrial gaseous atmospheres may, in addition to air, consist of complex gases (CO_2, H_2O, SO_2, SO_3, etc.) or mixtures of several gases or contain the gaseous products of corrosion or of the thermal decomposition of corrosion products [44–46]. Despite the complexity of corrosion phenomena, the problem can be solved, in some cases, using simple thermodynamic calculations from simplifying hypotheses. In other situations involving numerous components, it is necessary to use software that minimizes the total free energy of the system [47–53].

B2. Volatility of Oxides

Some oxides exhibit high vapor pressures at very high temperatures (e.g., above 1000°C). Oxide scales become less protective when their vapor pressures are high. Chromium, molybednum, tungsten, vanadium, platinum, rhodium, and silicon are metals for which volatile species are important at high temperature. Vanadium is typically used in small quantities as a carbide former in alloy steels. Thus, the volatility of VO_2 is generally of no concern in oxidation of alloys.

The oxidation of Pt and Pt group metals at high temperatures is influenced by oxide volatility in that the only stable oxides are volatile. This results in a continuous mass loss. Alcock and Hooper [54] studied the mass loss of Pt and Rh at 1400°C as a function of oxygen pressure. The gaseous species were identified as PtO_2 and RhO_2. These results have an extra significance because Pt and Pt–Rh wires are often used to support specimens during high-temperature oxidation experiments. If these experiments involve mass change measurements, it must be recognized that there will be a mass loss associated with volatilization of oxides from the support wires.

The oxidation of pure Cr is, in principle, a simple process since a single oxide, Cr_2O_3, is observed to form. However, under uncertain exposure conditions, several complications arise which are important both for the oxidation of pure Cr and for many important engineering alloys which rely in a protective Cr_2O_3 layer for oxidation protection. The two most important features are scale thinning by CrO_3 evaporation and scale buckling as a result of compressive stress development [55–58].

The formation of CrO_3 by the reaction

$$Cr_2O_3 + \tfrac{3}{2}O_2 = 2CrO_3 \qquad (20.6)$$

becomes significant at high temperatures and high oxygen partial pressures. The evaporation of CrO_3, shown schematically in Figure 20.2, results in the continuous thinning of the protective Cr_2O_3 scale so the diffusive transport through it is rapid. The effect of the volatilization on the oxidation kinetics has been analysed by Tedmon [59]. Caplan and Cohen [57] also observed that resistance promoted volatilization of Cr_2O_3. Asteman et al. [58] indicated that high vapor pressure of $CrO_2(OH)_2$ can form by reacting Cr_2O_3 with H_2O in O_2-containing environments.

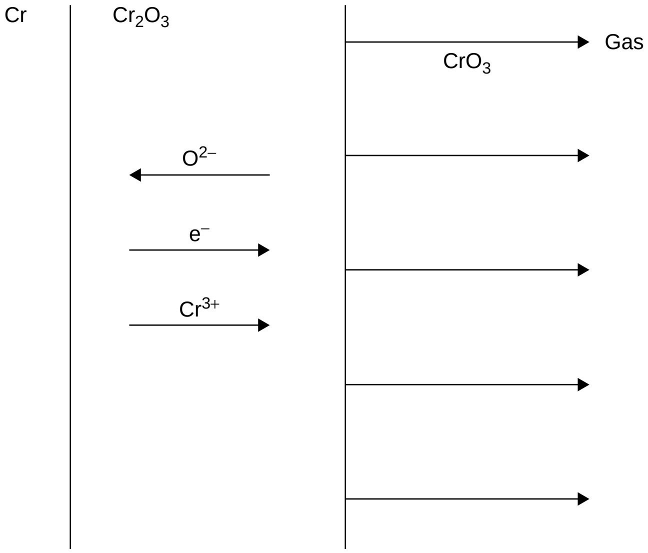

FIGURE 20.2. Schematic diagram of combined scale growth and oxide volatilization from Cr [12].

The volatilization of oxides is particularly important in the oxidation of Mo and W at high temperatures and high oxygen pressures. Unlike Cr, which develops a limiting scale thickness, complete oxide volatilization can occur in these systems. The condensed and vapor species for the Mo–O and W–O systems have been reviewed by Gulbransen and Meier [60] and the vapor species diagrams for a temperature of 1250 K are presented in Figures 20.3 and 20.4. The effects of oxide volatility on the oxidation of Mo have been observed by Gulbransen and Wysong [61] at temperatures as low as 475°C and the rate of oxide evaporation above 725°C was such that gas-phase diffusion became the rate-controlling process [62]. Naturally, under these conditions, the rate of oxidation is catastrophic. Similar behavior is observed for the oxidation of tungsten, but at higher temperatures because of the lower vapor pressures of the tungsten oxides. The oxidation behavior of tungsten has been reviewed in detail by Kofstad [8].

The formation of SiO_2 on silicon-containing alloys and Si-based ceramics results in very low oxidation rates. However, this system is also one that can be influenced markedly by oxide vapor species. Whereas the oxidation of Cr is influenced by such species at high oxygen pressures, the effects for Si are important at low oxygen partial pressures.

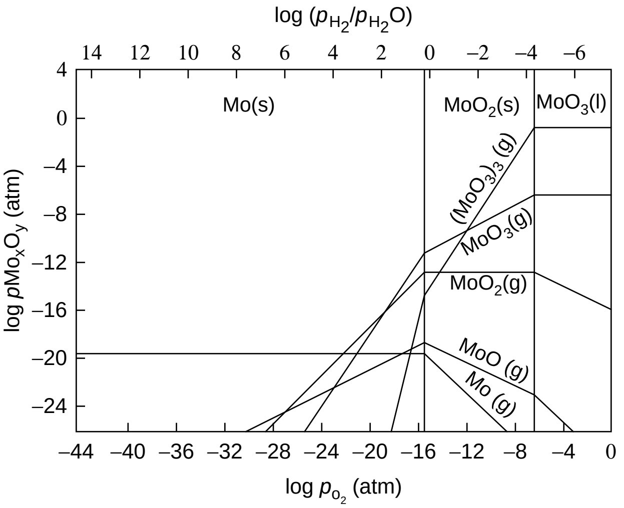

FIGURE 20.3. The Mo–O system volatile-species diagram for 1250 K [12].

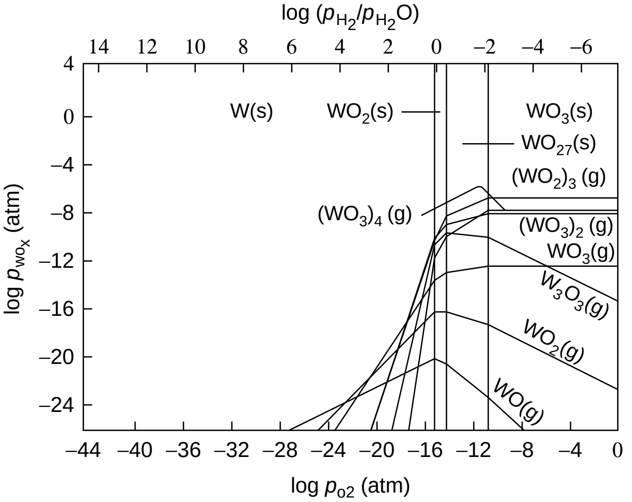

FIGURE 20.4. The W–O system volatile-species diagram for 1250 K [12].

The reason for this may be seen from the volatile-species diagram for the Si–O system [45]. A significant pressure of SiO is seen to be in equilibrium with SiO_2(s) and Si(s) at oxygen pressures near the dissociation pressure of SiO_2. This can result in a rapid flux of SiO away from the specimen surface and the subsequent formation of a nonprotective SiO_2 smoke. This formation of the SiO_2 as a smoke, rather than as a continuous layer, allows continued rapid reaction [63, 64].

C. KINETIC CONSIDERATIONS

Consider the oxidation reaction

$$M + \tfrac{1}{2}O_2 = MO \qquad (20.7)$$

The progress, W, of this reaction can be characterized using several definitions of the reaction rate. It can, for example, be defined as the rate of oxygen pickup, $dn_o/A\,dt$, where dn_o corresponds to the number of moles of oxygen consumed during time dt and A the sample area. From an experimental point of view, though, it is easier to use the sample weight gain Δm. The reaction rate can then be expressed as $d\,\Delta m/A\,dt$, where $d\,\Delta m$ is the weight change occurring during time dt. These expressions are linked by the equation

$$\frac{dn_o}{dt} = \frac{1}{16}\frac{d\,\Delta m}{dt} \qquad (20.8)$$

where Δm is expressed in grams. Integration of the rate equation leads to the rate law corresponding to the corrosion process and defines the progress, W, of the reaction with time. We obtain either an implicit form,

$$f(W) = kt \qquad (20.9)$$

where k is the rate constant for the reaction process, or an explicit form,

$$W = g(t) \qquad (20.10)$$

In any fundamental study of the oxidation mechanism of a metal or an alloy, one of the main factors that needs to be determined is the variation of the oxidation rate with temperature and with the pressure of the oxidizing gas.

This type of investigation has sometimes been neglected because of difficulties controlling precisely the gas pressure in thermobalances. However, for some years, it has been possible to couple such thermogravimetric equipment to devices capable of controlling and monitoring the oxygen partial pressure in a gas (e.g., an electrochemical oxygen pump, oxygen sensor). The oxygen pressure then can be precisely controlled between 1 and 10^{-25} bar in gas mixtures, for example, inert gas–oxygen, CO–CO_2, or H_2–H_2O mixtures [65].

The rate constants of the kinetic laws often obey, under constant pressure, an Arrhenius-type equation:

$$k = k^0 \exp\left(-\frac{E_a}{RT}\right) \quad (\text{at given } P) \qquad (20.11)$$

where E_a is the apparent activation energy of the process, R the gas constant, and T the absolute temperature. The apparent activation energy can be easily determined by plotting k as a function of $1/T$. The slope of the straight line obtained is equal to $-E_a/2.303R$. A change in the activation energy could indicate a corresponding change in the limiting process for the corrosion reaction.

The main kinetic laws are of linear, parabolic, logarithmic, or cubic types, but it should be noted that these are

limiting cases and deviations from them are often encountered. In some cases, it is difficult, or even impossible, to obtain such simple kinetic laws from the experimental results [11, 66–74].

At high temperatures, the oxidation kinetics of numerous metals obey a parabolic law:

$$W^2 = k_p t \qquad (20.12)$$

where k_p is the parabolic constant. Such a law corresponds, as will be shown later, to a corrosion rate limited by diffusion through the compact scale that is formed.

The reaction rate constant may be expressed in different units depending on the actual parameter used to define the progress of the reaction. For example, if the extent of reaction is characterized by the mass gain per unit surface area of the metal during the exposure period t, the kinetic law is given by $(\Delta m/A)^2 = k_p t$ and the rate constant is expressed in $kg^2/m^4/s$. If the reaction rate is defined by the increase in thickness, y, of the scale, the kinetic law has the form $y^2 = k'_p t$ and the parabolic rate constant k'_p is expressed in m^2/s. On the other hand, if the reaction rate is defined by the number of moles of the compound MX formed per unit area during the exposure period t, the kinetic law has the form $(\Delta n_{MX}/A)^2 = k''_p t$. In this case, the rate constant k''_p is expressed in $mol^2/m^4/s$. There is a simple relationship between the rate constants k_p, k'_p, and k''_p:

$$k'_p = \Omega^2 k''_p = \left(\frac{\Omega}{M_x}\right)^2 k_p \qquad (20.13)$$

where Ω is the molar volume of compound MX and M_x is the atomic weight of the nonmetallic element (oxygen, sulfur, etc.).

In some cases, the oxidation rate is constant, which means that the kinetic law is linear:

$$W = k_l t \qquad (20.14)$$

where k_l is the linear rate constant. As will be shown later, the oxidation rate is then governed by an interfacial process such as sorption or reaction at the metal/oxide interface. Using similar nomenclature as for the parabolic rate constants, k_l characterizes the reaction measured by the mass gain per unit surface area during time t and k'_l if the rate is defined by the increase in thickness of the growing scale.

The cubic law ($W^3 = k_c t$) has been observed during the oxidation of several metals, for example, copper, nickel, and zirconium.

Logarithmic laws are observed typically in the case of many metals at low temperatures (generally below 673 K). The initial oxidation rate, corresponding to the growth of oxide layers of thickness generally less than a few tens of nanometers, is quite rapid and then drops off to low or negligible values. This behavior can be described by a direct logarithmic law:

$$W = k_{\log} \log(at + 1) \qquad (20.15)$$

or by an inverse logarithmic law,

$$\frac{1}{W} = B - k_{\text{inv}} \log t \qquad (20.16)$$

The evaluation of the kinetic parameters in the case of the logarithmic law is, generally, not very precise and this makes it difficult to validate experimentally proposed mechanisms.

The oxidation rate is frequently found to follow a combination of rate laws.

As an example, at low temperatures, a logarithmic law followed by a parabolic rate equation can be observed. At high temperature, oxidation reactions are often described by a parabolic rate equation followed by a linear law ("paralinear" regime) or a linear rate equation followed by a parabolic law [75].

Typical kinetic laws characteristic of the oxidation of a large number of metals as a function of temperature were fully analyzed by Kubaschewski and Hopkins [9], Kofstad [11], and others.

Besides the variation of the kinetic laws with temperature, a change of these rate equations with time can sometimes occur. A typical example characteristic of the changes that may be observed as functions of temperature and time is given in Figure 20.5. At 800°C, for example, the following rate equations are successively observed: parabolic, paralinear, and finally linear after extended oxidation. In many cases, it may be difficult to fit experimental data to simple rate equations, but a first approach can be to plot the $W = f(t)$ curve using double-logarithmic coordinates. In the case of a law of type $W^n = kt$, the slope of the straight line then gives the value of n, that is, 1, 2, and 3 for linear, parabolic, and cubic laws, respectively.

Some authors, using computer software, fit the data to a third-degree polynomial in W:

$$AW^3 + BW^2 + CW + D = t \qquad (20.17)$$

Difficulties in evaluating the proper kinetic law are particularly important in the case of changes in the oxidation behavior during the corrosion process.

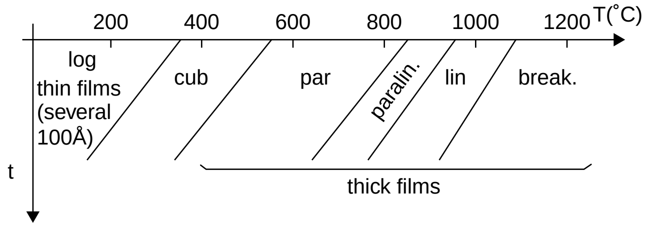

FIGURE 20.5. Successive kinetic laws observed for the oxidation of a given metal as functions of temperature and time.

An elegant method consists of continuously monitoring the kinetic curves with exposure time and calculating, for each experimental point, the rate constant appropriate to the expected model. Deviations from this model can be readily identified [76].

D. DEFECT STRUCTURES

The formation of an oxide scale starts with the adsorption of oxygen gas on the metal surface. During adsorption, oxygen molecules of other gaseous species in the environment dissociate and are adsorbed as atoms. These atoms initially adsorb at sites where the atom is in contact with the maximum number of surface atoms in the metal substrate. Therefore, in polycrystalline materials, grains of preferential orientation exist where the number of adsorbed atoms from the gaseous atmosphere is highest. The result of this process is a two-dimensional adsorption layer. The presence of adsorbed layers may increase the rates of surface diffusion by orders of magnitude compared with those for surfaces with none or small amounts of adsorbate.

When the metal surface which is saturated with adsorbed oxygen atoms or atoms from other gaseous species is further exposed to the gas, the gaseous species may dissolve in the metal and nuclei of the corrosion product are formed on the surface. These nuclei grow laterally and form a continuous film on the surface. Generally nucleation and growth of the nuclei are dependent on the composition of the substrate, the grain orientation, the temperature, and the gas partial pressure. The nuclei grow in thickness and lateral direction and the reaction rate increases with time. As soon as the nuclei impinge on each other, the growth rate decreases. Therefore, the general reaction kinetics can be described by an S-shaped curve [11].

Nuclei of all potential corrosion products can be formed on alloys initially, that is, those that are possible from thermodynamic stability considerations. After the initial stage of oxidation, which is determined by the behavior of the nuclei, growth of the continuous scale occurs in the thickness direction. In dense oxide scales, the growth is determined by solid-state diffusion through the scale. Corrosion products, which include the oxide scales, are ionic structures and diffusion in such structures requires lattice disorder; that is, the corrosion products need to be nonstoichiometric compounds. Therefore, an understanding of reaction mechanisms in high-temperature conditions requires a precise knowledge of defect structures in solids. Extensive studies of defect theory have been provided by Kröger [77, 78], Philibert [79], Kofstad [80], Mrowec [81], and others, but here only an oversimplified discussion will be presented.

Various types of defects may affect scale growth, but we shall only consider the crystalline defects that determine the growth of a compact layer and the three-dimensional defects, such as cracks and pores, that determine the growth of a porous scale. The crystalline defects represent departures from the perfect crystalline array and include point defects (imperfections in the distribution of ions within the lattice), line defects (displacements in the periodic structure of the crystal in certain directions or dislocations), and planar defects or grain boundaries (regions of lattice mismatch).

The point defects comprise either empty crystallographic sites (vacancies) or atoms occupying the interstices between the regular lattice sites (interstitial atoms). Their mole fraction in each sublattice, that is, either the cation or anion sublattice, generally does not exceed 10^{-3}–10^{-2} and is frequently much less. For point defect mole fractions sufficiently high, the defects may associate or cluster to form complex defects such as extended defects or aggregates of point defects (clusters). Point defects strongly influence the growth of compact scales and will be briefly treated hereafter.

D1. Point Defects

D1.1. Real Oxide Structures. A complete development of defect chemistry of inorganic compounds requires a system of notation to describe all the elements of the crystal or "structural elements," that is, not only regular crystallographic sites but also lattice imperfections. The Kröger and Vink notation [78], recommended by the International Union of Pure and Applied Chemistry (IUPAC) because of its great simplicity, will be used here. Thus, in a crystal MO, a structural element of the cation sublattice has a normal charge of $+2$ and, consequently, an effective charge equal to zero. The electronic defects may be considered as structural elements. The electronic defect with positive charge will be written $h^{\bullet}$ (h with a superscript dot). This defect corresponds to the removal of an electron from a regular site of the cation sublattice and can also be written as $M_M^{\bullet}$ (a superscript prime is used for a negative charge). These rules must be followed in writing defects in equilibrium reactions:

- Electroneutrality of the total charges of the structural elements, that is, involving normal charges, actual charges, and effective charges.
- Mass balance, that is, the number of atoms of each chemical species involved in the defect reaction must be the same before and after the defect formation.
- Ratio of regular lattice sites, that is, for a crystal M_pX_q: number of M sites/number of X sites should be equal to p/q.

Following these rules, it is possible to write equilibrium reactions that occur internally without involving the external environment and external equilibria involving mass exchange with the environment. The equilibrium constants will

then be evaluated assuming that the activities of atoms on their normal lattice positions can be considered as unity and the activities of point defects will be approximated by their concentration, usually indicated by a double bracket and expressed as the number of moles per mole of compound.

D1.2. Stoichiometry. Alkali halides, silver halides, and several oxides (e.g., Al_2O_3, MgO) are stoichiometric compounds. Some of them are characterized by vacancies and interstitials in one sublattice (e.g., AgBr, with Frenkel disorder); others possess defects in both sublattices (e.g., NaCl, with Schottky disorder). However, it is apparent that neither of these defects can be used to explain material transport during oxidation reactions, because neither defect structure provides a mechanism by which electrons may migrate.

Considering a diagrammatic representation of the oxidation process shown in Figure 20.6, it is seen that either neutral atoms or ions and electrons must migrate in order for the reaction to proceed. In these cases, the transport step of the reaction mechanism links the two phase boundary reactions as indicated. There is an important distinction between scale growth by cation migration and scale growth by anion migration in that cation migration leads to scale formation at the scale–gas interface whereas anion migration leads to scale formation at the metal–scale interface. In order to explain simultaneous migration of ions and electrons, it is necessary to assume that the oxides, for example, that are formed during oxidation are nonstoichiometric compounds. From a macroscopic viewpoint, two alternative classes of nonstoichiometric compounds can be considered:

(i) M_aX_b compounds for which atom number of M/atom number of X $> a/b$. These compounds are ionic semiconductors with metal excess ($M_{a+\delta}X_b$, where δ is the deviation from stoichiometry in comparison with the stoichiometric composition M_aX_b), or with nonmetal deficit ($M_aX_{b-\delta}$). ZnO is a typical *n*-type semiconductor with a metal excess; TiO_2, Nb_2O_5, MoO_3, and WO_3 are typical *n*-type semiconductors with nonmetal deficit.

(ii) M_aX_b compounds for which atom number of M/atom number of $X < a/b$. These include the *p*-type semiconductors with metal deficit (FeO, NiO, Cr_2O_3, Al_2O_3) or with an excess of nonmetal (UO_2).

In order to allow extra metal in ZnO, it is necessary to postulate the existence of interstitial cations with an equivalent number of electrons in the conduction band. The structure may be represented as shown in Figure 20.7. Here, both Zn^+ and Zn^{2+} are represented as possible occupiers of interstitial sites. Cation conduction occurs over interstitial sites, and electrical conductance occurs by virtue of having the "excess" electrons excited into the conduction band. These, therefore, are called excess or "quasi-free" electrons.

The formation of this defect may be visualized, conveniently, as being formed from a perfect ZnO crystal by losing oxygen, the remaining unpartnered Zn^{2+} leaving the cation lattice and entering interstitial sites and the two negative charges of the oxygen ion entering the conduction band. In this way, one unit of ZnO crystals is destroyed and the formation of the defect may be represented by

$$ZnO = Zn_i^{\bullet\bullet} + 2e' + \tfrac{1}{2}O_2 \qquad (20.18)$$

for the formation of $Zn_i^{\bullet\bullet}$, doubly charged Zn interstitials, or

$$ZnO = Zn_i^{\bullet} + e' + \tfrac{1}{2}O_2 \qquad (20.19)$$

for the formation of $Zn_i^{\bullet}$, singly charged Zn interstitials. The two equilibria shown above will yield to thermodynamic treatment, giving Eq. (20.20) for the equilibrium in Eq. (20.18),

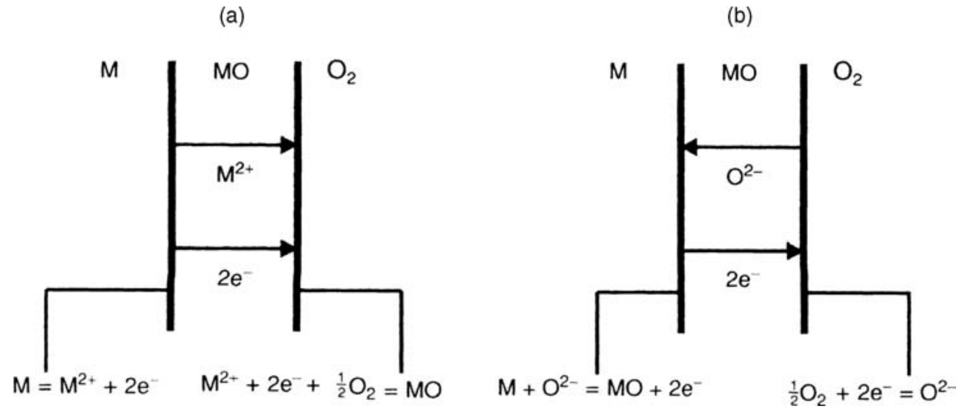

FIGURE 20.6. Interfacial reactions and transport processes for high-temperature oxidation mechanisms: (a) cation mobile; (b) anion mobile [12].

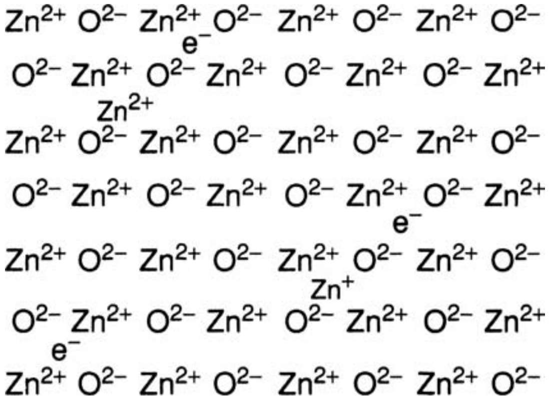

FIGURE 20.7. interstitial cations and excess electrons in ZnO—an *n*-type metal-excess semiconductor [12].

$$K = a_{\mathrm{Zn}_i^{\bullet\bullet}} a_{e'}^2 p_{O_2}^{1/2} \tag{20.20}$$

or, since the defects are in very dilute solution, we may assume that they are in the range obeying Henry's law, when the equilibrium may be written in terms of concentrations $[\mathrm{Zn}_i^{\bullet}]$ and $[e']$ as in Eq. (20.21):

$$K' = [\mathrm{Zn}_i^{\bullet\bullet}][e']^2 p_{O_2}^{1/2} \tag{20.21}$$

If Eq. (20.18) represents the only mechanism by which defects are created in ZnO, then Eq. (20.22) follows:

$$2[\mathrm{Zn}_i^{\bullet\bullet}] = [e'] \tag{20.22}$$

Hence, putting Eq. (20.22) into Eq. (20.21), we obtain

$$K' = 4[\mathrm{Zn}_i^{\bullet\bullet}]^3 p_{O_2}^{1/2} \tag{20.23}$$

or Eq. (20.24) and therefore we obtain Eq. (20.25):

$$[\mathrm{Zn}_i^{\bullet\bullet}] = \left(\tfrac{1}{4}K'\right)^{1/3} p_{O_2}^{-1/6} = \mathrm{const}\, p_{O_2}^{-1/6} \tag{20.24}$$

$$[e'] \propto p_{O_2}^{-1/6} \tag{20.25}$$

Similarly, applying the same analysis to the reaction shown in Eq. (20.19), the result shown in Eq. (20.26) is obtained:

$$[\mathrm{Zn}_i^{\bullet}] = [e'] \propto p_{O_2}^{-1/4} \tag{20.26}$$

Measurement of electrical conductivity as a function of oxygen partial pressure carried out between 500 and 700°C [82] indicated that the conductivity of ZnO varied with oxygen partial pressure having exponents between 1/4.5 to 1/5. This result indicates that neither defect mechanism predominates, and the actual structure could involve both singly and doubly charged interstitial cations [80].

Similar approaches can be applied to nonstoichiometric compounds with cation vacancies ($Cu_{2-\delta}O$-type oxide), oxygen interstitials ($UO_{2+\delta}$-type oxide), and so on [80, 82–86].

D1.3. Mass and Electrical Transport. Intragranular or volume diffusion in crystalline compounds takes place through crystal imperfections and mainly through the movement of point defects. Several types of mechanisms may be considered, as shown schematically in Figure 20.8, but mass transport generally occurs by hopping mechanisms from a well-defined site of the crystal into another adjacent site. Consider a one-dimensional flux of particles (atoms, ions, point defects, or electrons) in the Ox direction. Let $C(x, t)$ be the defect concentrations (number of particles per unit volume) at the coordinate x and at time t. In a chemical potential gradient and without an electrical potential gradient or other type of driving force, a flux J of particles occurs in the Ox direction:

$$J = -\frac{CD}{RT}\frac{\partial \mu}{\partial x} \quad \text{(generalized Fick's law)} \tag{20.27}$$

where D is the diffusion coefficient of the particle.

Under an additional electrical potential gradient, the particle flux would obey the following general equation:

$$J = -\frac{CD}{RT}\frac{\partial \tilde{\mu}}{\partial x} \tag{20.28}$$

where $\tilde{\mu}$, termed the electrochemical potential, is related to the chemical potential μ by the equation

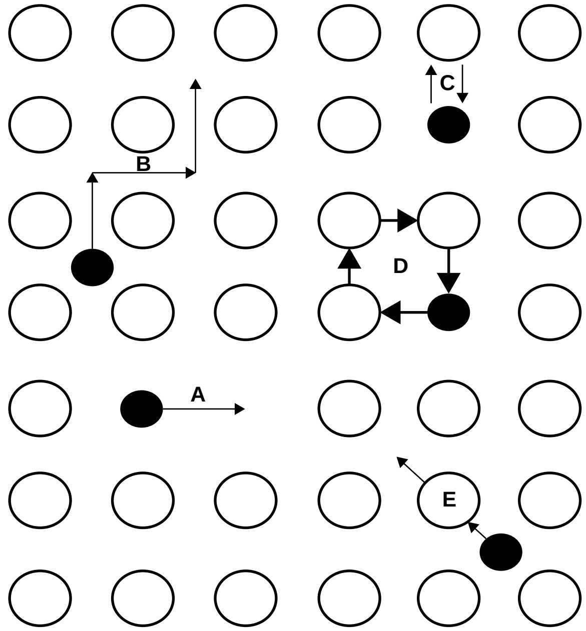

FIGURE 20.8. Schematic illustration of transport mechanisms in crystalline solids [87].

$$\tilde{\mu} = \mu \pm zF\phi \tag{20.29}$$

where z is the particle charge number, F the Faraday constant, ϕ the electrical potential, and $\pm zF$ the electrical charge.

If the ion movements within one sublattice of the binary compound M_aX_b produce displacements of ions only in that sublattice, M or X diffusion is termed self-diffusion, and the self-diffusion coefficient D_j of component j will obey the following equation:

$$J_j = -\frac{C_jD_j}{RT}\frac{\partial\mu_j}{\partial x} \tag{20.30}$$

where C_j is the concentration of component j.

Let J_δ be the flux of the defect, δ, in the j sublattice at the coordinate x and in the absence of an electric field. The diffusion coefficient D_δ of the defect δ is defined by the equation

$$J_\delta = -\frac{C_\delta D_\delta}{RT}\frac{\partial\mu_\delta}{\partial x} \tag{20.31}$$

where C_δ is the concentration of the defect δ.

As a general rule, the relationship between D_j and D_δ may be written as

$$C_\delta D_\delta = C_jD_j \tag{20.32}$$

If N_δ is the mole fraction of defects δ in the j sublattice, we may write

$$D_j = N_\delta D_\delta \quad \text{since} \quad N_\delta = \frac{C_\delta}{C_\delta + C_j} \approx \frac{C_\delta}{C_j} \tag{20.33}$$

This relationship shows that the self-diffusion of component j is proportional to the mole fraction of defect δ contained in the j sublattice.

A comparison of the self-diffusion coefficients of anions and of cations may allow identification of the component which provides the majority of mass transport within the crystal. Thus, nonstoichiometric oxides such as NiO, FeO and Cu_2O contain metal vacancies; this observation is in agreement with the order of magnitude of the diffusion coefficients, that is, $D_M \gg D_O$ ($D_M/D_O \approx 10^2$–10^4). In contrast, in some oxides such as TiO_2 that have an oxygen deficit, it has been observed that $D_O \approx D_{Ti}$. This result is not in contradiction with the assumption of several authors who postulate that both oxygen vacancies and titanium interstitials are simultaneously present in this oxide.

Electrical transport in ionic compounds does not necessarily occur by means of point defects. Electrical conductivity due to a charge carrier is given by

$$\sigma = CUzF \tag{20.34}$$

where C is the molar concentration of charge carriers per unit volume and U is the electrical mobility (expressed in m^2/s/V). The mobility U corresponds to the velocity of the charged particles under an electric field equal to unity.

In ionic crystals, the total conductivity σ_t is generally written in terms of ionic and electronic conductivities as

$$\sigma_t = \sigma_{\text{ionic}} + \sigma_{\text{electronic}} \tag{20.35}$$

Let σ_δ be the partial conductivity relevant to the defect δ, and considering the definition of the electrical mobility U_δ, we obtain

$$\sigma_\delta = zFC_\delta U_\delta = z^2F^2\frac{C_\delta D_\delta}{RT} \tag{20.36}$$

If σ_j is the contribution to the total conductivity of the charged species j, we can write

$$\sigma_j = \sigma_\delta \tag{20.37}$$

Since

$$C_\delta D_\delta = C_jD_j \tag{20.38}$$

we obtain the Nernst–Einstein equation

$$\sigma_j = z^2F^2\frac{C_jD_j}{RT} \tag{20.39}$$

In this equation, σ_j is the ionic contribution of species of type j to the total conductivity, D_j is the self-diffusion coefficient of particles j, and C_j is the volume concentration of regular sites in the sublattice that contain species j.

Since the mobility of electronic defects is much higher than that of point defects ($U_\varepsilon \gg U_\delta$), it can be said that the total electrical conductivity is essentially electronic. Also, it is easy to show that the conductivity varies with oxygen pressure in the same way as does the concentration of the predominant ionized defect (although the current is carried by electronic defects).

The temperature dependence of the conductivity is determined by both the charge carrier mobility and concentration terms.

When ion movements involve jumps between definite sites of the crystal, an energy barrier ΔG_m has to be overcome. The defect mobility then increases strongly with temperature according to an exponential law (*activated process*):

$$U_\delta = U_\delta^0 \exp\left(-\frac{\Delta G_m}{RT}\right) \tag{20.40}$$

ΔG_m is the free energy of migration of the defect.

The temperature dependence of electron mobility is a function of the electronic structure of the crystal. The

electron movement is an activated process and the electronic mobility obeys the equation

$$U_\varepsilon = U_\varepsilon^0 \exp\left(-\frac{E_\varepsilon}{RT}\right) \quad (20.41)$$

where E_ε is the overall activation energy for polaron migration in the periodic field within the crystal or, in other words, for polaron (electron and distortion field) scattering by lattice vibrations and/or imperfections, also known as polaron hopping and usually treated as a diffusion process.

The determination of the variation of the electronic mobility with temperature may allow us to identify the migration mechanism of electrons in the lattice. Whatever the nature of the charge carrier (ionic or electronic defects), the concentration increases with temperature according to

$$[\text{defect}] = [\text{defect}]_0 \exp\left(-\frac{\Delta G_\text{f}}{RT}\right) \quad (20.42)$$

ΔG_f is the free energy of formation of defects.

Whatever the nature of the conduction mechanism, the electrical conductivity is proportional to the product of the drift mobility and the charge carrier concentration, which varies exponentially with temperature. The crystal conductivity always increases with increasing temperature due to the exponential increase in the number of charge carriers. This characteristic differentiates covalent/ionic compounds from metallic conductors, which exhibit a decrease of the electrical conductivity with increasing temperature [77–81].

D2. Line and Planar Defects

As diffusion along line and surface defects, including dislocations, grain boundaries, and internal and external surfaces, is generally more rapid than lattice diffusion, they are termed high diffusivity or easy diffusion paths. This type of diffusion is often called "short-circuit diffusion." The contribution of grain boundary diffusion to the total diffusion flux decreases as the temperature increases for two main reasons:

- The grain size is larger, the higher the temperature, because of grain growth.
- The activation energy for grain boundary diffusion is less than that for intracrystalline diffusion (from 20 to 30% smaller).

The effective diffusion coefficient may be defined by the Hart equation:

$$D_\text{eff} = fD_\text{gb} + (1 - f)D_\text{v} \quad (20.43)$$

where f is the volume fraction of short-circuit paths, D_v the lattice diffusion coefficient, and D_gb the short-circuit diffusion coefficient; D_eff may be identified with D_V, the intracrystalline diffusion coefficient, at high temperatures but, at low temperatures, the short-circuit contribution to diffusion can become significant. In general, in accordance with Tamann's empirical law, grain boundary diffusion would be expected to dominate at lower temperatures, say below a transition temperature of between one-half to two-thirds of the absolute melting temperature of the crystal. Conversely, the contribution made by short-circuit diffusion processes will be negligible at higher temperatures. Grain boundary diffusion in growing oxide scales has been reported for NiO [88, 89], Cr_2O_3 [90], Al_2O_3 [91], and other product films.

D3. Three-Dimensional Defects

Stress generation in the oxide layer and the underlying metal may cause through-scale cracking, spalling of the oxide, stratification phenomena, or even detachment of the scale. These phenomena lead to loss of protective properties and faster degradation of metals and alloys. The sources of stress may be either internal (scale growth) or external (mechanical and/or thermal stresses). Often, due to mechanical stresses, a porous layer may develop after the oxide scale has reached a critical thickness. The two main sources of stress are growth stresses, which develop during isothermal formation of the scale, and thermal stresses, which arise from differential thermal expansion between the oxide scale and the metal or alloy during temperature changes.

D3.1. Growth Stresses. Observed stresses depend on the oxidation mechanism and on the physicochemical properties of the alloy and of the oxide. The most important causes of growth stresses include [11, 16] the volume difference between the oxide and the metal (Pilling and Bedworth rule), the oxidation mechanism (e.g., internal or external oxidation of alloys), oxygen dissolution in alloys, epitaxial constraints, physicochemical changes in the alloy or scale during the growth, and specimen geometry.

Two different types of growth stresses can be distinguished, geometrically induced growth stresses caused by the surface curvature of components and the intrinsic growth stresses. As can often be seen in oxidation experiments, the oxide scales crack at the edges of the specimens, initially leading to a locally increased attack at these sites. Such cracking is usually due to geometrically induced growth stresses that arise at edges and corners due to the small surface curvature radius. This situation has been dealt with quantitatively by Manning [92].

With the help of models, the tangential and radial stresses can be calculated for the ideal case of curved surfaces with a constant radius of curvature. Introduction of the oxide

displacement vector M is helpful here; M lies perpendicular to the oxide–metal interface and describes the displacement of a reference point in the film resulting from the oxidation. The magnitude and sign of M are incorporated in M, which is calculated as follows:

$$M = \text{PBR}(1 - a) - (1 - V) \tag{20.44}$$

where a is the fraction of oxide formed on the scale surface, $1 - a$ is the fraction of oxide formed at the metal–oxide interface, V is the volume fraction of metal consumed in the oxidation by injecting vacancies into the metal, $1 - V$ is the volume fraction of metal consumed in the oxidation which originates directly from the metal surface, and PBR is the Pilling–Bedworth ratio (see later in this section).

Oxidation leads to an increase in the strain in the circumferential direction (tangential strain ε^{t}_{Ox}) with a rate of

$$\frac{d\varepsilon^{t}_{Ox}}{dt} = \left(\frac{M}{R_s}\right)\frac{dh}{dt} = \frac{M}{R_s \cdot \text{PBR}}\frac{dx}{dt} \tag{20.45}$$

where R_s is the radius of curvature of the surface (concave $R_s < 0$, convex $R_s > 0$) and h is the metal recession (increase in oxide film thickness $dx = \text{PBR}\ dh$). Equation (20.45) allows the tangential stresses σ^{t}_{Ox} to be calculated assuming linear elastic behavior. The magnitude of the maximum radial stresses, σ^{r}_{Ox}, is given by

$$\sigma^{r}_{Ox} = \frac{\text{PBR}\, h}{R_s}\sigma^{t}_{Ox} \tag{20.46}$$

The relationship between the signs of the tangential and radial strains and stresses in the scale and at the metal–oxide interface, respectively, are

$$\text{sign}\,\varepsilon^{t}_{Ox} = \text{sign}(-\varepsilon^{r}_{Ox}R_s) \tag{20.47}$$

$$\text{sign}\,\sigma^{t}_{Ox} = \text{sign}(-\sigma^{r}_{Ox}R_s) \tag{20.48}$$

A plus sign indicates tensile stress, a minus sign means compressive stress. The sign and level of the stresses in the scale depend on its growth direction and on the radius of service curvature as well as the PBR. The latter was introduced in 1925 in order to explain the formation of growth stresses during oxidation and describes the volume change that is involved in the transition from the metal lattice to the cation lattice of the oxide when only the oxygen anions are diffusing. In other words, the PBR corresponds to the ratio of the volume per metal ion in the oxide to the volume per metal atom in the metal [13]:

$$\text{PBR} = \frac{1}{a}\frac{V_{eq}(M_aO_b)}{V_{eq}(M)} \tag{20.49}$$

It was argued that if the PBR was less than 1, the growth stresses would be tensile and the oxide would crack and not cover the entire metal surface. As indicated in Table 20.1, alkali and alkaline earth metals belong to this class of materials. On the other hand, if the PBR was higher than 1, compressive stresses would develop and the oxide could be protective, at least during the early stages of oxidation. The majority of metals fall into this category.

We now know that the Pilling–Bedworth rule regarding protective behavior exhibits several exceptions. Important examples are tantalum or niobium where, even though the PBR is substantially larger than unity, cracks develop in the oxide scale after extended exposure and these produce nonprotective conditions. Whereas the Pilling–Bedworth paper was a significant advance at the time, it is now recognized that the approach was incomplete and that the influence of the difference between the molar volume of metal and oxide depends on the oxide growth mechanism. However, the Pilling–Bedworth approach may be of great help for the assessment of the geometrically induced growth stresses, as shown earlier.

D3.2. Thermal Stresses. In most applications, high-temperature alloys are subjected to temperature fluctuations even under nominally isothermal conditions. In this case, though, the resultant stresses in the oxide layer resulting from the difference in the coefficient of thermal expansion (CTE) of the metal and oxide (see Table 20.2) are small and may be neglected. This will not be the case, however, for large thermal cycles or during cooling to room temperature when large stresses, perhaps of 1-GPa order, are produced in the oxide layer. Metals have generally a higher coefficient of thermal expansion than oxides (Table 20.2), and consequently, tensile stresses are induced in the oxide scale on heating and compressive stresses during cooling.

The thermally induced stresses can be calculated from the coefficients of thermal expansion according to the equation [94]

TABLE 20.1. Pilling–Bedworth Ratios for Some Metal–Oxygen Systems

Oxide	K_2O	CaO	MgO	CeO_2	Na_2O	CdO	Al_2O_3	ZnO	ZrO_2
PBR	0.45	0.64	0.8	0.90	0.97	1.21	1.28	1.55	1.56
Oxide	Cu_2O	NiO	FeO	TiO_2	CoO	SiO_2	Cr_2O_3	Ta_2O_5	Nb_2O_5
PBR	1.64	1.65	1.7	1.73	1.86	1.9	2.07	2.5	2.7

TABLE 20.2. Linear Coefficients of Thermal Expansion of Metals and Oxides, °C^{-1} [95]

System	Oxide: $10^6\alpha_{ox}$	Metal: $10^6\alpha_M$	Ratio: α_M/α_{OX}
Fe/FeO	12.2	15.3	1.25
Fe/Fe_2O_3	14.9	15.3	1.03
Ni/NiO	17.1	17.3	1.03
Co/CoO	15.0	14.0	0.93
Cr/Cr_2O_3	7.3	9.5	1.30
Cu/Cu_2O	4.3	18.6	4.32
Cu/CuO	9.3	18.6	2.0

$$\sigma_{therm} = \frac{-E_{Ox}\Delta T(\alpha_M - \alpha_{Ox})}{\left(1 + 2\frac{E_{Ox}}{E_M}\frac{d_{Ox}}{d_M}\right)(1-\nu)} \qquad (20.50)$$

where α is the CTE for the metal and the oxide, E is Young's modulus for the metal and the oxide, d is the thickness for the metal and the oxide, respectively, and ν is Poisson's ratio. Here, ΔT stands for the temperature change. The CTEs for technical materials can be found in many of the materials producers' brochures, and those for corrosion products are given in the literature [95]. In most cases, the CTEs can be approximated by linear behavior in the temperature range concerned, but in some cases, where phase changes occur in the scale during the temperature change, nonlinear temperature dependence is found for the CTE. This is, for example, the case for several sulfide layers [96] and is particularly important for magnetite and some iron-based spinels [97], affecting stresses in oxide scales on low-alloy steels. This naturally decisively affects the stress situation in the oxide scales on low-alloy steels [98]. In the temperature range between about 600 and 450°C, the magnetite partial layer is under tensile stress when cooling from 600°C. At lower temperatures, this oxide partial layer may come under compressive stresses, depending on the metallic substrate and its CTE. In the hematite layer, the stresses are always compressive, as the CTE always lies below that of the low-alloy steel (the exception is 9% chromium steel at temperatures below 150°C).

D3.3. Mechanical Scale Failure. Growth stresses and thermal stresses may be relieved through various mechanisms that could operate simultaneously:

- Plastic deformation of the oxide scale
- Plastic deformation of the metal substrate
- Spalling of the oxide from the alloy
- Cracking of the scale

When plastic deformation is not sufficient for stress relief, cracking may develop in the scale. It is the more efficient relaxation mechanism but will result in a sudden increase in corrosion rate. The metal oxidation may exhibit repeated regular sequences of cracking and healing of the scale.

Under tensile stresses (heating to temperatures higher than the oxidation temperature or over convex regions of a nonplanar surface) cracks appear as soon as the elastic fracture strain is reached. This critical value will be significantly less than 1% even at high temperatures.

Under compressive stresses, the degradation leads to spallation and the mechanisms are more complex. Two processes are necessary to produce spalling: transverse cracking through the oxide and decohesion along the metal–oxide interface. Two routes of spallation have been identified: the case corresponding to a low cohesive strength of the oxide and a high adhesive strength of the scale on the substrate surface (route 1: cracking of the oxide before decohesion) and the case corresponding to a high cohesive strength of the oxide and poor adhesion of the oxide to the metal (route 2: decohesion before metal cracking). Figure 20.9 illustrates these two distinct mechanisms.

E. COMPACT SCALE GROWTH

E1. Elementary Chemical Steps

The overall oxidation reaction of a metal M may be written as

$$a\text{M} + \frac{b}{2}\text{O}_2 = \text{M}_a\text{O}_b \qquad (20.51)$$

The reaction can proceed only if diffusion of matter (oxygen or metal) occurs through the solid scale M_aO_b. If the scale is porous, mass transport occurs by oxygen diffusion; if the scale is compact, mass transport occurs by means of solid-state diffusion. In the latter case, the oxidation mechanism consists of at least four steps [100–104]:

- Surface step—oxygen adsorption on the oxide
- External step—matter exchange at the adsorbed phase/oxide interphase
- Diffusion step—ionic transport through the oxide scale
- Internal step—matter exchange at the oxide/metal interphase

Of course, mass transport by migration of ionized point defects is accompanied by simultaneous electrical transport, which complicates the process. In this section, the kinetics of the oxidation process leading to the growth of a compact scale are analyzed.

Let a chemical elementary step be a local reversible reaction that occurs without the formation of a distinct intermediate product, that is, the reaction proceeds in a single step, and let an interphase elementary step be a chemical

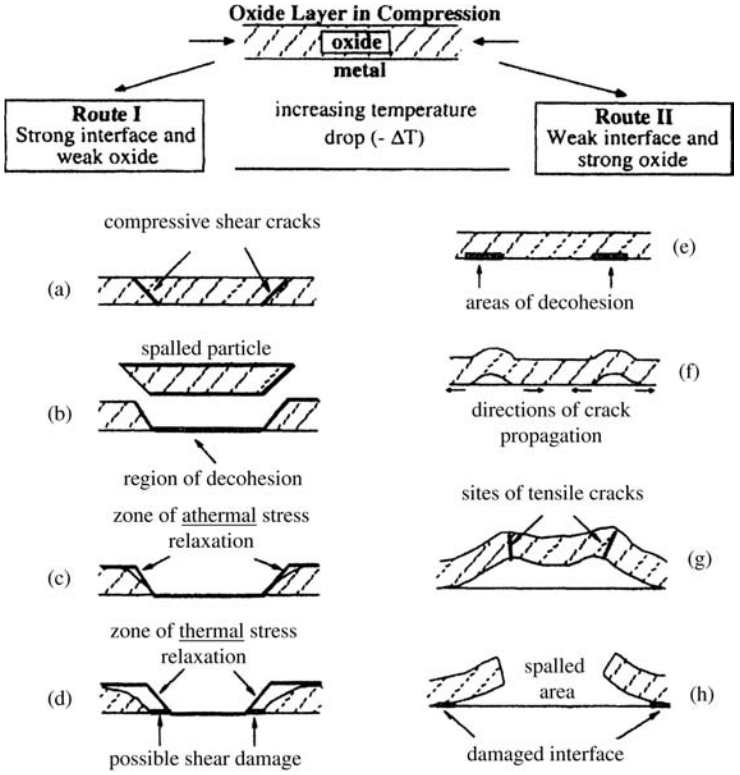

FIGURE 20.9. Cracking and spallation by compressive oxide stresses [99].

process involving matter exchange between two distinct phases. The main difficulty encountered for the formulation of these steps relates to the conditions required for the application of classical theories (Eyring theory) for the calculation of the step rates [105]. We will have to choose, for the adsorbed phase as well as for the oxide, structural models that exhibit ideal behavior for the reacting species in their own phase. Moreover, we will assume that the theory of absolute rates can, under these conditions, be extended to heterogeneous elementary steps involving matter exchange between two different phases.

On a solid surface, the atomic environment is modified in comparison with that in the bulk. The resulting imbalance of the forces in the surface of solids produces attractive forces for gas molecules or atoms. The phenomenon of adsorption can then produce an excess of gas atoms or molecules on the surface compared with the concentration in the adjacent gas phase. For adsorption to occur spontaneously, the process must produce a decrease in free energy, but since that is also a decrease in system entropy, adsorption is always an exothermic process. Consequently, the amount of adsorbed gas at equilibrium at constant pressure (the "adsorption isobar") decreases with increasing temperature.

Depending on the nature of the forces involved, adsorption processes may be classified as physical adsorption (also termed van der Waals adsorption or physisorption) or chemical adsorption, usually abbreviated to chemisorption [106, 107]. Physisorption is generally quasi-instantaneous while chemisorption often proceeds slowly, involving an activation energy E_a. Thus, the chemical adsorption rate becomes appreciable only at sufficiently high temperature.

Many theories and models have been proposed to explain the shape of adsorption isotherms that represent the variation of adsorbed volume as a function of gas pressure or of the p/p_0 ratio (p_0 is the saturation vapor pressure at the experimental temperature). The description of monolayer adsorption can be made using as variable the fraction of the available adsorption sites which are occupied by adsorbed atoms or molecules, $\upsilon = s/s_0$, where s_0 is the number of adsorption sites that are initially available per unit surface area and s is the number of occupied surface sites per surface area unit (thus, υ is the fraction of occupied sites).

Chemisorption involves partial electronic transfer between adsorbed molecules and the substrate. The solid surface appears inhomogeneous and exhibits specific "active" sites on which chemisorption takes place preferentially. When temperature is increased, the amount of adsorbed gas by chemisorption increases because it is an activated process; then the adsorption isobar passes through a maximum because chemisorption is an exothermic process. Since the establishment of high-temperature oxidation requires at least the presence of one monolayer on the surface, it can be assumed that a chemisorbed phase is produced as a surface step.

In this discussion, this adsorbed phase is considered as a two-dimensional solution (i.e., sorption of a monolayer) of free surface sites, s, and of occupied sites leading to the formation of a superficial compound referred to as O-s (atomically chemisorbed oxygen) where O is a particle of the gas phase (O_2). Such a solution may be considered as ideal since it is assumed that no interaction occurs between the free and occupied sites. The sorption process may then be described by an equation representing the balance between two opposite reactions with rate constants K'_a and K''_a, respectively:

$$O_2 + 2s = 2\text{O-s} \tag{20.52}$$

with $K_a = K'_a/K''_a$ denoting the equilibrium constant of the elementary step of sorption.

Under these conditions, if p denotes the partial pressure of the p_{O_2} species, υ^{eq} the fractional surface coverage, the law of mass action applied to the equilibrium leads to

$$\Theta^{eq} = \frac{\sqrt{K_a p_{O_2}}}{1 + \sqrt{K_a p_{O_2}}} \tag{20.53}$$

indicating that the sorption is governed by the Langmuir equation (dissociation occurs on chemisorption, which is likely at high temperature). If $dn_{\text{O-s}}$ is the number of O-s particles formed by adsorption per unit area during the time dt, the rate of the sorption process can be given by the equations

$$\frac{dn_{\text{O-s}}}{dt} = K'_a(1-\Theta)^2 p_{O_2} - K''_a \Theta^2 \tag{20.54}$$

or

$$\frac{dn_{\text{O-s}}}{dt} = K'_a \frac{\Theta^2}{K_a}\left[\left(\frac{1-\Theta}{\Theta}\right)^2 K_a p_{O_2} - 1\right] \tag{20.55}$$

with

$$K_a p_{O_2} = \left(\frac{\Theta^{eq}}{1-\Theta^{eq}}\right)^2 \tag{20.56}$$

The proposed model to account for the external and internal steps uses the concept of point defects and, for simplicity, it can be assumed that only one defect is predominant in the lattice, that is, either the metal vacancy V''_M or the oxygen interstitial O''_i for the case of a p-type semiconductor and either the oxygen vacancy $V^{\bullet\bullet}_O$ or the metal interstitial $M^{\bullet\bullet}_i$ for the case of an n-type semiconductor. The defects are then generated at the external interphase (cationic diffusion, p-type semiconductor) or at the internal interphase (anionic diffusion, n-type semiconductor) (see Fig. 20.6).

Then, in the case of an n-type semiconductor with metal vacancies, the external step can be described by

$$\text{O-s} = O_O + V''_M + 2h^\bullet + s \tag{20.57}$$

with $K_e = K'_e/K''_e$ denoting the equilibrium constant of the external step of matter exchange. The external reaction rate is given by

$$\frac{dn_e}{dt} = K'_e\,\Theta - K''_e\,[V''_M]_e[h^\bullet]^2_e(1-\Theta) \tag{20.58}$$

Under equilibrium conditions, for a given value of υ, we have

$$\frac{dn_e}{dt} = K'_e\,\Theta\Big[1 - \big([V''_M]_e/[V''_M]^{eq}_e\big)^3\Big] \tag{20.59}$$

with

$$[V''_M]^{eq}_e = \frac{(1/4)K_e\Theta}{1-\Theta} \tag{20.60}$$

Again for a p-type semiconductor with metal vacancies, we have for the internal step

$$V''_M + 2h^\bullet + M = M_M \tag{20.61}$$

$$\frac{dn_i}{dt} = 4K'_i\,[V''_M]^3_i - [V''_M]^{eq3}_i \tag{20.62}$$

with

$$[V''_M]^{eq}_i = \left(\frac{1}{4}\frac{1}{K_i}\right)^{1/3} \tag{20.63}$$

In a thick, growing oxide scale, a positive space charge can appear in contact with the metal balanced by a negative space charge localized near the external interphase. This charge distribution induces, at any point within the scale, an electric field that both accelerates the positively charged ionic defects and slows down the negatively charged electronic defects until no net electrical current flows through the scale. Consequently, stationary concentration profiles are established in the MO scale, the electrically neutral zone extending over practically all of the scale thickness [108, 109].

Taking into account the possible electrical potential gradient through the scale, the particle fluxes are given by

$$J_z = -\left[D_\delta \frac{\partial c_\delta}{\partial x} \pm C_\delta U_\delta \frac{\partial \phi}{\partial x}\right] \tag{20.64}$$

$$J_\varepsilon = -D_\varepsilon\left[\frac{\partial c_\varepsilon}{\partial x} \pm C_\varepsilon U_\varepsilon \frac{\partial \phi}{\partial x}\right] \tag{20.65}$$

In these expressions, C_δ (C_ε) is the volume concentration of point (electronic) defects with z degree of ionization, D_δ (D_ε) is the diffusion coefficient, U_δ (U_ε) is the electric mobility of these charge carriers, and ϕ the electric potential at the coordinate x. The C_δ and $[\delta]$ are linked by the relationship $C_\delta = [\delta]/\Omega$, Ω being the volume of 1 mol of oxide. A positive sign has to be used if the defects are positively charged and a negative sign for negatively charged defects.

A brief kinetic analysis of the four elementary steps for reaction (51) has been presented in this section. The rate expressions of the elementary steps were expressed in a form involving the deviation from equilibrium, that is, within the framework of the thermodynamics of irreversible processes. The general system of equations relating to the growth of an oxide scale MO can then be established by expressing the mass balance at both sides of each interphase in the adsorbed phase and within the scale. These equations, being differential, cannot be solved analytically. However, it is possible to make the simplifying assumption that the concentrations tend to become time independent, that is, a quasi–steady state develops. On this basis, the system of differential equations allowing calculation of the reaction rate can be solved analytically, leading to considerable simplifications. It should be recalled that if one of the rate constants or the diffusion coefficient has a finite value, all the other constants having very large values, we deal with what is called a pure regime [110–113]. In all other cases, it is called a mixed regime [75, 114–116]. Hereafter, we describe pure diffusional regimes.

E2. Diffusion-Controlled Oxidation

Assuming that cationic transport across the growing oxide layer controls the rate of scaling and that thermodynamic equilibrium is established at each interphase, the outward cation flux $J_{M^{2+}}$ is equal and opposite to the inward flux of cation vacancies and we can write

$$J_{M^{2+}} = -J_{V''_M} = D_{V''_M} \frac{[V''_M]'' - [V''_M]'}{y} \tag{20.66}$$

where y is the oxide thickness, $D_{V''_M}$ is the diffusion coefficient for cation vacancies, and $[V''_M]'$ and $[V''_M]''$ are the vacancy concentrations at the scale–metal and scale–gas interphases, respectively.

Since there is thermodynamic equilibrium at each interphase, the volume of $[V''_M]'' - [V''_M]'$ is constant and we have

$$J_{M^{2+}} = \frac{1}{\Omega}\frac{dy}{dt} = \frac{1}{\Omega}\frac{K'}{y} \tag{20.67}$$

where

$$K' = D_{V''_M}\Omega\left([V''_M]'' - [V''_M]'\right). \tag{20.68}$$

Integrating and noting that $y = 0$ at $t = 0$ we obtain

$$y^2 = 2K't \tag{20.69}$$

which is the common parabolic rate law. Furthermore, it has been shown that the cation vacancy concentration is related to the oxygen partial pressure by the equation

$$[V''_M] = \text{const}\, p_{O_2}^{1/n} \tag{20.70}$$

The variation of the parabolic rate constant with oxygen partial pressure can be predicted by

$$K' \alpha \left[\left(p''_{O_2}\right)^{1/n} - \left(p'_{O_2}\right)^{1/n}\right] \tag{20.71}$$

and since p'_{O_2} is usually negligible compared with p''_{O_2}, we have

$$K' \alpha \left(p''_{O_2}\right)^{1/n} \tag{20.72}$$

Clearly, the concentration gradient in the scale never equals zero and, therefore, scale growth never stops.

Originally, Eq. (20.69) was derived by Wagner in a theoretical, detailed analysis of the electrochemical potential situation and the transport conditions in the scale. Figure 20.10 gives a summary of the conditions for which the theory is valid. Assumptions are as follows:

- The oxide layer is a compact, perfectly adherent scale.
- Migration of ions or electrons across the scale is the rate-controlling process.
- Thermodynamic equilibrium is established at both the metal–scale and scale–gas interfaces.
- The oxide scale shows only small deviations from stoichiometry and, hence, the ionic fluxes are independent of position within the scale.
- Thermodynamic equilibrium is established locally throughout the scale.
- The scale is thick compared with the distances over which space charge effects (electrical double layer) occur.
- Oxygen solubility in the metal may be neglected.

This model led to the final equation of the parabolic rate constant, which is [11, 109, 117, 118]

$$K'_p = \frac{1}{2}\int_{p'_{O_2}}^{p''_{O_2}} \left\{\frac{z_c}{|z_a|} D_M + D_O\right\} d\ln p_{O_2} \tag{20.73}$$

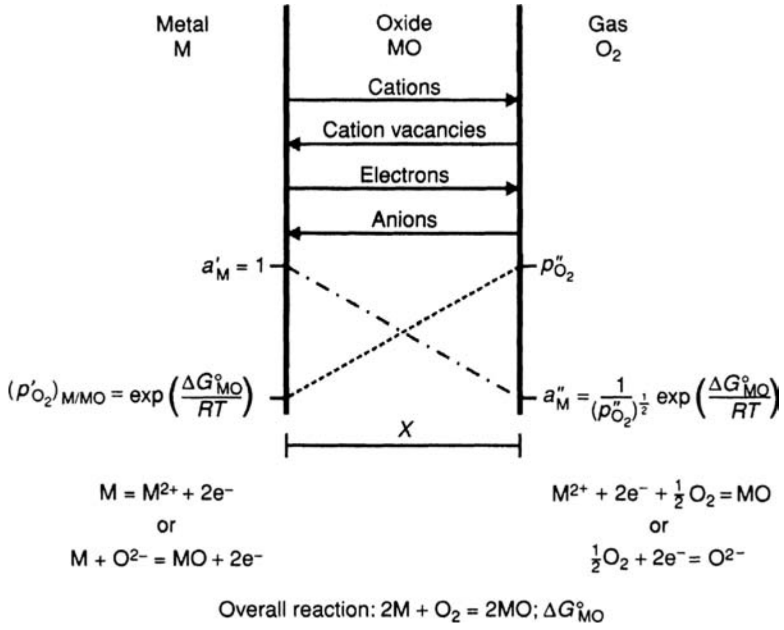

FIGURE 20.10. Diagram of scale forming according to Wagner's model [12].

where K'_p, D_M, and D_O are given in units of centimeters squared per second, with D_M and D_O the self-diffusion coefficients for random diffusion of the respective ions (metal and oxygen) and z the valence of the respective ion (anion and cation).

The parabolic rate law that was derived for thickness growth can also be modified for weight gain by oxidation. In this case, K'_p has to be replaced by K''_p according to the equation

$$K''_p = 2\int_z^2 K'_p \qquad (20.74)$$

Values of $\int_z$ are given in Table 20.3 for several oxides. These values are, however, based on the assumption that the scale is free of pores and cavities and consists of only one phase. Under practical conditions, this is not usually the case, and therefore these values should only be used as estimations.

TABLE 20.3. Calculation Factor $\int_z$ for Conversion of Mass Gain Data into Scale Thickness Data Using Equation (20.74) for Several Oxides and Sulfides [119]

Corrosion Product	$\int_z$ (g/cm^3)
FeO	1.28
Fe_3O_4	1.43
Fe_2O_3	1.57
Cr_2O_3	1.64
$FeCr_2O_4$	1.45
FeS	1.76
FeS_2	2.60

The oxidation rate constant K_p is the most important parameter for describing oxidation resistance. If K_p is low, the overall oxidation rate is low and metal consumption occurs at a very low rate. This is typical for protective oxidation. If K_p is high, metal consumption occurs at a high rate and the case of nonprotective oxidation exists. From K_p the metal consumption rate can also be calculated [120]. This requires knowledge of the stoichiometry of the oxide and the specific weight values as well as the molar weights of the reactants. Then the metal consumption can be calculated.

The real value of Wagner's analysis lies in providing a complete mechanistic understanding of the process of high-temperature oxidation under the conditions set out. The predictions of Wagner's theory for n-type and p-type oxides have been extensively examined by several workers [120–129]. For many systems, the obtained rate constants are generally several orders of magnitude larger than those which one would calculate from lattice diffusion data from Eq. (20.73). This discrepancy indicates that "short-circuit transport" is contributing to growth of the oxide film.

E3. Short-Circuit Diffusion

Lattice diffusion is the dominant process of mass transport at high temperature provided there is a sufficiently high defect concentration, but mass transport can also occur along dislocations or grain boundaries. Thus, the overall transport in polycrystalline oxide scales generally results from two fluxes of matter in parallel: an intragranular flux J_V and a flux along grain boundaries J_{gb}.

The oxidation rate may be expressed as a function of the effective diffusion coefficient defined by Eq. (20.43) (see Section D2). The scale growth rate obeys the differential equation

$$\frac{dy}{dt} = \Omega D_{\text{eff}} \frac{\Delta C}{y} \tag{20.75}$$

where ΔC is the defect concentration difference through the oxide scale and Ω the molar volume of the oxide. Integration of Eq. (20.75) leads to

$$y^2 = 2D_{\text{eff}} \Delta C\, t = K'_{\text{p(eff)}} t \tag{20.76}$$

where $K'_{\text{p(eff)}}$ is the effective parabolic constant.

Assuming that the oxide is dense and pure and the grains are spherical, the following rate equation can be obtained [110, 130–132]:

$$y^2 = 2\Omega\, \Delta C \left[D_{\text{V}} t + 4D_{\text{gb}} \frac{1}{K} (Kt + r_0^2)^{1/2} \right] \tag{20.77}$$

where r_0 is the initial grain radius and K is a constant which is a function of, among others, the surface energy of grain boundaries, their thickness, and the diffusion coefficient of matter across the grain boundaries. Further numerical development of this simple model has allowed a grain size distribution, different grain boundary widths, or different laws of grain growth to be taken into consideration.

F. MULTILAYERED SCALE GROWTH

The formation of several corrosion scales on metals or alloys is often observed. In order to understand clearly the growth mechanisms of these scales, it is of major importance to know whether they form concurrently or sequentially.

F1. Compact Subscales

The theory of multilayered scale growth on pure metals has been treated by Yurek et al. [133]. The hypothetical system treated is shown in Figure 20.11. It is assumed that the growth of both scales is diffusion controlled with the outward migration of cations large relative to the inward migration of anions. The flux of cations in each oxide is assumed to be independent of distance. Each oxide exhibits predominantly electronic conductivity and local equilibrium exists at the phase boundaries. The total oxidation reaction is

$$2V_{\text{M}_2} + M_{\text{M}_1} = 3V_{\text{M}_1} + M_{\text{M}_2} + O_{\text{O}_1} \tag{20.78}$$

The cation vacancies are assumed to be neutral. The cation flux in subscale 1 is

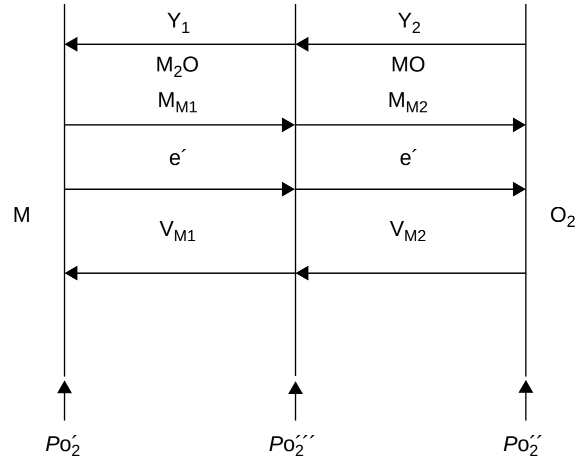

FIGURE 20.11. Schematic diagram of hypothetical two-layered scale.

$$J_{\text{M}} = \frac{1}{\Omega_1} \frac{K'_{\text{p}_1}}{y_1} \tag{20.79}$$

and the amounts Q of metal consumed per unit area to form layers 1 and 2 are, respectively,

$$Q_1 = \frac{2y_1}{\Omega_2} \qquad Q_2 = \frac{y_2}{\Omega_2} \tag{20.80}$$

The fractions of the cation flux involved in the growth of subscales (1) and (2) are, respectively,

$$J_{\text{M}_1} = \frac{Q_1}{Q_1 + Q_2} J_{\text{M}} = \frac{2y_1}{\Omega_1} \cdot \frac{K'_{\text{p}_1}/\Omega_1 y_1}{(2y_1/\Omega_1) + (y_2/\Omega_2)} \tag{20.81}$$

$$J_{\text{M}_2} = \frac{Q_2}{Q_1 + Q_2} J_{\text{M}} = \frac{y_2}{\Omega_2} \cdot \frac{K'_{\text{p}_2}/\Omega_2 y_2}{(2y_1/\Omega_1) + (y_2/\Omega_2)} \tag{20.82}$$

with $J_{\text{M}} = J_{\text{M}_1} + J_{\text{M}_2}$.

With this model, it is not possible to express simply the ratio of the thickness of both subscales. However, the ratio of parabolic rate constants can be obtained as

$$\frac{K'_{\text{p}_2}}{K'_{\text{p}_1}} = \left(\frac{y_2}{y_1}\right)^2 \frac{1 + (\Omega_1 y_1 / 2y_2\, \Omega_2)}{1 + (2\Omega_2 y_2 / \Omega_1 y_1)} \tag{20.83}$$

When one of the layers is much larger than the other, this expression simplifies to

$$\frac{y_2}{y_1} = \frac{K'_{\text{p}_2}}{K'_{\text{p}_1}} \times \frac{\Omega_1}{\Omega_2} \tag{20.84}$$

for example, if $y_2 \ll y_1$. It appears that this ratio is directly proportional to the ratio of parabolic rate constants for the

growth of each layer alone, that is, roughly proportional to the ratio of the self-diffusion coefficients of the mobile species.

This theory has been shown by Garnaud [134] to describe the growth of CuO and Cu_2O on Cu, by Garnaud and Rapp [135] to describe the growth of Fe_3O_4 and FeO on Fe, and by Hsu and Yurek [136] to describe the growth of Co_3O_4 and CoO on Co.

F2. Paralinear Oxidation

Generally, experience shows that the oxidation of a metal is often protective during the early stages but the protective properties of the scale can be partially or totally lost during later stages. For example, according to the Haycock–Loriers model [137, 138], the oxidation process involves the concurrent growth of an inner compact layer of MO, controlled by a diffusion mechanism, and its progressive transformation at its outer interface into an external porous layer MO′. The rate of growth of the inner compact layer controlled by diffusional transport is given by

$$\frac{d(\Delta m_1)}{dt} = \frac{K_p}{2\,\Delta m_1} - K_1 \tag{20.85}$$

where Δm_1 is the mass of oxygen in the compact scale, K_p is the parabolic rate constant for growth of the layer, and K_1 is the rate constant for its transformation. The growth rate of the outer porous layer controlled by the reaction at its interface with the inner compact layer is given by

$$\frac{d(\Delta m_2)}{dt} = fK_1 \tag{20.86}$$

where f is the ratio of the oxygen content in the oxide MO′ to that in the oxide MO. If the scale consists of two layers of the same oxide, $f = 1$, and the weight gain Δm is given by the rate equation

$$\Delta m + \frac{K_p}{2K_1}\ln\left[1 - \frac{2K_1}{K_p}(\Delta m - K_1 t)\right] = 0 \tag{20.87}$$

where the rate constant K_1 is characteristic of a transformation in the solid state that does not depend on the oxygen pressure. The function $\Delta m = \Delta m_1 + \Delta m_2 = F(t)$ can be approximated by the equation

$$\Delta m = \sqrt{K_p t} + fK_1 t \tag{20.88}$$

which describes paralinear oxidation for which parabolic kinetics predominate during the early stages of oxidation, becoming linear at longer times. This is illustrated in Figure 20.12. Paralinear oxidation is observed during the oxidation of a wide range of metals, especially if mechanical damage occurs to the scale during thermal cycling [139–141].

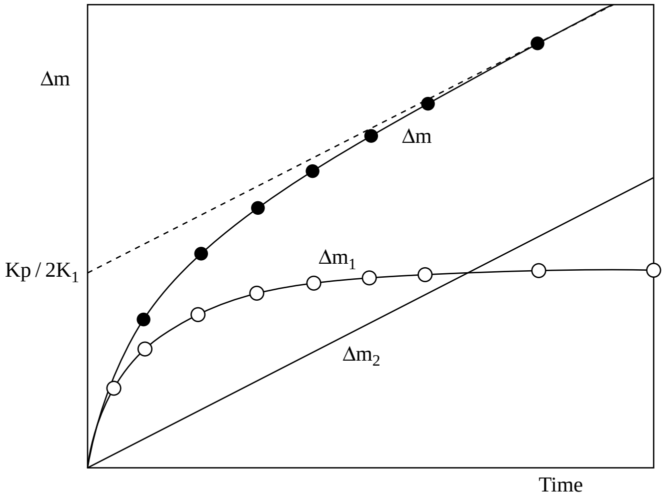

FIGURE 20.12. Schematic representation of total weight gain Δm illustrating paralinear rate equation.

This is more likely to be the case if the thermal expansion coefficient of the oxide is much less or greater than unity. The simultaneous oxidation and evaporation leads to the formation of porous and partially porous scales [59].

F3. Stratified Scales

Several metals, particularly in columns IV and V (Ti, Zr, Nb, Ta) of the periodic table, form stratified scales during their oxidation at high temperatures as a result of periodic cracking of the growing oxide. From a kinetic point of view, such cracking leads to two types of rate laws (Fig. 20.13): The first one is described by successive parabolic or cubic periods

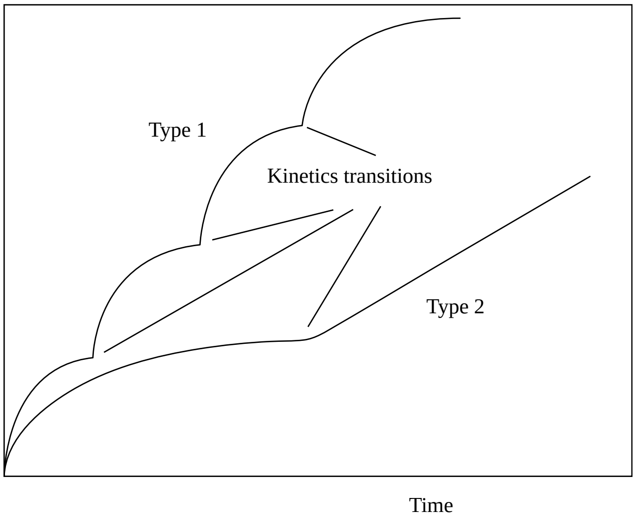

FIGURE 20.13. Schematic rate laws associated with formation of stratified scales.

(type 1), the second one by an initial parabolic or cubic period followed by a near-linear period.

Examination of the scale formed on such specimens, either on fractured or polished cross sections, shows that for both type 1 and type 2 rate laws:

- A compact and adherent scale is formed before the first transition.
- After the first transition, a porous scale exists which consists of well-defined layers formed essentially parallel to the metal surface; these may be separated by isolated cracks, also parallel to the metal surface, or by connected pores.

Mass transport through the oxide occurs by oxygen, mainly by vacancies V_0 (diffusing from the internal to the external interface). Since the scale grows in a confined space at the internal interface, the increase in volume on oxide formation, associated with a Pilling–Bedworth ratio greater than unity, may generate large compressive stresses in the oxide (several gigapascals have been measured). The metal is concurrently submitted to tensile stresses of smaller magnitude (several tens of megapascals) due to its larger thickness. The high compressive stresses in the oxide are probably responsible for the observed tendency for the kinetics to approach a cubic rate law due to an associated reduction in the oxygen diffusion flux. In all cases, oxygen pressure has no influence on the rate constants.

As oxide thickness increases, compressive stresses may also increase and result in localized spallation and/or cracking [142, 143]. Then, free access of the gas to a bare metal surface occurs and reoxidaton results. Two cases can be envisaged. In the first, the bare metal is unchanged compared with that at the beginning of oxidation, in terms of composition, microstructure, or mechanical properties. Reoxidation occurs exactly as in the initial period and the rate law is the exact repetition of the first pretransition curve. Kinetics of type 1 (Fig. 20.13) are then observed with a succession of parabolic-type periods.

In the second example, the bare metal differs from the initial state, for example, dissolution of oxygen may have occurred, leading to increased hardness and lower creep relaxation rates. The second oxide layer that forms does not then reach the thickness of the first since stress increases at a higher rate and early separation occurs from the metal. In the case of TiO_2 growth on titanium at 850°C, for example, the second and all subsequent layers have a thickness of 1–2 µm, whereas the first attains 10–15 µm. The spallation or cracking of these scales does not occur at the same time for all locations on the specimen surface and the resulting law is approximately linear with an increased rate compared to that in the pretransition period. The system can be described as a metal covered by an oxide of statistically constant thickness [8, 144–146].

G. OXIDATION RESISTANCE

The oxidation of alloys and other metallic materials is a complex process consisting of a large number of phenomena which may, themselves, depend on material composition and environment, that is, temperature, mechanical stress, gas composition, and so on. To obtain effective protection of a metallic material, the oxide formed must lead to a continuous scale (external oxidation) and not to precipitates within the alloy (internal oxidation).

Although numerous studies have been devoted to oxidation of alloys, the oxidation mechanisms are often still not fully understood. In fact, the models have usually been developed for the oxidation of the relatively simple example of pure metals and are inadequate to describe alloy oxidation. In order to do this, additional factors have to be taken into account, for example, the different affinity for oxygen of each of the alloy's constituents, dissolution of oxygen into the alloy, solid solubility between the oxides formed, formation of complex oxides, and different mobilities of the various metal ions in the oxide phases. Moreover, alloy oxidation involves complex processes for which the equilibrium state is reached very slowly or may never be reached. It is unrealistic to try to classify all the various types of alloy oxidation using simple criteria. However, several classification systems have been proposed [67, 147] to account for the diverse morphologies of oxidation scales. They use thermodynamic diagrams and kinetic considerations and, for simplicity, we can consider that three methods are available to protect metals and alloys from high-temperature oxidation: (i) control of the atmosphere, (ii) alloying addition of species more easily oxidized than the base metal (chromium, aluminum) and which form a protective scale during oxidation, and (iii) use of protective coatings deposited by various methods (cementation, plasma spraying, ion bombardment, etc.). Some considerations of these three approaches are presented in the following paragraphs.

G1. Atmosphere Control

When a process is considered for use in industry, it must be effective, reliable, and economical. For most applications these requirements rule out systems based on high vacuum and the general practice is to use atmospheres derived from fuels. The gases used are therefore mixtures of N_2, CO, CO_2, H_2, H_2O, and CH_4, which make up the products of combustion of fuels. More recently, atmospheres based on nitrogen have been increasingly used.

Starting from the fuel and air, various types of atmospheres can be produced. The main, or common, differentiation is between "exothermic" and "endothermic" atmospheres. The nomenclature is ambiguous and it is well to be clear about its meaning. An exothermic atmosphere is produced exothermically by burning the fuel with measured

amounts of air. This type of atmosphere has the highest oxygen potential. An endothermic atmosphere is produced by heating, by external means, a mixture of fuel gas with air over a catalyst to provide a gas containing reducing species. This atmosphere has a low oxygen potential and heat is absorbed during its preparation; hence the atmosphere is described as endothermic. A glance at the analysis of dried, stripped, exothermic atmospheres will confirm that they are predominantly pure nitrogen. Basically, the fuel has been used to remove oxygen from the air.

The economics of using nitrogen as a controlled-atmosphere source become more attractive when such factors as safety, reliability, and productivity are considered. Furthermore, the present tendency is to move away from oil toward electricity, in which case nitrogen atmospheres will be particularly attractive.

Modern techniques are currently available using carburizing and nitriding systems under vacuum. In these processes of vacuum carburizing and plasma carburizing, the components are heated under vacuum to around 950°C. Methane is leaked into the chamber to a pressure of between 3 and 30 mbar to add carbon to the system. In the absence of a plasma, the methane will only decompose to the extent of about 3%, probably on the surface of the components according to a sequence such as

$$CH_4 \rightarrow CH_3 + H \rightarrow CH_2 + 2H \rightarrow CH + 3H \rightarrow C + 4H \qquad (20.89)$$

These reactions may be stimulated to provide 80% decomposition by using a plasma process to excite the methane molecule. In this case, the molecular breakdown may occur in the plasma to produce charged species. Hydrocarbons other than methane may be used as the feedstock. The usual operating sequence involves flushing and evacuation, heating to a temperature under the inert atmosphere, and carburizing for a predetermined time followed by a diffusion anneal in a carbon-free atmosphere. This cycle is designed to provide optimum surface carbon content and carburized depth [9, 10, 12, 13, 148].

The main application of controlled atmospheres is in the area of heat treatment of finished, machined components or of articles of complex shape, which cannot easily be treated subsequently for the removal of surface damage. In this context, the atmosphere is controlled for one of two reasons: to prevent surface reaction or to cause a surface reaction, such as carburizing or nitriding.

Prevention or control of oxide layer formation is primarily a matter of controlling the oxygen partial pressure of the atmosphere at a value low enough to prevent oxidation, as described in Section B1. For a metal that undergoes oxidation according to the reaction shown in Eq. (20.7) (Section C), where MO is the lowest oxide of M, the oxygen partial pressure must be controlled so as not to exceed a value p_{O_2}:

$$p_{O_2} = \exp\left(\frac{2\,\Delta G^\circ}{RT}\right) \qquad (20.90)$$

where ΔG° is the standard free energy of reaction (20.7).

Unfortunately, $(p_{O_2})_{\text{M-MO}}$ is a function of temperature and has lower values at lower temperatures. Thus, if an atmosphere is designed to be effective at high temperatures, it may become oxidizing as the temperature is reduced during cooling. A surface oxide layer may therefore form as the metal is cooled. Although the metallurgical damage to the surface will be negligible, the surface may be discolored, that is, not bright. This condition can be overcome to some extent by rapid cooling or by changing the atmosphere to a lower oxygen partial pressure just before or during cooling.

For alloys, the most critical reaction must be considered when deciding on the composition of the atmosphere to be used. For this purpose, the activities of the alloy components must be known since, if the metal M in Eq. (20.7) exists at an activity a_M, the corresponding equilibrium oxygen partial pressure will be given by p'_{O_2}:

$$p'_{O_2} = \frac{1}{a_M^2}\exp\left(\frac{2\,\Delta G^\circ}{RT}\right) \qquad (20.91)$$

If the metal activities in the alloy are not known, then, by assuming the solution to be ideal, mole fractions may be used instead of activities to give a value of the oxygen partial pressure at which experiments must be performed to establish the correct atmosphere composition.

Low oxygen partial pressures can be provided and, more importantly, controlled by using "redox" gas mixtures. These mixtures consist of an oxidized and a reduced species, which equilibrate with oxygen, for example,

$$CO + \tfrac{1}{2}O_2 = CO_2$$

$$\Delta G^{\circ\prime} = -282200 + 86.7T J \qquad (20.92)$$

from which p''_{O_2} or, more importantly, p_{CO_2}/p_{CO} can be obtained:

$$p''_{O_2} = \left(\frac{p_{CO_2}}{p_{CO}}\right)^2 \exp\left(\frac{2\Delta G^{\circ\prime}}{RT}\right) \qquad (20.93)$$

$$\frac{p_{CO_2}}{p_{CO}} = p_{O_2}^{1/2} \exp\left(\frac{-\Delta G^{\circ\prime}}{RT}\right) \qquad (20.94)$$

Thus, from Eq. (20.93) the ratio of carbon dioxide to carbon monoxide may be calculated for any oxygen partial pressure and temperature.

Further discussion of protective atmospheres can be found in references [8], [11], and [36].

G2. Alloying

For engineering applications, metals are strengthened and their environmental resistance improved by appropriate alloying. The basic mechanisms operating in pure metal oxidation are also operative in the oxidation of alloys with added complications. These complications include the formation of multiple oxides, mixed oxides, internal oxides, and diffusion interactions within the metals. The effect of alloying on oxidation behavior can be understood first by considering binary alloy model AB consisting of element A, the major component, and B, the minor component [149]. There are two distinct possibilities [150]: (i) One considers element A as more noble and B as more reactive. Thus, at atmospheric pressure of oxygen, B converts to BO, and if the alloy is dilute in B, dispersed precipitates of BO form in A. If the alloy is concentrated in B, a continuous BO scale forms on top of AB. (ii) The other case considers that A and B are both reactive to oxygen with BO more stable than AO. The concentration of B again dictates the oxide morphologies. If the alloy is dilute in B, a stable oxide AO forms as the outer scale. Below the oxide scale, at the AO–alloy interface, the O_2 activity is high enough to oxidize B into BO precipitates. If the concentration of B exceeds the critical level required to form a continuous BO scale, then BO forms on top of AB. The oxide growth rate is parabolic, with activation energy characteristic of the growth of BO. The actual rate depends on how protective the BO scale is and on the presence of additional alloying elements.

Binary alloys of Ni with Cr or Al form the basis of many oxidation-resistant commercial materials. There are three composition (in wt %) regimes, with distinct oxidation characteristics for each family:

Ni–Cr < 10%: Such alloys form an NiO external scale and internal Cr_2O_3.

Ni-30% > Cr > 10%: In such alloys the outer scale consists of NiO on grains and Cr_2O_3 in grain boundaries.

Ni–Cr > 30%: For such alloys the external scale consists of Cr_2O_3, which is maintained because of the large Cr reservoir.

Ni–Al < 6%: Such alloys form an NiO external scale and internal Al_2O_3 and $NiAl_2O_4$.

Ni-17% > Al > 6%: In such alloys the outer scale initially consists of Al_2O_3. However, on continuous exposure, Al depletion occurs in the alloy adjacent to the oxide scale. In the depleted zone, the Al activity is well below the requirement to form continuous Al_2O_3. Therefore, NiO overtakes Al_2O_3. The overall result is the formation of a mixture of NiO, $NiAl_2O_4$ spinel formed by the combination of NiO and Al_2O_3.

Ni–Al > 17%: For such alloys, the external scale of Al_2O_3 is maintained because of the large Al reservoir.

Practical alloys and metallic coatings for high-temperature applications are seldom binary. These alloys are typically Cr_2O_3 and Al_2O_3 formers. Silica (SiO_2) also forms a protective scale, particularly for refractory metals with which it has better thermal expansion matching. However, SiO_2 is not stable at low pressures. It decomposes to gaseous species such as SiO. It also reacts with water vapor at high temperatures, forming $Si(OH)_4$ gas. The use of Cr_2O_3 scale-forming alloys is limited to temperatures below 1000°C.

Volatile CrO_3 forms above this temperature in the presence of oxygen due to the reaction

$$\tfrac{1}{2}Cr_2O_3 + \tfrac{3}{4}O_2 = CrO_3 \qquad (20.95)$$

Thermodynamic analysis of the foregoing reaction shows oxygen partial pressure dependence to be $p_{O_2}^{3/4}$. Thus, the volatilization becomes important at high oxygen partial pressures. Volatilization of Cr_2O_3 has been observed even at lower temperatures, between 850 and 900°C. Also, in the presence of water vapor, $CrO_2(OH)_2$ forms above the Cr_2O_3 scale. The scale rapidly vaporizes, resulting in continuing metal recession. The SiO_2 scales are also subject to water vapor–enhanced volatility. For high-temperature application, above 1000°C, useful alloys are therefore designed to be Al_2O_3 formers. In such alloys, the alumina scale can have one of several allotropic forms, depending on the alloy composition and temperature of oxidation. The allotropes include the transient phases γ, δ, and υ which, on thermal exposure, convert into the stable phase α [151]. The composition of the scale formed and its stability depend on the alloy composition, the temperature, and the cyclic nature of thermal exposure [150, 152–156].

Commercial superalloys contain many alloying elements of significance over and above chromium and aluminum. The oxidation behavior of these alloys is very complex and oxidation resistance varies widely, although the general mechanisms described earlier still apply. The complexities arise from significant influence of the individual elemental constituents. Nickel-based superalloys containing elements such as Co, Cr, Al, Ti, W, and Ta exhibit general behavior similar to simple NiCrAl alloys.

The cyclic oxidation of superalloys consists of several steps. The process involves an initial transient period during which the oxides of the individual constituents form. These include NiO, CoO, Cr_2O_3, TiO_2, and Ta_2O_5. Continued oxidation leads to the formation of the most stable oxide, which is Al_2O_3 for alumina-forming alloys. The parabolic rate constants of the transient oxides are larger than that of the stable oxide. In a cyclic environment the oxide scale cracks and spalls. Aluminum in the alloy diffuses to the oxide–alloy interface to reform the scale. The oxide scale spalling followed by the reformation process continues. An aluminum-depleted zone forms in the alloy below the oxide

scale. The thickness of the depleted zone depends on the aluminum content of the alloy. Isothermal oxidation of NiCoCrAlY with 12 wt % Al, for example, exhibits depleted zone thickness three times the thickness of the alumina scale [157]. Because of the loss of aluminum, the depleted zone becomes enriched with the other alloying constituents, some of which, having low solubility in the depleted zone, precipitate out in the form of acicular phases. Additionally, nitrogen, which diffuses into the alloy during oxidation, now exceeds its solubility limit and precipitates out as nitrides of such elements as Ti. The new precipitate phases penetrate into the alloy. The alloy is finally depleted of aluminum to below such a critical level that the regeneration of a continuous scale of Al_2O_3 is no longer feasible. At this stage, for nickel-based alloys, breakaway oxidation starts with the formation of continuous NiO, which is not protective. As a result, oxygen diffuses into the alloy, forming internal oxides of the remaining aluminum, chromium, and other reactive constituents of the alloy. The alloy substrate loses wall thickness and load-bearing capability.

To help maintain oxidation resistance, the following steps can be taken: (i) increase aluminum activity as much as possible; (ii) increase aluminum diffusivity to the alloy surface; (iii) inhibit diffusivity of oxygen into the alloy; and (iv) improve the adherence of the alumina scale to the substrate.

Similar processes and arguments also hold true for cobalt-based alloys, although some differences exist in the detail. For comparable oxidation resistance, cobalt-based alloys need higher combined aluminum and chromium than do nickel-based alloys. Also, once the protective alumina scale fails, CoO forms on cobalt-based alloys, which spalls off catastrophically as opposed to the gradual failure of NiO formed on nickel-based alloys.

The substrate alloy compositions are generally a result of an effort to maximize structural properties such as creep, tensile, and fatigue strength. The alloying constituents, however, affect the oxidation resistance significantly [158–162].

G3. Protective Coatings

The focus on the development of substrate alloys discussed in this chapter is generally to achieve high strength, high ductility, and efficient production. Oxidation resistance may not be consistent with achieving these goals. For example, increased Al and Cr result in improved oxidation resistance; however, beyond a certain level, these elements reduce creep strength of the resulting alloys. To achieve both strength and resistance to environmental degradation, the two functions are separated. The load capability is provided by the application of thin coatings with adequate Al and Cr. The thickness of the coating is controlled so that it does not carry any significant load. Depending on the temperature of use, many high-temperature alloys require coatings compatible with its composition and structural (modulus) and thermal (coefficient of thermal expansion) properties. Diffusion, overlay, and thermal barrier coatings are discussed in the following paragraphs.

G3.1. Diffusion Coatings. In diffusion coating, the substrate surface is enriched in an element that will provide high-temperature corrosion resistance. Typical elements are chromium (chromizing), aluminum (aluminizing), or silicon (siliconizing). The substrate is involved in the formation of the coating, and substrate elements are incorporated in the coating; in addition, a diffusion zone is developed in the substrate beneath the coating. Such enrichment not only allows a protective scale to form by selective oxidation but also provides a substantial reservoir of the protective element to delay the inevitable breakaway oxidation to substantially longer times. A wide variety of diffusion coatings are used [163–165].

The most common method of aluminizing is pack cementation, which has been a commercially viable process for many years [166, 167].

Pack cementation and vacuum pack coating techniques can be generalized as methods in which a chemical vapor deposition (CVD) process takes place with the substrate surrounded by a mass of the depositing medium. "Cementation" is a misnomer. The substrate is "packed" in a "cement" consisting of a mixture of the master alloy (the source alloy), a salt as activator, and an inert or reducing hydrogen atmosphere. The coating is carried out over a wide range of pressures from a low, near-vacuum 1–20 torr to near-atmosphere, that is, 360 torr, in the enclosed "retorts" (cf. "reactors" for conventional CVD) [168]. The substrate to be coated is surrounded by the pack; various alignments within this principle are possible depending on the substrate requirements.

The first known cementation process was that of Al on steel in 1914 [166, 167]. However, much attention was given to the process, and its variety and development occurred during the mid-1960s to the late 1970s on Ni- and Co-based alloys and iron alloys when the protection of high-temperature gas turbine alloys became paramount together with rocket and space hardware, that is, refractory alloys, mainly Ta, Nb, Mo, and Cr based. The technique itself, in principle, has changed remarkably little since 1914. The composition and quality of the substrate–deposit configuration have been modified as a result of research carried out in the last 10–20 years.

Even now, aluminum stands foremost among pack-coated deposits, closely followed by Cr, Si, and alloys of Al–Cr, and Al–Si can be coated as one- or two-stage packs [169]. Most of the literature referred to here is on Al, Cr–Al, Ni–Al, and Fe–Al systems. Pack coating is particularly suited to treat large substrates either singly or in bulk and can handle intricate shapes as it is not a

line-of-sight method. Much of the earlier literature is available in references [169]–[171].

Aluminiding was one of the first high-temperature metallic coating systems. Alumina scale-forming coatings are very protective in high-velocity gas turbines. Uncoated alloys containing Al as a minor constituent are rapidly depleted of Al, which diffuses to the surface to maintain alumina formation due to recurring oxide spallation. Diffusion-coated alloys form a surface alloy layer, for example, NiAl and CoAl, which develop the protective alumina layer under more controlled kinetics and reform on spalling without affecting the substrate alloy properties. A renewal is possible before excessive depletion occurs. Brittle intermetallics can be a danger in this system.

A diffusion barrier layer between the coating and the substrate is necessary to prevent interdiffusion of elements within the coating system. Multicomponent diffusion coatings (Al, B, Cr, Si, Ti, Zr) to protect machines from liquid Al and for brass corrosion have been used [172]. More studies are needed in this area.

On steel, Al coatings are protective up to 500°C, above which brittle intermetallics are formed. Thermal stress-induced cracks then propagate into the substrate metal. Aluminide coatings protect steel from oxidation and corrosion in hydrocarbon and sulfur-containing atmospheres. Aluminized steel is better than stainless steel where oxidation carburization occurs [173].

Chromized steel (diffused in) is resistant to air oxidation up to 700°C. Above 800°C Cr diffuses into the steel, reducing oxidation resistance. At higher temperatures brittle intermetallics form. Good chromized sheet can be bent 180° without damage and is suitable for most firebox and heat exchanger applications up to 600°C. Addition of Al or Si to the chromizing pack process confers oxidation resistance up to 900°C on mild steel, although continuous use at 900°C causes brittle intermetallics and consequent cracking on thermal cycling.

On superalloys, alumina-forming diffusion-bonded coatings provide an Al-rich surface to gas turbine environment. Aluminiding superalloys involve formation of more than one phase in the Ni–Al (and Co–Al) systems. Heat treatment is given to stabilize the NiAl phase. NiAl with some Cr and Ti improves the hot corrosion resistance [174]. Oxide particles (e.g., Y_2O_3) reduce spalling; defects like pinholes, blisters, and cracks may be avoided by a combination of minor additives.

Aluminide coatings lack ductility below 750°C and on thermal cycling undergo surface cracking resulting in spalling of the alumina scale. To overcome these two problems, the coating composition was adjusted to embed the brittle β-NiAl or β-CoAl in a ductile γ solid-solution matrix. Addition of yttrium improved oxide adherence. Improvements in mechanical properties were achieved by HIP (hot isostatic pressing)–densified, argon-atomized prealloyed powder ingots; tensile ductilities of over 20% were produced using the finer precipitate with its better distribution [175]. Studies in which minor amounts of Si, Fe, and Ti were added to improve the scale resulted in little improvement [176]. Platinum electroplate followed by aluminiding gives improved oxidation resistance which offsets the higher cost [177].

Cobalt-based superalloys for higher temperature but less stressed gas turbine vanes have no Al, and this limits the aluminide coating thickness that can be applied without spalling. Superalloy compositions avoiding sigma and other embrittling phases can be destabilized by coating interdiffusion [178]. Structural strengtheners, such as submicrometer oxides in alloys with oxide dispersion strengthening (ODS) and carbides in eutectic alloys with dispersion strengthening (DS), can also limit coating selection [178].

Further research is needed in these areas as higher performance alloys will restrict the choice of acceptable coatings. In a recent five-year period, over 50 production coatings became necessary to replace an original selection of only one to two compositions [179, 180].

G3.2. Overlay Coatings. Overlay coatings are distinguished from diffusion coatings in that the coating material is deposited onto the substrate in ways that give only enough interaction with the substrate to provide bonding of the coating. Since the substrate does not enter substantially into the coating formation, in principle, much greater coating composition flexibility is achievable with overlay coatings. Also, elements, such as Cr, that are difficult to deposit into diffusion coatings can be included in overlay coatings. Although Cr is difficult to incorporate into diffusion aluminide coatings, it is readily incorporated into overlay coatings. Overlay coatings based on the Ni–Cr–Al and Co–Cr–Al systems are commonly used to protect superalloys. Also, small amounts of the reactive elements (e.g., Y, Hf) are routinely incorporated into overlay coatings but are difficult (or sometimes impossible) to incorporate into diffusion coatings. The flexibility in composition of the overlay coatings also allows mechanical properties to be tailored for a given application.

Overlay coatings are deposited by physical techniques. The most common are physical vapor deposition (PVD), which includes evaporation, sputtering, and ion plating, and spray techniques (e.g., plasma spraying, flame spraying).

Diffusion-type coatings, used successfully on early gas turbines, were tied to the substrate composition, microstructure, and design. Some changes introduced later were (i) superalloy composition, such as reduction in Cr and increase in other refractory metals; (ii) microstructure, in castings with more segregation; and (iii) design, by air cooling and with thin walls (which introduced higher thermal stresses). These changes required coatings that were much more independent of the substrate. Overlay coatings met this necessity.

Overlay coatings also overcome the process restrictions encountered in diffusion coatings, especially the variants, namely, Cr/Al, Ta + Cr, or the Pt aluminides, all of which give better stability and oxide hot corrosion resistance than Al alone. MCrAlY compositions (M = Ni, Co, Fe alone or in combination) are the main ones in the series of overlay coatings developed by electron beam evaporated physical vapor deposition (EBPVD) for multiple load. This technique is one of the two most important manufacturing techniques widely used for deposition of thermal barrier coatings (TBCs) onto substrates. Due to its feasibility of varying coating structure, it has great potential for multiple load, for example, to produce functionally graded TBCs.

MCrAlY overlays used in gas turbines are usually Ni and/or Co with high Cr, 5–15% Al, and Y addition less than about 1% for stability during cyclic oxidation. They are multiphase alloys with ductile matrix (e.g., γ Co-Cr) containing a high fraction of brittle phase (e.g., β CoAl). The Cr provides oxidation and hot corrosion resistance, but too much Cr affects substrate-phase stability. The success of most overlay coatings is the presence (and perhaps location) of oxygen-active elements, such as Y and Hf, which promote alumina layer adherence during thermal cycling, giving increased coating protection at lower Al levels. Yttrium appears mostly along grain boundaries if MCrAlY is cast but is homogeneous if plasma sprayed. Thus MCrAlY with 12% Al is more protective than the more brittle diffusion aluminides with 30% Al.

Overlay claddings deposited by hot isostatic processing (HIP), electron beam evaporation, or sputtering methods are diffusion bonded at the substrate–coating interface, but the intention here is not to convert the whole coating thickness to NiAl or CoAl. There is, thus, more freedom in coating composition, so that properties can be maximized to the extent required. Compositions based on NiCr, CoCr, NiCrAl, CoCrAl, NiCrAlY, FeCrAlY, and NiCrSi have been used successfully in gas turbine engines. They are generally alumina formers with only 10% Al, unlike the 30% in nickel aluminide coatings. Chromium increases the Al activity allowing this advantage. Higher Al levels cause brittleness and a higher Ductile-Brittle Transition Temperature (DBTT) and the Al levels are generally held below 12% (5–10% preferred). The coatings are also more ductile than NiAl and CoAl and can be rolled and bonded by HIP. In general, NiCrAlY gives best results against high-temperature oxidation whereas CoCrAlY is best for hot corrosion [181].

G3.3. Thermal Barrier Coatings. Thermal barrier coatings are ceramic coatings that are applied to components for the purpose of insulation rather than oxidation protection. The use of an insulating coating coupled with internal air cooling of the component lowers its surface temperature with a corresponding decrease in its creep and oxidation rates. The use of TBCs has resulted in a significant improvement in the efficiency of gas turbines [12].

The earliest TBCs were frit enamels that were applied to aircraft engine components in the 1950s. The first ceramic TBCs were applied by flame spraying and, subsequently, by plasma spraying. The ceramic materials were alumina and zirconia (MgO or CaO stabilized), generally applied directly to the component surface. The effectiveness of these coatings was limited by relatively high thermal conductivity of alumina and problems with destabilization of the zirconia-based materials. Important developments included the introduction of Ni–Cr–Al–Y bond coats and plasma-sprayed Y_2O_3-stabilized zirconia topcoats in the mid-1970s and the development of EBPVD to deposit the topcoat in the early 1980s. Plasma-sprayed TBCs have been used for many years on combustion liners but, with advanced TBCs, vanes, and even the leading edges of blades, can now be coated. The use of TBCs can achieve temperature differentials across the coating of as much as 175°C [182].

Typical systems consist of a nickel-based superalloy substrate coated with M–Cr–Al–Y (M = Ni,Co) or a diffusion aluminide bond coat, which forms an alumina layer [thermally grown oxide (TGO)]. Onto this is deposited a yttria-stabilized zirconia (YSZ) TBC. The TBC can be deposited by air plasma spraying (APS), or EBPVD. The EBPVD coatings are used for the most demanding applications, such as leading edges of airfoils.

The APS coating consists of layers of *splats* with clearly visible porosity and is microcracked. This microcracking is necessary for strain tolerance. The EBPVD coating consists of columnar grains separated by channels similar to the leaders seen in metallic overlay coatings. These channels are responsible for the high strain tolerance of EBPVD TBCs.

In summary, a wide variety of coatings are used for oxidation protection at high temperature. It is a huge field dealing with different compositions, production methods, properties, degradation, characterization, repair and function of coatings, and so on. These aspects have been surveyed by Bose [183], Khanna [14], Birks et al. [12], Sato et al. [184], Stern [185], Dahotre and Hampikian [186], Gao [179], and Schütze and Quadakkers [180], among others.

H. OXIDATION OF ENGINEERING MATERIALS

There is a large spectrum of engineering materials available for applications subject to oxidation in different temperature ranges. This section focuses on laboratory and field experience of many materials that are being considered for applications in various temperature regimes. They range from carbon and Cr–Mo steels to advanced superalloys.

At temperatures below 550°C, carbon steel in air shows very little weight gain after exposure for nearly one month. As the temperature is increased to 700°C, the oxidation rate is significantly increased, exhibiting a linear rate of oxidation

attack. Test results by John [187] showed that carbon steel exhibited about 0.25 mm/year (10 mpy) of oxidation at 604°C; at 650°C, carbon steel exhibited oxidation rates of the order of 1.25 mm/year (50 mpy). The beneficial effects of chromium and silicon additions to carbon steel were reported by Zeuthen [188]. Chromium–molybdenum steels are used at higher temperatures than carbon steel because of higher tensile and creep rupture strengths as well as better microstructural stability. Molybdenum and chromium provide not only solid-solution strengthening but also carbide strengthening.

Silicon is very effective in improving the oxidation resistance of Cr–Mo steels, but the most important alloying element for improving oxidation resistance is chromium.

The superior oxidation resistance of martensitic and ferritic stainless steels to that of carbon and Cr–Mo steels is well illustrated in the open literature [189]. The 25Cr steel (type 446 = S44600) is the most oxidation resistant among the 400 series stainless steels, due to the development of a continuous Cr_2O_3 scale on the metal surface. In Fe–Cr alloys, a minimum of approximately 18 wt % Cr is needed to develop a continuous Cr_2O_3 scale against further oxidation attack [190]. Cyclic oxidation studies conducted by Grodner [191] also revealed that type 446 was the best performer in the 400 series stainless steels, followed by types 430 (S43000; 14–18Cr), 416 (S41600; 12–14Cr), and 410 (S41000; 11.5–13.5Cr). The growth of a thin, adherent $(Fe,Cr)_2O_3$ scale as a function of the accumulated isothermal hold time up to 1000 h was observed by Walter et al. [192] at 650°C in air during cycling from 650 to 300°C.

The 300 series austenitic stainless steels have been widely used for high-temperature components because they exhibit higher elevated-temperature strength than do ferritic stainless steels. Furthermore, they do not suffer 475°C embrittlement or ductility loss problems in thick sections and in heat-affected zones as do ferritic stainless steels. Nevertheless, some austenitic stainless steels can suffer some ductility loss upon long-term exposure to intermediate temperatures (e.g., 540–800°C) due to sigma-phase formation [193]. Moccari and Ali [194] observed the beneficial effects of nickel in improving the oxidation resistance of austenitic stainless steels.

In evaluating materials for automobile emission control devices, such as thermal reactors and catalytic converters, Kado et al. [195] carried out cyclic oxidation tests on various stainless steels. In cyclic oxidation tests performed in still air at 1000°C for 400 cycles (30 min in the furnace and 30 min out of the furnace), types 409 (S40900; 12Cr), 420 (S42000; 13Cr), and 304 (S30400; 18Cr–8Ni) suffered severe attack. Type 420 (S42000; 13Cr) was completely oxidized after only 100 cycles, although the sample did not show any weight changes. Alloys that performed well under these conditions were types 405 (S40500; 14Cr), 430 (S43000; 17Cr), 446 (S44600; 25Cr), 310 (S31000; 25Cr–20Ni), and DIN 4828 (19Cr–12Ni–2Si).

When cycled to 1200°C for 400 cycles (30 min in the furnace and 30 min out of the furnace), all alloys tested except F-1 alloy (Fe–15Cr–4Al) suffered severe oxidation attack. This illustrates the superior oxidation resistance of alumina formers (i.e., alloys that form Al_2O_3 scales when oxidized at elevated temperatures). Their data also illustrate that, for temperatures as high as 1200°C, Cr_2O_3 oxide scales can no longer provide adequate oxidation resistance.

Oxidation data generated in combustion atmospheres are relatively limited. No systematic studies have been reported that varied combustion conditions, such as air-to-fuel ratios. In combustion atmospheres, the oxidation of metals or alloys is not controlled by oxygen only. Other combustion products, such as H_2O, CO, CO_2, N_2, hydrocarbon, and others, are expected to influence oxidation behavior. When air is used for combustion, nitride formation in conjunction with oxidation can occur in combustion atmospheres under certain conditions.

The presence of water vapor can also be an important factor in affecting oxidation behavior of alloys, as discussed later in this section.

Manufacturing processes can greatly influence the surface chemistry of an alloy product. Stainless steels can be finished into the final product by bright annealing (i.e., annealing is performed in a protective atmosphere, such as hydrogen environment or dissociated ammonia environment). This process generally produces a product with minimal depletion of chromium at or near the surface. On the other hand, when the alloy product is finished by black annealing (i.e., annealing is performed in air or combustion atmosphere in the furnace) and followed by acid pickling, there is a good chance that the alloy product may exhibit surface depletion of chromium. This is particularly important for thin-gage sheet products or thin tubular products [196].

Some stainless steel producers may manufacture stainless steels at the bottom of the specification range for key alloying elements, such as chromium, to reduce materials cost. Accordingly, the chromium content can be insufficient to maintain a continuous chromium oxide scale during prolonged service or when subjected to thermal cycling or overheating conditions, thus promoting breakaway oxidation. The oxidation resistance of these “lean” stainless steels can be further degraded by the surface depletion of chromium resulting from manufacturing processes that may involve excessive pickling after “black” annealing (annealing in air or combustion atmosphere), during successive reductions in cold rolling in flat product manufacturing, or pilgering in tubular manufacturing. The chromium concentration at the surface of such a product, particularly a thin-gage sheet or tube, may be too low to form or maintain a continuous chromium oxide scale during service. As a result, iron oxides and isolated nonprotective Fe–Cr oxide nodules can develop on the metal surface, thus resulting in breakaway oxidation, as discussed later.

Some commercial electrical resistance heating elements are made of Fe–Cr–Al alloys, such as Kanthal® alloys, which rely on the formation of the Al_2O_3 scale for applications up to 1400°C [197]. For example, some of the Kanthal alloys that are available in wire, strip, and ribbon product forms are Kanthal A-I (K92500; Fe–22Cr–5.8Al), AF (Fe–22Cr–5.3Al), and D (Fe–22Cr–4.8Al). Since these wrought alloy products are essentially ferritic alloys, they exhibit low creep rupture strengths when the temperature exceeds 650°C and cannot be used for high-temperature structural components. Thus, the electrical resistance heating elements made of these alloys must be properly supported to avoid creep deformation, such as sagging. These Kanthal wires can be used in arc or flame spraying to produce an oxidation-resistant coating or in weld overlay cladding by using a gas metal arc welding (GMAW) process. A powder metallurgy (P/M) process was used to produce a new alloy product, Kanthal APM, reported to exhibit improved creep rupture strength [198]. Other commercial Fe–Cr–Al alloys include ALFA-I™ (Fe–13-Cr–3Al), ALFA-II™ (Fe–13Cr–4Al), and ALFA-IV™ (Fe–20Cr–5Al–Ce) developed by Allegheny Ludlum [199] and Fecralloy® (Fe–16Cr–4Al–0.3Y) developed by Atomic Energy Authority [200].

As the nickel content in the Fe–Ni–Cr system increases from austenitic stainless steels to a group of iron-based alloys with 20–25Cr and 30–40Ni, the alloys become more stable in terms of metallurgical structure and more resistant to creep deformation (i.e., higher creep rupture strengths). In general, this group of alloys also exhibits better oxidation resistance. Some of the wrought alloys in this group are 800H/800HT (Fe–21Cr–32Ni–Al–Ti), RA330 (N08330; Fe–19Cr–35-Ni–1.2Si), HR120 (Fe–25Cr–37Ni–0.7Nb-N), AC66 (N33228; Fe–27Cr–32Ni–0.8Nb–Ce), 353MA (Fe–25Cr–35Ni–1.5Si–Ce), and 803 (Fe–26Cr–35Ni–Al–Ti) [201].

In many Ni–Cr alloys, many alloying elements, such as those for solid-solution strengthening (e.g., Mo, W) and precipitation strengthening (e.g., Al, Ti, Nb), are added to the alloys to provide strengthening of the alloy at elevated temperatures. Many of these alloys are commonly referred to as "superalloys." The superalloys also include oxide dispersion–strengthened (ODS) alloys, which are briefly discussed later.

Similar to Fe–Cr–Al alloys, aluminum is also used as an alloying element in Ni–Cr alloys to improve the oxidation resistance. Although a Ni–Cr alloy generally requires a minimum of 4% Al to form a protective Al_2O_3 scale, the addition of less than 4% Al can significantly improve the oxidation resistance of the alloy. Alloy 601 (N06601), with only about 1.3% Al, shows excellent oxidation resistance [202].

Nickel–chromium alloys containing about 4% Al or higher form a very protective Al_2O_3 scale when heated to very high temperatures; for example, Lai [203] compared alloy 214 (Ni–16Cr–4.5Al–Y) with alloy 601 and alloy 800H in cyclic oxidation tests performed in still air at 1150°C with specimens cycling to room temperature once a day except weekends. Alloy 214 showed essentially no weight loss after 42 days of testing, whereas alloy 601 showed a linear weight loss.

For applications at high temperatures, many superalloys contain numerous alloying elements for increasing the elevated-temperature strength of the alloy. Molybdenum and tungsten are common alloying elements for providing solid-solution strengthening for increasing the creep rupture strength of the alloy. Two iron-based superalloys, Multimet alloy (R30155; Fe–20Ni–20Co–21Cr–3Mo–2.5W–1.0Nb + Ta) and alloy 556 (R30556; Fe–20Ni–18Co–22Cr–3Mo–2.5W–0.6Ta–0.02La–0.02Zr), are good examples. However, the oxides of both molybdenum and tungsten (MoO_3 and WO_3) exhibit high vapor pressures at very high temperatures. Multimet alloy showed rapid oxidation attack at 1150 and 1200°C, with specimens completely consumed at both temperatures. However, formation of the volatile oxides of MoO_3 and WO_3 can be minimized by modification of some key alloying elements in Multimet alloy. The development of alloy 556 was aimed at improving the oxidation resistance of Multimet alloy without losing the elevated-temperature strength by modifying the Multimet alloy composition. The modification involved a slight increase in chromium, a decrease in cobalt, replacement of niobium with tantalum, and addition of a rare earth element, lanthanum, and a reactive element, zirconium, but the concentrations of molybdenum and tungsten were not changed. The result was a much more oxidation-resistant alloy, alloy 556, at 1095 and 1150°C, although rapid oxidation nevertheless occurred at 1200°C.

Cobalt-based alloys with tungsten, such as alloy 188 (R30188; Co–22Cr–22Ni–14W–0.04La), alloy 25 (R30605; Co–20Cr–10Ni–15W), and alloy 6B (Co–30Cr–4.5W–1.2C), showed rapid oxidation at 1205°C. A cobalt-based alloy, alloy 150 (Co–27Cr–18Fe), containing no tungsten also showed rapid oxidation attack at 1205°C.

Again, the oxidation of a cobalt-based alloy can be significantly improved with some modification of alloying elements. Alloy 25 with 15% W exhibits excellent creep rupture strength at high temperatures. However, because of the high level of tungsten, the alloy shows high oxidation rates at very high temperatures, such as 1095 and 1150°C. With a slight increase in chromium and nickel along with the addition of lanthanum, the result of the modification was alloy 188, which has significantly better oxidation resistance than alloy 25 at 1095 and 1150°C.

Oxide-dispersion-strengthened alloys use very fine oxide particles that are uniformly distributed throughout the matrix to provide excessive strengthening at very high temperatures. These oxide particles, typically yttrium oxide, do not react with the alloy matrix, and so no coarsening or dissolution occurs during exposure to very high temperatures, thus

maintaining the strength of the alloy. This group of superalloys is produced using specialty powders that are manufactured by the mechanical alloying process. These powders are essentially composite powders with each particle containing a uniform distribution of submicrometer oxide particles in an alloy matrix. The process of producing these ODS powders involves repeated fracturing and rewelding of a mixture of powder particles in vertical attritors or horizontal ball mills [204]. A vertical attritor is a high-energy ball mill (like the conventional horizontal ball mill) in which the balls and the metal powders are charged into a stationary vertical tank and are agitated by impellers rotating from a central rotating shaft. The shaft turns, but the jar stays put. As the balls are stirred, they fall on the contents and grind whatever is between the balls. Alloy powders are then canned, degassed, and hot extruded followed by hot working and annealing to produce a textured microstructure. Alloys are available in mill products such as bar, plate, and sheet or custom forgings.

Oxidation of alloys can significantly increase under high-velocity gas streams, as in, for example, combustors and transition ducts in gas turbines. These components are also subject to severe thermal cycling, particularly gas turbines in airplane engines. Laboratory burner rigs have been developed to evaluate the type of oxidation, often referred to as "dynamic oxidation," under conditions of very high gas velocities. Some of these dynamic oxidation burner rigs are described elsewhere [204–206].

Hicks [207] performed dynamic oxidation tests with 170 m/s gas velocity at 1100°C with 30-min cycles for several wrought chromia former superalloys and an ODS alumina former (MA956). Alumina former MA956 was found to be considerably better than chromium formers, such as alloys 191, 86, 617, 188, and 263.

MA956, along with some ODS alloys, was studied by Lowell et al. [204] with 0.3 Mach gas velocity at 1100°C with 60-min cycles. ODS alloys included in the study were MA956 (Fe–19Cr–4.4Al–0.6Y_2O_3), HDA8077 (Ni–16Cr–4.2Al–1.6Y_2O_3), TD-NiCr (Ni–20Cr–2.2ThO_2), and STCA264 (Ni–16Cr–4.5Al–1Co–1.5Y_2O_3). Also included in the study was a PVD coating of Ni–15Cr–17Al–0.2Y on MAR-M-200 alloy (Ni–9Cr–10Co–12W–1Nb–5Al–2Ti). MA956 and HDA8077 as well as PVD Ni–Cr–Al–Y coating were found to perform well. No explanation was offered for STCA264, which did not perform as well as HDA8077, although both alloys had similar chemical compositions.

In Fe–Cr, Fe–Ni–Cr, Ni–Cr, and Co–Cr alloy systems, the formation of an external Cr_2O_3 oxide scale provides the oxidation resistance for the alloy. The growth of the Cr_2O_3 oxide scale follows a parabolic rate law as the exposure time increases. As the temperature increases, the oxide scale growth rate also increases. The growth of the Cr_2O_3 scale requires that a continuous supply of chromium from the alloy interior diffuses to the oxide–metal interface. Continued oxidation can eventually deplete chromium in the alloy matrix immediately under the oxide scale. When the chromium concentration in the alloy matrix immediately beneath the oxide scale is reduced to below a critical concentration, the alloy matrix no longer has adequate chromium to reform a protective Cr_2O_3 oxide scale when the scale cracks or spalls due to oxide growth stresses or thermal cycling. Once this occurs, fast-growing, nonprotective iron oxides, or nickel oxides, or cobalt oxides (i.e., oxides of base metal) form and grow on the alloy surface. Breakaway oxidation initiates, and the alloy begins to undergo oxidation at a rapid rate. The alloy thus requires the level of chromium immediately under the chromium oxide scale to reheal [206–211].

To prolong the time for initiation of breakaway oxidation, it is necessary to have an adequate reservoir of chromium immediately below the oxide scale to provide adequate chromium to maintain a protective chromium oxide scale or to reheal the oxide scale after local cracking or failure.

For alumina formers such as Fe–Cr–Al alloys and Fe–Cr–Al- and Ni–Cr–Al-based ODS alloys, breakaway oxidation occurs when aluminum concentration under the Al_2O_3 scale has been reduced to a critical level such that healing of the Al_2O_3 is no longer possible, thus resulting in the formation of nonprotective, fast-growing oxides of base metals (e.g., iron oxides or nickel oxides). The breakaway oxidation due to rapid growth of iron oxides or nickel oxides becomes essentially a life-limiting factor. This critical aluminum concentration was found to be about 1.0–1.3% for Fe–Cr–Al-based ODS alloys (e.g., MA956, ODM751) at 1100–1200°C [210, 211]. These values were obtained from foil specimens (0.2–2 mm thick) tested in still air at 1100–1200°C. For the non-ODS Fe–20Cr–5Al alloy, this critical aluminum concentration was found to be higher (about 2.5%) at 1200°C [210]. Since breakaway oxidation is related to the aluminum reservoir in the alloy, this reservoir is a critical issue when the component is made of thin sheet or foil. Because of excellent oxidation resistance at very high temperatures, there is increasing interest in considering alumina formers for products that require thin foils, such as honeycomb seals in gas turbines, metallic substrates for automobile catalyst converters, and recuperators in microturbines.

For alumina formers to improve their resistance to breakaway oxidation, yttrium is frequently used to increase the adhesion of the aluminum oxide scale. Other alloying elements that are known to increase the adhesion of the aluminum oxide scale include zirconium and hafnium. Quadakkers [212] shows that both MA956 (Fe–20Cr–4.5Al–0.5Y_2O_3) and Aluchrom (Fe–20Cr–5Al–0.01Y) exhibited much more cyclic oxidation resistance than Fe–20Cr–5Al when tested at 1100°C in synthetic air with an hourly cycle to room temperature.

Addition of Y_2O_3 to an alumina former has a similar beneficial effect as yttrium added as an alloying element.

Klower and Li [213] studied the oxidation resistance of Fe–20Cr–5Al alloys in 10 different compositions containing various amounts of yttrium ranging from 0.045 to 0.28%. All 10 compositions contained 0.002% S, and 8 compositions contained 0.04–0.06% Zr with two compositions containing no zirconium. The cyclic oxidation tests were performed at 1100 and 1200°C, respectively, with each cycle consisting of 96 h at temperature and rapid air cooling to room temperature. These authors concluded that the yttrium addition of about 0.045% was sufficient to prevent the oxide scales from spalling, and when the yttrium concentration was increased to more than 0.08%, substantial internal oxidation could occur, resulting in rapid metal wastage [213].

Sulfur in the alloy is known to play a very significant role in adhesion of the aluminum oxide scale to the alloy substrate for alumina formers. The role of yttrium is believed to prevent the preferential segregation of sulfur in the alloy to the scale–metal interface to weaken the adhesion of the oxide scale [214–216]. Reducing the concentration of sulfur in a Ni–Cr–Al alloy can significantly improve the oxidation resistance of the alloy. Smeggil [217] compared cyclic oxidation resistance between the normal purity Ni–Cr–Al alloys (approximately 30–40 ppm S) with the high-purity Ni–Cr–Al alloys (approximately 1–2 ppm S), showing a significant improvement in cyclic oxidation resistance when sulfur in the alloy was significantly reduced. Also demonstrated was the beneficial effect of yttrium addition to the normal purity Ni–20Cr–12Al alloy, showing significant improvement in the cyclic oxidation resistance of the alloy without reducing the sulfur content in the alloy. Sulfur was found to segregate to the oxide–alloy interface during oxidation in Fe–Cr–Al alloys [218, 219]. Yttrium is believed to tie up sulfur at the oxide–metal interface, thus improving the oxide scale adhesion [217].

There are some industrial applications that require thin-gage sheet materials or thin foils for construction of critical components. As the component thickness decreases, oxidation becomes a major factor that limits service life. When the component is made of thin foil, prolonging the incubation time before initiation of breakaway oxidation is the controlling factor for extending the service life of the component. Thus, as applications are being pushed toward higher and higher temperatures, alloys that form aluminum oxide scales can offer significant advantages in performance over those alloys that form chromium oxide scales [220–222].

In high-temperature combustion atmospheres, water vapor is invariably present in the environment. The effect of water vapor on the oxidation of alloys is an important factor in the alloy selection process. Most oxidation data are generated in laboratory air, which generally contains low levels of water vapor [223–225]. The effect of water on oxidation, and its detrimental effect, has been established by Onal et al. [226] and many others [2, 4, 12, 16, 170, 183, 227].

As temperature increases, metals and alloys generally suffer increasingly higher rates of oxidation. When the temperature is excessively high, metals and alloys can suffer rapid oxidation. There is, however, another mode of rapid oxidation that takes place at relatively low temperatures, often referred to as "catastrophic oxidation," associated with the formation of a liquid oxide that disrupts and dissolves the protective oxide scale, causing the alloy to suffer rapid oxidation at relatively low temperatures. This phenomenon has been observed by, for example, Meijering [228], Brennor [229], Sawyer [230], Brasunas [231], and Sequeira [232]. The most effective way to alleviate the potential catastrophic oxidation problem is to avoid a stagnant condition of the gaseous atmosphere.

I. CONCLUSIONS

This chapter is a summary of the main factors for determining the nature and extent of gas–metal reactions, the comprehension of which is of paramount importance to understand the subject. Some of these factors are metal structure, oxide structure, metal diffusion, oxygen or metal diffusion at grain boundaries or on the surface, metal and oxide volatility, oxygen solution in metal, cracking, spalling, blistering, sintering, oxide nucleation, electronic conductance, oxide adhesion, and oxide plasticity.

A. INTRODUCTION

The understanding of corrosion of metals and alloys in hot gases can be assisted by analysis of the thermodynamics of the formation of corrosion product phases involving elements in the alloy and species in the gas. Since the service temperatures and pressures in high-temperature applications may vary over large ranges and the gas phase may involve many species, the stable corrosion products are only known with certainty for applications of specific alloys. It is often helpful to employ a multielement stability (or phase) diagram, which considers the thermodynamic properties of the possible compounds, to establish the most stable corrosion products before the kinetics associated with growth can be treated. Thermochemical analysis of the potential corrosion products can help identify the corrosion mechanisms important for the process conditions and also suggest which alloy types might have sufficient corrosion resistance based upon knowledge of how corrosion products influence corrosion rates. Examples of processes that corrode metals in high-temperature gases include coal gasification, crude oil distilling, steam-methane re-forming, catalytic cracking, fluid bed coal combustion, petroleum coking, combustion, incineration, hydrocracking, naphtha cracking to ethylene, and other energy conversion processes. All involve the presence of gases containing H–O–S–C at temperatures of 600–1300 K ($\sim$300–1000°C) [1].

B. THERMODYNAMICS

B1. Gas Phase

In many processes, the nominal gas composition may not represent the composition present at the corroding surface. In the process of sampling gases containing H, O, S, and C at high temperature and pressure, part of the water vapor may condense during subsequent cooling and pressure reduction. Furthermore, in mixtures rich in CO, there is the possibility of carbon precipitation:

$$2CO = CO_2 + C \qquad (21.1)$$

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie
Copyright © 2011 John Wiley & Sons, Inc.

resultant from a shift in the equilibrium with falling temperature given approximately by

$$\log\left[\frac{(P_{CO_2})(a_C)}{(P_{CO})^2}\right] = \frac{8916}{T} - 9.15 \qquad (21.2)$$

Even if the concentrations of the most abundant gases change little with temperature, the partial pressures of the constituent elements such as O_2 or S_2 may vary considerably. It may be necessary to infer, from a gas composition at ambient temperature and pressure, what the gas composition is likely to be at the service condition for the alloy.

Table 21.1 shows the computed equilibrium composition at 900 K (627°C) and 1100 K (827°C) for a gas with an initial composition of 35% CO, 25% H_2, 20% CO_2, 19% H_2O, and 1% H_2S. In both cases, the total pressure is 30 atm. This type of gas composition might be found in coke/coal/oil gasification, Flexicoking (trade name of Exxon Corporation), catalytic cracking in a petroleum refinery, steam-methane re-forming, or instances of fuel-rich conditions of fossil fuel combustion. The nominal (molar) composition may be regarded as the reactants in a chemical process leading to the equilibrium products. In the product equilibrium, the mole fraction is given adjacent to each species considered. The total number of moles of gas appears near the bottom of each listing and is, of course, larger for the higher temperature reflecting the greater degree of dissociation. Although graphite is a potential phase in both figures, it only appears at the lower temperature; at the higher temperature the activity of carbon with respect to graphite is less than 1.

The equilibrium was established by the Gibbs energy minimization [2, 3]. In this versatile computational procedure, the molar concentration of candidate equilibrium species (containing some or all of the elements in the nominal gas) are systematically varied subject to the condition of mass balance for each element. For each such mixture, the total (relative) Gibbs energy, G_t, is calculated by evaluating the following function:

$$G_t = \sum_{i=1}^{\text{gases}} \left(n_i\{\Delta G_i^\circ + RT\ln[(X_i)(P)]\}\right) + \sum_{i=1}^{\text{solids}} n_i\,\Delta G_i^\circ \qquad (21.3)$$

where ΔG_i° are the standard Gibbs energies of formation per mole of each species in the equilibrium gas mixture, R is the gas constant, n_i is the number of moles, X_i is the mole fraction of species in the gas phase at absolute temperature, T, and total pressure, P. The equilibrium is found when successive (and progressively smaller) adjustments in molecular concentrations provide negligible reduction in G_t. The equilibrium partial pressure of the elemental species ($P_{H_2}, P_{O_2}, P_{S_2}$) and the activity of carbon (graphite, a_C) are a by-product of the computation.

B2. Corrosion Product Formation

Having established the equilibrium gas composition at the temperature of interest, it is now possible to consider the reaction of that gas with the elements in the alloy. Consider the case of Inconel 671 (trade name of Huntington Alloys International), which is nearly a binary alloy containing 54% Ni and 46% Cr. This alloy is not widely used but is chosen for this example to illustrate the concepts used to calculate corrosion product stabilities. The most stable chemical phase of nickel can be determined by computing the Gibbs energy change for all possible reactions of nickel with hydrogen, oxygen, sulfur, and carbon, assuming that the composition of the voluminous gas phase is not influenced by reactions with a relatively minor mass of the alloy. The reactions, all based on 1 mol of nickel reacting to form a series of Ni compounds with the general formula $NiH_aO_bS_cC_d$, have the form:

$$Ni + \left(\frac{a}{2}\right)H_2 + \left(\frac{b}{2}\right)O_2 + \left(\frac{c}{2}\right)S_2 + (d)C \rightarrow (NiH_aO_bS_cC_d) \qquad (21.4)$$

where the constants a, b, c, and d are ≥ 0. When the Gibbs energy change is computed, allowance is made for P_{H_2}, P_{O_2}, and P_{S_2}, and the activity of C appropriate to the gas mixture at the temperature and total pressure involved using the equation

$$\Delta G = \Delta G^\circ - \left(\frac{a}{2}\right)RT\ln P_{H_2} - \left(\frac{b}{2}\right)RT\ln P_{O_2} - \left(\frac{c}{2}\right)RT\ln P_{S_2} - (d)RT\ln a_C \qquad (21.5)$$

where ΔG° is the standard Gibbs energy of formation for the nickel-containing compounds (per mole of Ni) obtained from tables or databases of thermochemical properties. The reaction with the most negative Gibbs energy change identifies the most stable compound containing nickel coexisting in direct contact with the gas phase.

In order to evaluate the potential of changes in the gas composition to alter the most stable nickel compound, a diagram may be constructed by systematically varying the partial pressures of two particular elements while holding the partial pressure or activity of the third and fourth elements constant. Such a predominance or phase stability diagram is shown in Figure 21.1 for 1100 K (827°C) [2, 4]. Note that the suggested methodology for the diagram construction does not begin with potentially false suppositions of coexistence of particular combinations of nickel containing phases as a basis for developing equations for each phase boundary. Therein lies the power of the suggested computational procedure. Precision in locating the boundary for graphical purposes simply involves selecting suitably small steps in the variation of the partial pressures for the species used for the

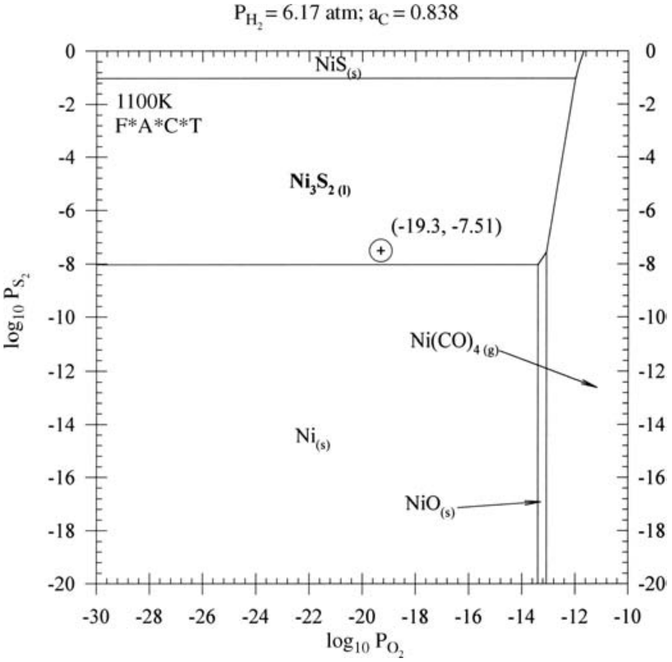

FIGURE 21.1. The **Ni**-H, O, S, C predominance diagram at 1100 K (827°C) prepared using the FACT system [2]. The coordinate ⊕ is consistent with Table 21.1.

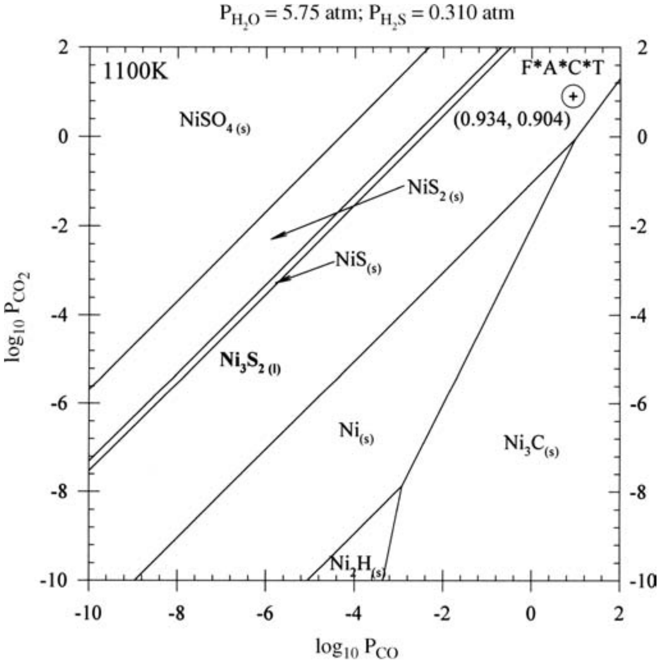

FIGURE 21.2. The **Ni**-H, O, S, C predominance diagram at 1100 K (827°C). The diagram is similar to Figure 21.1 but a different selection of axes and constant conditions has been made. The coordinate ⊕ is consistent with Figure 21.1 and Table 21.1.

axes. Many computations of Gibbs energy can be eliminated following the realization that phase fields must be contiguous. The computational power of a personal computer is more than ample to develop diagrams as in Figure 21.1 in a few seconds [2].

When it is more informative to employ the dominant gas species for the axes and fixed partial pressures in the diagram, a variation on the foregoing methodology is invoked Suppose, for example, log P_{CO_2} is used as oidinate and log P_{CO} as abscissa. The equilibrium constant for the process

$$CO + \tfrac{1}{2}O_2 = CO_2 \tag{21.6}$$

$$\log\left[\frac{P_{CO_2}}{(P_{CO})(P_{O_2})}\right] = \frac{14,764}{T} - 4.537 \tag{21.7}$$

enables P_{O_2} to be found for any pair of values of P_{CO} and P_{CO_2}.

Similarly, the carbon (graphite) activity can be found using Eqs. 21.1 and 21.2.

If, for the diagram development, the P_{H_2O} and P_{H_2S} were fixed, then P_{H_2} could be found from the equilibrium constant for

$$H_2 + \tfrac{1}{2}O_2 = H_2O \tag{21.8}$$

and P_{S_2} from the equilibrium constant for

$$H_2 + \tfrac{1}{2}S_2 = H_2S \tag{21.9}$$

These preliminary steps reduce the computations used to construct Figure 21.2 to those of Figure 21.1. The two diagrams are consistent in indicating that Ni_3S_2 (liquid) is the most stable phase of nickel in equilibrium with the gas. Comparable points, representative of the equilibrium gas in Table 21.1, are shown on both figures. The two diagrams are *not* topologically the same with respect to triple points and adjacent phase fields since the chemical potentials of all elements in the gas phase are only the same at the coordinates marked.

In the case of corrosion of Inconel 671, it is of course necessary to also consider the chemical compounds of Cr. By procedures similar to that described for Ni, a diagram similar to Figure 21.2 may be developed for Cr. This diagram superimposed on that for Ni is shown in Figure 21.3. The overlapping stability fields give rise to the double labeling of each area on the resultant diagram. For the conditions of temperature, total pressure, and gas compositions covered by Figure 21.3, there are no stable compounds containing both Ni and Cr and little or no mutual solubility of the various nickel- or chromium-containing compounds. Thus the superimposition of Ni and Cr stability diagrams leads to the conclusion, for the gas with the equilibrium composition in Table 21.1 at 1100 K, that liquid Ni_3S_2 and Cr_2O_3 are the most stable corrosion products.

As evidence that Ni_3S_2 and Cr_2O_3 cannot react to form, for example, $NiCr_2O_4$ in contact with the equilibrium gas

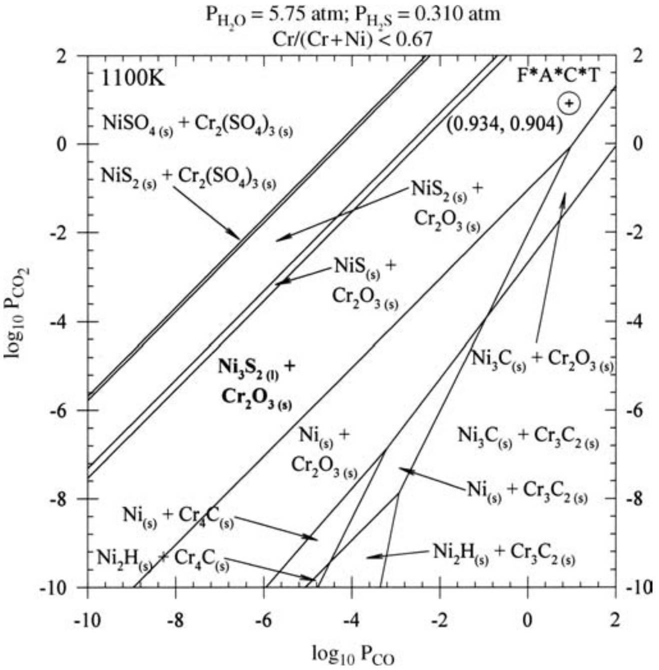

FIGURE 21.3. The **Ni, Cr**-H, O, S, C predominance diagram at 1100 K (827°C). The diagram in this case is the superimposition of Figure 21.2 and a similar one for Cr since, within the field of view, there are **no phases that contain both Ni and Cr (such as $NiCr_2O_4$)**. The placement of the coordinate ⊕ consistent with Table 21.1 shows that **liquid Ni_3S_2** is a stable phase.

TABLE 21.1. Equilibrium Computations for the Initial Gas Composition of 35 Mol CO, 25 Mol H_2, 20 Mol CO_2, 19 Mol H_2O, and 1 Mol H_2S, Shown as Mole Fractions Adjacent to the Given Species

Species	(900 K, 30 atm) X_i	(1100 K, 30 atm) X_i

O_2	0.457×10^{-23}	0.493×10^{-19}
Total moles of gas	75.3	92.8
Activity of C	1	0.838
Moles of C	12.8	0

composition in Table 21.1 at 1100 K, it is necessary to evaluate the Gibbs energy change for the reaction of Ni_3S_2 and Cr_2O_3 to form $NiCr_2O_4$ (balanced using CO_2, CO, H_2O, and H_2S).

$$Ni_3S_2 + 3Cr_2O_3 + CO_2 + 2H_2O \rightarrow 3NiCr_2O_4 + 2H_2S + CO \qquad (21.10)$$

In finding the Gibbs energy change at 1100 K [2], allowance is made for the partial pressures of the gas species at the composition of interest using an equation similar to Eq. (21.5). The positive value of 146 kJ/mol affirms the inability of the sulfide and oxide to react; that is, the stability of Ni_3S_2 and Cr_2O_3 in direct contact in this particular atmosphere.

Although the superimposition of Ni and Cr stability diagrams provides (by good fortune, in this particular case) a suitable corrosion product stability diagram, superimposition is not sufficiently general to create a reliable diagram in all cases. A more universally applicable approach is a necessity. To take the case of Inconel 671, the construction of a composite stability diagram for two (or more) alloying elements can be undertaken by finding the Gibbs energy changes for all reactions of the type:

$$(1-r)\mathbf{Ni} + r\,\mathbf{Cr} + \left(\frac{a}{2}\right)H_2 + \left(\frac{b}{2}\right)O_2 + \left(\frac{c}{2}\right)S_2 + (d)C$$
$$\rightarrow m[\mathbf{Ni}_w\mathbf{Cr}_x(H, O, S, C,)] + n[\mathbf{Ni}_y\mathbf{Cr}_z(H, O, S, C,)] \qquad (21.11)$$

In this generalized methodology [5], following the constraints of the phase rule, groups of compounds equal in number to the components in the alloy phase are considered. All the candidate corrosion product compounds in the group must contain some or all of the alloying elements and the molar amounts given by m and n must both of course be nonnegative for the proportion of elements in the alloy given by r. With all equations balanced in terms of 1 mol of alloy with appropriate zero or positive coefficients a, b, c, and d, the Gibbs energy change for each is found in a manner similar to that for reactions of the type given by Eq. (21.4). The corrosion product pair that is most stable is associated with the reaction with the most negative Gibbs energy change. The topology of such diagrams is sensitive to the value of r. Under more oxidizing conditions than those usually associated with coal gasification applications, $NiCr_2O_4$ may be a stable corrosion product. Clearly, whether $NiCr_2O_4$ coexists with a Cr- or a Ni-containing compound depends on whether r is greater or less than $\frac{2}{3}$.

C. KINETICS

The qualitative characterization of corrosion rate in high-temperature systems may sometimes be gleaned from a

combination of stability diagrams and corrosion rate data. Clearly, the stability diagram for Inconel 671 at 1100 K shown in Figure 21.3 is revealing in terms of indicating liquid sulfide corrosion products, which invariably have high corrosion rates, in contact with the equilibrium gas compositions represented in Table 21.1. Liquid Ni_3S_2, as a stable corrosion product (coexisting with solid Cr_2O_3), would be expected to corrode rapidly in the gas at 1100 K. At the lower temperature (900 K) associated with Figure 21.4, where Ni_3S_2 is solid, somewhat slower corrosion rates might be expected. Thermochemical information is valuable in organizing and interpreting data on corrosion at high temperatures, for design and selection purposes, in combination with corrosion rates measured in actual exposure testing.

To quantitatively represent *isothermal* corrosion testing, it is possible to provide empirical constants in an equation of the form

$$p = kt^n \qquad (21.12)$$

where p is the penetration (or depth of loss of internally oxidation free alloy) and k and n are characteristic parameters established by a statistical treatment of sufficient test data [6]. For a pure metal with only one corrosion product, a value of n near 1 may indicate that the superficial scale is not protective but rather spalls at a constant rate perhaps due to excessive volume in comparison to the volume of metal replaced (Pilling–Bedworth ratio [7]). In other cases, corrosion rate is limited by arrival of a corrosion species or removal of a volatile corrosion product compound. Protective corrosion products must have a value of $n < 1$. If the growth of the scale is characterized by a constant diffusion coefficient in the alloy or corrosion product compound, n should be $\frac{1}{2}$. This is sometimes termed parabolic growth. Defects in the crystallinity of the scale, particularly as affected by impurities or alloying elements incorporated into the growing scale, may lead to values other than $\frac{1}{2}$. Many corrosion–resistant alloys often have both a value of n of $\frac{1}{2}$ and a small value for k. The parameter k is temperature dependent and is sensitive to the equilibrium partial pressure of the elements in the gas phase as well.

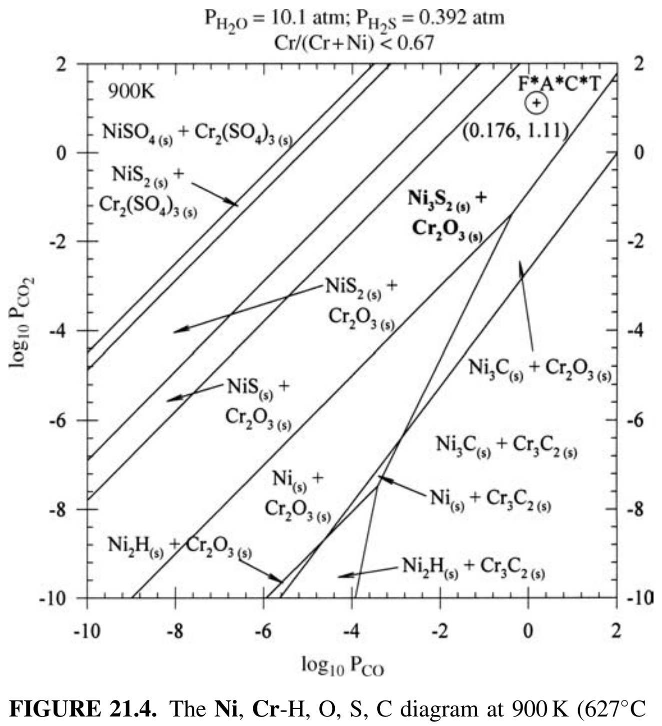

FIGURE 21.4. The **Ni**, **Cr**-H, O, S, C diagram at 900 K (627°C similar to Figure 21.3. The placement of the coordinate ⊕ consistent with Table 21.1 shows that solid Ni_3S_2 is a stable phase coexisting with **solid Cr_2O_3**.

When Inconel 671 is exposed to oxidizing and sulfidizing atmospheres such that Ni_3S_2 and Cr_2O_3 are the *stable corrosion products*, Eq. (21.12) may be generalized [8] to yield

$$\log\left[\frac{p}{(t)}\right] = a + b\left[\log(P_{S_2}) - \frac{3}{2}\log(P_{O_2})\right] + \frac{c}{T} \qquad (21.13)$$

Extensive exposure testing for many alloys and corrosive gases has shown that this form provides a good correlation of the corrosion data with the exposure conditions. For the specific case of Inconel 671 exposed to gas with the composition given in Table 21.1 for 900 K and 30-atm total pressure, the penetration is predicted by Eq. (21.13) to be 2.1 mils after 1 year, 4.6 mils after 5 years, and 6.5 mils after 10 years of exposure time [9]. For the same alloy under different service conditions (temperature, pressure, or gas composition), leading to a *different combination* of stable corrosion products, another empirical rate equation of a different form would be required.

D. SOFTWARE

The foregoing approach to alloy selection is computationally intensive and the following logical steps are used:

(a) The equilibrium partial pressures of elements in the corrosive gas must be found.
(b) The stable corrosion product phases on the candidate metal or alloy must be predicted based upon (a).
(c) A suitable empirical corrosion rate expression is selected, as appropriate for the likely corrosion mechanism [i.e., corrosion phases in (b)].

To assist in this manually cumbersome methodology, a user-friendly Windows 95 (trade name of Microsoft Corporation) program called ASSET (Alloy Selection System

for Elevated Temperatures) has been developed [9]. The thermochemical predictions involved in steps (a) and (b) are performed in a user transparent way with an appropriate subset of programming and databases of Facility for the Analysis of Chemical Thermodynamics (FACT) [2]. Regression analysis is used to produce correlations of alloy corrosion for four different corrosion mechanisms as named for the types of corrosion products that form:

1. Sulfidation
2. Sulfidation/oxidation
3. Oxidation
4. Carburization

A large selection of data has been compiled for these conditions representing nearly 4.7 million h of exposure for 71 commercially available alloys. Details of the program are provided elsewhere [9].

E. CONCLUSION

An engineering approach to the selection of alloys for high-temperature service in many different types of fossil fuel combustion and energy conversion processes, can, with suitable software [2, 9, 10], involve a blend of fundamental science and exposure testing. Thermodynamics is used to compute the equilibrium gas-phase chemical speciation and predict stable corrosion products on commercial alloys. Extensive exposure testing conducted on commercially available alloys is then correlated to those computations to provide a reliable guide to metal loss as a function of time, temperature, gas composition, and pressure. The reader is referred to readily available literature [8, 11–22] for a more comprehensive treatment of the corrosion of metals and alloys in high-temperature gases.

A. INTRODUCTION

In comparison to corrosion at near ambient temperatures, the oxidation of metals and alloys at high temperatures puts greater emphasis on chemical thermodynamics. Fortunately, the difficulties posed by experimental measurements at high temperatures are offset by more rapid chemical kinetics making computations of equilibrium especially useful as a predictive tool. In some cases, the decreasing stability of metal oxides with increasing temperature also makes exploiting conditions of immunity a practical possibility. A procedure is described in Chapter 21 of this *Handbook* to locate domains of immunity by computational means on isothermal diagrams in which the partial pressures of gases are used as axes on logarithmic scales. These are sometimes called predominance diagrams and have a long history of usage in high-temperature corrosion as well as other matters involving chemical reactions at high temperatures between condensed phases and process gases, such as in smelting and refining. As the gas mixtures become more complex, particularly with respect to the number of elements, predominance diagrams become increasingly difficult to interpret. It is generally not evident how to create in a reacting gas mixture (such as CH_4 and O_2) the equilibrium partial pressures (CO, CO_2, etc.) used as axes on predominance diagrams. Additionally, gas-phase equilibria controlling the speciation in the gas mixture are sensitive to temperature and pressure. Therefore, combinations of alloys and gas mixtures that perform well at one temperature may not do so at another. In these situations, multiphase equilibria states and speciation may be computed through numerical optimization techniques [1–5]. This method is applied to homogeneous gas-phase equilibrium in Section B and heterogeneous equilibrium of a condensed solid phase coexisting with an ideal gas in Section C.

B. HOMOGENEOUS EQUILIBRIUM IN AN IDEAL GAS SOLUTION

High-temperature oxidation and corrosion requires the computation of gas-phase speciation at the temperature and pressure of exposure in a system comprised of several elements. To give focus to the computational methods, consider a hydrocarbon combustion situation. The usual

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

excess of oxygen in relation to a hydrocarbon fuel at high temperature makes it possible to exploit knowledge that the main product species are $CO_{2(G)}$ and $H_2O_{(G)}$, with most of the sulfur appearing as $SO_{2(G)}$. However, with the same collection of elements involved in, for example, coal gasification, the deficiency of oxygen in relation to carbon and the large number of possible chemical compounds makes the computation of molecular concentrations more difficult. A general method to compute gas-phase equilibrium in a system with several elements is therefore a necessity. Even when the gas composition is known from chemical analysis at room temperature, the composition of the gas at the temperature and pressure of exposure must be computed.

Gas-phase speciation is generally discussed with reference to equilibrium constants relating, for example, concentrations of $CO_{(G)}$, $CO_{2\,(G)}$; and $O_{2\,(G)}$:

$$CO_{(G)} + \tfrac{1}{2}O_{2(G)} = CO_{2(G)} \tag{22.1}$$

where

$$K_{eq} = \exp\left[\frac{-\Delta G^\circ}{RT}\right] = \frac{P_{CO_2}}{P_{CO}\,P_{O_2}^{\;0.5}} \tag{22.2}$$

where K_{eq} is the equilibrium constant, ΔG° (J·mol^{-1}) is the Gibbs energy of reaction, R (J·mol^{-1}K^{-1}) is the universal gas constant, T (K) is the absolute temperature, and P_i (atm) is the partial pressure of species i in the gas. In an ideal gas mixture, the fugacity is numerically equivalent to the partial pressure in dimensionless units when the reference pressure is 1 atm. The difficulty with pursuing this method is incorporating the overall atomic proportion of carbon and oxygen in the system to express constraints on the partial pressures. Nonetheless, in a system where experience provides a basis for knowing the dominant gas species, and where the number of those species does not significantly exceed the number of elements, this traditional method of computing gas-phase equilibrium is quite serviceable. However, it does not lend itself to generalization, even when applied to common combustion gases with several possible elements (C, H, S, O, N), particularly for the case of fuel consumed in a deficiency of air.

B1. Thermodynamic Data

As a basis of discussion that can be related to familiar expectations, consider the binary carbon–oxygen system at 1000 K and 1 atm. The Gibbs energy, G_i° (J·mol^{-1}), of an individual species i may be initially defined as [6]

$$G_i{}^\circ = \left(\Delta H_i{}^\circ + \int_{298}^{T} C_{p,i}\,dT\right) - T\left(S_i{}^\circ + \int_{298}^{T} \frac{C_{p,i}}{T}dT\right) + \int_{1}^{P_i} V_i\,dP \tag{22.3}$$

where $\Delta H_i{}^\circ$ (J·mol^{-1}) and $S_i{}^\circ$ (J·mol^{-1}K^{-1}) represent the standard enthalpy of formation and absolute entropy, respectively, at 298 K and 1 atm, $C_{p,i}$ (J·mol^{-1}K^{-1}) is the molar heat capacity at constant pressure, P_i (atm) is the partial pressure, and V_i (m^3·mol^{-1}) is the molar volume occupied by i. Division by the total number of atoms in the formula mass ($M_{i,T}$) provides units of joules per gram-atom (J·g at^{-1}). The use of this latter unit in expressing an extensive property provides a basis for comparing Gibbs energies of compounds with different numbers of atoms per molar mass on an equivalent basis.

Although it is a misnomer, the Gibbs energy in Eq. (22.3), $G_i{}^\circ$, is sometimes called the "absolute" Gibbs energy. This nomenclature draws attention to the use of the absolute entropy in the formulation of $G_i{}^\circ$. The more usual Gibbs energy of isothermal formation from the most stable form of the elements appears on the extreme right side of Table 22.1.

TABLE 22.1. Gibbs Energies for Selected Species in C–O System at 1000 K and 1 atm

	Mole Fraction of Element		Atoms/ Molecule	"Absolute" Gibbs Energy[a] [7]		Gibbs Energy of Formation[a]	
Species	$c_{i,C}$	$c_{i,O}$	$M_{i,T}$	(J·g mol^{-1})	(J·g at^{-1})	(J·g mol^{-1})	(J·g at^{-1})
$C_{(G)}$	1	0	1	547,992	547,992	559,952	559,952
$C_{2(G)}$	1	0	2	618,794	309,397	644,114	322,057
$C_{3(G)}$	1	0	3	563,277	187,759	601,255	200,418
$C_{4(G)}$	1	0	4	711,512	177,878	762,151	190,538
$C_{5(G)}$	1	0	5	698,392	139,678	761,690	152,338
$O_{(G)}$	0	1	1	77,353	77,353	187,735	187,735
$O_{2(G)}$	0	1	2	– 220,764	– 110,382	0	0
$O_{3(G)}$	0	1	3	– 119,445	– 39,815	211,702	70,567
$CO_{(G)}$	0.5	0.5	2	– 323,264	– 161,632	– 200,222	– 100,111
$C_2O_{(G)}$	0.667	0.333	3	29,161	9,720	164,863	54,954
$CO_{2(G)}$	0.333	0.667	3	– 629,423	– 209,808	– 396,000	– 132,000
$C_3O_{2(G)}$	0.6	0.4	5	– 409,605	– 81,921	– 150,862	– 30,172
$C_{(S)}$	1	0	1	– 12,660	– 12,660	0	0

[a]In reference to iterations 0 and 1 in Table 22.2

Taking $CO_{(G)}$ as an example, the species of pure carbon with the lowest "absolute" Gibbs energy ($C_{(S)}$) and the lowest for pure oxygen ($O_{2(G)}$) may be deducted from the "absolute" Gibbs energy of $CO_{(G)}$ to yield a Gibbs energy of formation of $-100{,}111$ (J·g at^{-1}). Table 22.1 deliberately includes several species known to be of little consequence at 1000 K and 1 atm in order to illustrate the unbiased procedure by which the dominant chemical species are found as an initial step in computing the equilibrium composition of the gas phase. The atomic fractions of the elements in each species i are represented by $c_{i,\mathrm{C}}$ and $c_{i,\mathrm{O}}$ for carbon and oxygen respectively, as shown in Table 22.1 [7].

B2. Identification of Dominant Species

The initial elemental proportions of carbon and oxygen must be specified to identify the dominant gas species. Here, this proportion is arbitrarily set to be 0.65 atom fraction O (equivalently, 0.35 mol $C_{(S)}$ and 0.325 mol $O_{2(G)}$) for discussion purposes. This atomic proportion might be known from the relative flows of oxygen and pulverized carbon in a combustion situation. Temporarily setting aside the effect of concentration (or partial pressure) on the molar Gibbs energy of each species, the overall aim is to iteratively distribute the elements, subject to the constraint on their proportion, to make the Gibbs energy of the gas mixture the most negative. This approach could not be exploited in a practical way until the advent of digital computing using methods generally based on Lagrange multipliers [1–5] as Gibbs himself first recognized [8]. The present approach further exploits knowledge that Gibbs energy is, by nature, a relative quantity since it is not possible to chemically convert one element to another. Only changes in Gibbs energy, which involve processes of chemical conversion from one collection of C- and O-containing species to another, are measurable. Recognition of this thermodynamic principle permits systematic adjustment of the numerical values of the Gibbs energies for species in such a way as to preserve essential differences (as will be demonstrated later in Table 22.3).

The process of adjusting Gibbs energies to preserve Gibbs energy differences for chemical change was coined by Eriksson and Thompson as "leveling" [9]. Leveling is performed by representing the set of Gibbs energies relative to the collection of species assumed to be most stable. The Gibbs energy of species i that is represented relative to a particular assemblage is referred to as the "relative Gibbs energy," ΔG_i^m (J·g-at^{-1}).

The process is best understood using the sequence of diagrams in Figure 22.1 and the adjusted relative Gibbs energies in Table 22.2.

Leveling involves:

(i) Selecting any two species which represent the overall atomic proportion of oxygen to carbon
(ii) Setting the relative Gibbs energy of those species to zero when they are assumed to be the most stable pair
(iii) Readjusting the relative Gibbs energies of all other species relative to the two set to zero

The two species initially selected are the most stable form of each element; that is to say, the form of carbon and oxygen with the lowest Gibbs energy in units of J·g at^{-1}. The use of gram-atom in place of mole (or equivalently gram-mole) permits the direct comparison of equal amounts of monatomic $O_{(G)}$ with diatomic $O_{2(G)}$, as shown on the extreme right-hand side of Figure 22.1. With this initial selection of possible "dominant" species assures the ability to express the overall elemental proportion as represented by the vertical dotted line in Figure 22.1. All species are "leveled" with respect to $C_{(S)}$ and $O_{2(G)}$ in the first iteration, as represented by the horizontal dashed line at $m = 1$ in Figure 22.1. The adjustment made to species i as a result of leveling (δG_i) is represented by the following equation for the first iteration:

$$\delta G_i = c_{i,\mathrm{C}}\delta G_{\mathrm{C}_{(S)}} + c_{i,\mathrm{O}}\delta G_{\mathrm{O}_{2(G)}} \tag{22.4}$$

By deducting this Gibbs energy evaluated at the composition of each C–O species, the relative Gibbs energies for all species are thereby set relative to $C_{(S)}$ and $O_{2\,(G)}$ in the first iteration, and both elements in their most stable form necessarily become zero. This is depicted graphically at iteration $m = 1$ in Figure 22.1 and tabulated in column 3 in Table 22.2.

The next step involves selecting the species with the most negative relative Gibbs energy (i.e., $CO_{2(G)}$), which will

TABLE 22.2. Gibbs Energies Adjusted as Result of Leveling to Identify Dominant Species

	Relative Gibbs Energy [ΔG_i^m(J·g at^{-1})] Iteration m			
Species	0[a]	1[a]	2	3
$C_{(G)}$	547,992	560,652	560,652	565,097
$C_{2(G)}$	309,397	322,057	322,057	326,502
$C_{3(G)}$	187,759	200,418	200,418	204,863
$C_{4(G)}$	177,878	190,538	190,538	194,983
$C_{5(G)}$	139,678	152,338	152,338	156,783
$O_{(G)}$	77,353	187,735	385,735	383,513
$O_{2(G)}$	− 110,382	0	198,000	195,777

$C_3O_{2(G)}$	− 81,921	− 30,172	49,028	50,806
$C_{(S)}$	− 12,660	0	0	4,445

[a]In reference to Table 22.1.

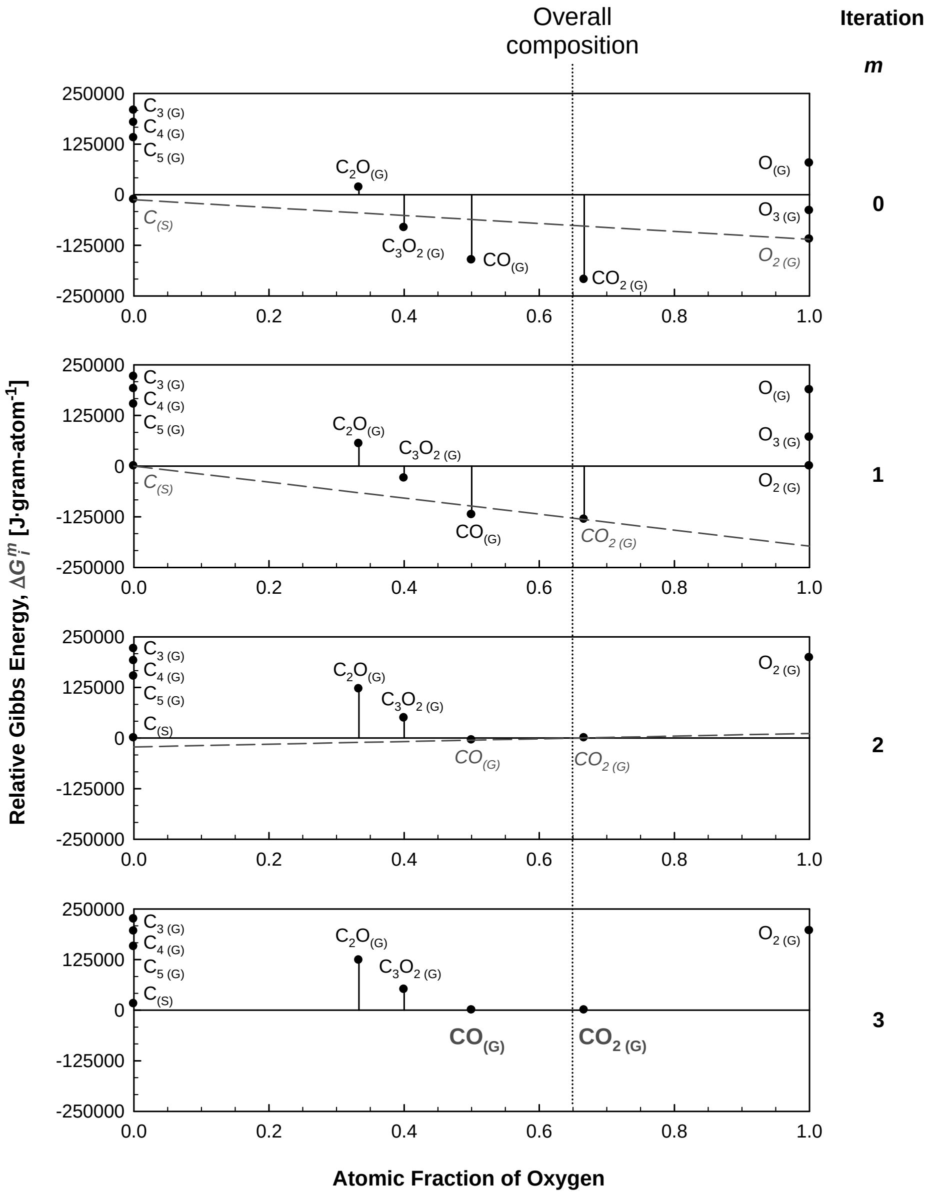

FIGURE 22.1. Illustration of leveling technique applied to C–O system to determine pair of dominant gaseous species at 0.65 atomic fraction of O at 1000 K and 1 atm.

replace one of the species from the first iteration. The choice of the species to be replaced from iteration $m = 1$ is made on the basis of being able to represent the fixed overall atomic fraction of O for the system as a whole. Thus, $CO_{2\ (G)}$ must be paired with $C_{(S)}$ rather than $O_{2\ (G)}$. A combination of $CO_{2\ (G)}$ and $C_{(S)}$ are together more negative than the previous estimated assemblage comprised of $C_{(S)}$ and $O_{2\ (G)}$. The equation representing the horizontal dashed line shown in Figure 22.1 is reestablished and leveling is advanced to iteration $m = 2$ in Figure 22.1 and column 4 in Table 22.2. Species that have positive relative Gibbs energies do not require further consideration as they are correspondingly less chemically stable than the current assemblage. Thus, a large proportion of possible species are withdrawn from further consideration with every additional iteration. This is a very significant feature when this method is applied to a gas mixture involving many elements and species. Eventually, all relative Gibbs energies are nonnegative, as in iteration $m = 3$ in Figure 22.1 and the extreme right column in Table 22.2. The two species that have zero relative Gibbs energies at the end of leveling ($CO_{2(G)}$ and $CO_{(G)}$) are the dominant gaseous species, and their proportions are as follows:

$$
\begin{aligned}
&0.35\ \text{mol}\ C_{(S)} + 0.325\ \text{mol}\ O_{2(G)} \\
&\quad = 0.3\ \text{mol}\ CO_{2(G)} + 0.05\ \text{mol}\ CO_{(G)}
\end{aligned}
\qquad (22.5)
$$

Although the magnitude of Gibbs energies of all species changes throughout the leveling procedure, elemental differences in these energies are preserved at all iterations. The change in relative Gibbs energy for the reaction in Eq. (22.5) at iteration m is thus

$$\Delta G^m_{\text{Reaction}} = \Delta G^m_{\text{Products}} - \Delta G^m_{\text{Reactants}}$$

$$\begin{aligned}\Delta G^m_{\text{Reaction}} &= \left(0.3\,\text{mol} \times 3 \times \Delta G^m_{CO_{2(G)}} + 0.05\,\text{mol} \times 2 \times \Delta G^m_{CO_{(G)}}\right)\\ &= -\left(0.35\,\text{mol} \times 1 \times \Delta G^m_{C_{(S)}} + 0.325\,\text{mol} \times 2 \times \Delta G^m_{O_{2(G)}}\right)\end{aligned} \tag{22.6}$$

The preservation of differences in Gibbs energy for the above reaction is demonstrated in Table 22.3 using relative Gibbs energies tabulated in Table 22.2 for all iterations. Differences in relative Gibbs energies of all other conceivable reactions in the system are also preserved.

The thermochemical activity, a_i^m (unitless), of species i is computed with respect to the relative Gibbs energy at iteration m through the following relation:

$$a_i^m = \exp\left[\frac{-\Delta G_i^m M_{i,\text{T}}}{RT}\right] \tag{22.7}$$

The activity of species i is equivalent to its concentration, $x^m_{i,\text{gas}}$ (and is correspondingly related to its partial pressure), in an ideal gas. $M_{i,\text{T}}$ is the previously defined number of total atoms per formula mass. The estimated concentrations of all species are computed with Eq. (22.7) in Table 22.4 using relative Gibbs energies from iteration $m = 3$. By the nature of this method, the mass constraints imposed on the system are in general not exactly satisfied after leveling. The overall mole fractions of carbon and oxygen in the gas are represented at iteration m by

$$\chi^m_{\text{C,gas}} = \frac{\sum_{i=1}^{N_{\text{gas}}} M_{i,\text{C}} x^m_{i,\text{gas}}}{\sum_{i=1}^{N_{\text{gas}}} M_{i,\text{C}} x^m_{i,\text{gas}} + \sum_{i=1}^{N_{\text{gas}}} M_{i,\text{O}} x^m_{i,\text{gas}}} \tag{22.8}$$

and,

$$\chi^m_{\text{O,gas}} = \frac{\sum_{i=1}^{N_{\text{gas}}} M_{i,\text{O}} x^m_{i,\text{gas}}}{\sum_{i=1}^{N_{\text{gas}}} M_{i,\text{C}} x^m_{i,\text{gas}} + \sum_{i=1}^{N_{\text{gas}}} M_{i,\text{O}} x^m_{i,\text{gas}}} \tag{22.9}$$

where $M_{i,\text{C}}$ and $M_{i,\text{O}}$ are the number of carbon and oxygen atoms, respectively, in a molecule of i. The overall mole fraction χ^m_{gas} representing the gas with estimated concentrations at iteration m will differ from the mole fraction that the gas is constrained by, χ'_{gas}. When the system is assumed to be homogeneous and comprised of a gas, the value for χ'_{gas} representing the gas is equal to the overall mole fraction of the system, χ^*. The mass constraint χ'_{gas} imposed on the gas is distinguished from the mass constraint χ^* imposed on the entire system for the condition where the system is heterogeneous and $\chi'_{\text{gas}} \neq \chi^*$. The treatment of heterogeneous systems involving an ideal gas coexisting with a pure condensed phase is addressed in Section C.

Discrepancies between $\chi^m_{\text{C,gas}}$ and $\chi^m_{\text{O,gas}}$ with respect to the fixed mole fractions of carbon and oxygen represented by the gas ($\chi'_{\text{C,gas}}$ and $\chi'_{\text{O,gas}}$) are evaluated on a relative basis. The relative errors representing the overall mass balances are as follows:

$$\xi^m_{\text{C}} = \left|\frac{\chi'_{\text{C,gas}} - \chi^m_{\text{C}}}{\chi'_{\text{C,gas}}}\right| \qquad \xi^m_{\text{O}} = \left|\frac{\chi'_{\text{O,gas}} - \chi^m_{\text{O}}}{\chi'_{\text{O,gas}}}\right| \tag{22.10}$$

By virtue of the dependency of concentrations of gaseous species on Gibbs energies, the sum of estimated concentrations in the gas, $x^m_{T,\text{gas}}$, will not equal unity. The relative error $\xi^m_{x,\text{gas}}$ representing the deviation of $x^m_{T,\text{gas}}$ from unity is thus defined

$$\xi^m_{x,\text{gas}} = \left|x^m_{T,\text{gas}} - 1\right| \tag{22.11}$$

The overall mole fraction χ^m_{gas} represented by the gas and the corresponding relative errors are computed in Table 22.4.

Table 22.4 demonstrates that the mass constraints imposed on the gas have not yet been satisfied at iteration $m = 3$. The effect of concentration on the molar Gibbs energy, which was temporarily superceded during leveling, must now be

considered. This matter is the principal cause of the relative errors shown at the bottom right of Table 22.4 (i.e., $\xi_{\mathrm{C}}^{m=3}$, $\xi_{\mathrm{O}}^{m=3}$). The identification of the dominant species by the leveling method provides good initial estimates for further computation.

B3. Computation of Equilibrium Concentrations of Gaseous Species

In many circumstances, depending on the temperature and pressure, the dominant species determined by the leveling algorithm are the only species that contribute significantly to the equilibrium population and all other species are of inconsequential proportions. However, further computation is often required when minor species contribute appreciably to the equilibrium composition in addition to the dominant species.

As a continuation of the concept of leveling, which exploits the fact that Gibbs energy is a relative function, a method is employed that exploits the knowledge that the equilibrium concentration of a solute species dissolved in a solution is related to its Gibbs energy. The objective is to further adjust the Gibbs energies of the pure elements to satisfy mass constraints within an admissible relative error. However, any slight numerical perturbation in the Gibbs energy of the pure elements (i.e., δG_{C} and δG_{O}) may result in large transformations in $\chi_{\mathrm{C,gas}}^m$ and $\chi_{\mathrm{O,gas}}^m$. To further complicate matters, changes made to the Gibbs energy of pure carbon will not only result in changes in the estimated number of moles of carbon but also in the number of moles of oxygen, since the dominant portion of molecules in the system are comprised of both carbon and oxygen atoms. Detailed explanations of the methodologies employed by this technique are discussed by Piro [10].

In view of the nonlinear dependency of $\chi_{\mathrm{C,gas}}^m$ on changes to Gibbs energies of both carbon and oxygen, $\chi_{\mathrm{C,gas}}^m$ is differentiated with respect to changes in the elemental Gibbs energies of both carbon and oxygen. The resulting partial differentials represent the individual contributions to changes in $\chi_{\mathrm{C,gas}}^m$ contingent on changes in elemental Gibbs energies. The numerical problem is reduced to a system of nonlinear equations in Eq. (22.12), which provides a mathematical framework for solving for a set of Gibbs energy adjustments to satisfy mass constraints [10]:

$$\begin{bmatrix} \dfrac{\partial \chi_{\mathrm{C,gas}}^m}{\partial G_{\mathrm{C}}} & \dfrac{\partial \chi_{\mathrm{C,gas}}^m}{\partial G_{\mathrm{O}}} \\ \dfrac{\partial \chi_{\mathrm{O,gas}}^m}{\partial G_{\mathrm{C}}} & \dfrac{\partial \chi_{\mathrm{O,gas}}^m}{\partial G_{\mathrm{O}}} \end{bmatrix} \begin{bmatrix} \delta G_{\mathrm{C}} \\ \delta G_{\mathrm{O}} \end{bmatrix} = \begin{bmatrix} \dfrac{\chi'_{\mathrm{C,gas}}}{x_{T,\mathrm{gas}}^m} - \chi_{\mathrm{C,gas}}^m \\ \dfrac{\chi'_{\mathrm{O,gas}}}{x_{T,\mathrm{gas}}^m} - \chi_{\mathrm{O,gas}}^m \end{bmatrix} \tag{22.12}$$

The partial differentials in Eq. (22.12) must be computed with respect to Eq. (22.7) in order to solve for the Gibbs energy adjustments for the succeeding iteration. Each term of the square matrix in Eq. (22.12) is computed with the following formulation:

$$\frac{\partial \chi_{j,\mathrm{gas}}^m}{\partial G_k} = \frac{\sum_{i=1}^{N_{\mathrm{gas}}} \left(\frac{M_{i,j} M_{i,k}}{RT} \right) x_{i,\mathrm{gas}}^m}{\sum_{i=1}^{N_{\mathrm{gas}}} M_{i,j} x_{i,\mathrm{gas}}^m + \sum_{i=1}^{N_{\mathrm{gas}}} M_{i,k} x_{i,\mathrm{gas}}^m} \tag{22.13}$$

Sum			2.00	2.41×10^{-4}	3.61×10^{-4}	3.61×10^{-4}	6.01×10^{-4}

Equation (22.13) demonstrates that the adjustments made to the Gibbs energies of the pure elements take into consideration the molecular composition of each species and its estimated concentration from the current iteration. For example, this method recognizes that one molecule of $CO_{2\,(G)}$ contains one carbon atom and two oxygen atoms. The computation of elemental Gibbs energy adjustments incorporates knowledge of the estimated contribution of all gaseous species in the system simultaneously to the overall mass balances of all elements represented by the gas. Table 22.5 exemplifies the computation of individual terms in Eq. (22.12) and (22.13) using estimated concentrations of species from iteration $m = 3$ in Table 22.4.

The coefficients of Eq. (22.12) incorporate values from the bottom of Tables 22.4 and 22.5. Components of the vector on the extreme right side of Eq. (22.12) are computed with Eq. (22.8) and (22.9), using mass constraints applied to the gas and the estimated mole fractions of the pure elements at iteration $m = 3$. Insertion of computed values from Tables 22.4 and 22.5 into Eq. (22.12) gives

$$\begin{bmatrix} \dfrac{2.41 \times 10^{-4}}{2.00 + 3.00} & \dfrac{3.61 \times 10^{-4}}{2.00 + 3.00} \\[2ex] \dfrac{3.61 \times 10^{-4}}{2.00 + 3.00} & \dfrac{6.01 \times 10^{-4}}{2.00 + 3.00} \end{bmatrix} \begin{bmatrix} \delta G_C \\ \delta G_O \end{bmatrix} = \begin{bmatrix} \dfrac{0.35}{2.00} - 0.40 \\[2ex] \dfrac{0.65}{2.00} - 0.60 \end{bmatrix} \tag{22.14}$$

The resulting system of linear equations can be solved with a standard linear equation solver to determine the adjustments made to the Gibbs energies of the pure elements in the next iteration:

$$\begin{bmatrix} 4.81 \times 10^{-5} & 7.22 \times 10^{-5} \\ 7.22 \times 10^{-5} & 1.20 \times 10^{-4} \end{bmatrix} \begin{bmatrix} \delta G_C \\ \delta G_O \end{bmatrix} = \begin{bmatrix} -0.225 \\ -0.275 \end{bmatrix} \tag{22.15}$$

The relative Gibbs energies of all species in the system are further altered using Eq. (22.4), analogous to the adjustments made in the leveling method discussed in Section B2. Table 22.6 summarizes the adjustments made to the relative Gibbs energies for all species and the subsequent changes to $x^m_{i,gas}$, χ^m_{gas} and ξ^m. The process is repeated until the maximum value for ξ^m is less than the specified error tolerance. A value of 10^{-5} has been found acceptable as the error tolerance limit for the majority of thermochemical scenarios. The concentrations of all gaseous species at iteration $m = 8$ on the extreme right column in Table 22.6 are representative of the equilibrium composition. The concentration of each gaseous species is equivalent to its partial pressure since the total applied hydrostatic pressure is 1 atm for this example.

The current example has involved a simple two-element system comprised of a few chemical species for discussion purposes. This algorithm can be easily extended to systems of many elements and a correspondingly large number of species. Performance statistics are shown in Figure 22.2 for thermochemical computations of homogeneous systems comprised of 200 species and up to 40 elements using the methodology described. Computation times are (obviously) dependent on many different factors, such as hardware performance, and are thus normalized relative to the computation time of 10 elements.

C. HETEROGENEOUS EQUILIBRIUM INVOLVING A PURE CONDENSED PHASE AND AN IDEAL GAS

The strategy discussed in Section B can be applied to heterogeneous systems involving various combinations of pure condensed phases in equilibrium with an ideal gas. The inclusion of pure condensed phases is illustrated through the

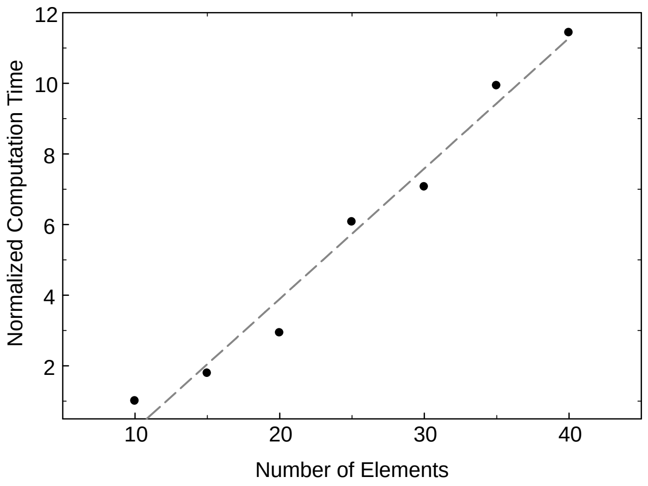

FIGURE 22.2. Performance statistics of thermochemical computations are shown for homogeneous systems (200 ideal species) represented by up to 40 elements. Computation times are averaged by one million unique thermochemical computations by varying composition, temperature, and pressure.

following example applied to the (C, O, H, S) system at 900 K and 30 atm in reference to the example in Chapter 21. The temperature, pressure, and elemental composition reflects coke/coal/oil gasification and several other industrial processes involving corrosion phenomena. The "absolute" Gibbs energies and Gibbs energies of formation computed at 900 K and 30 atm are listed in Table 22.7 for all species of interest in this system.

Leveling is performed using the same methodology described in Section B2 whereby all species are initially treated as pure separate phases. The adjustments made to the elemental Gibbs energies of the system can be interpreted graphically as a hyperplane in four-dimensional Euclidean space, analogous to the horizontal dashed line shown in Figure 22.1 for a binary system. The leveling algorithm determines that $C_{(S)}$, $CO_{2(G)}$, $H_2O_{(G)}$, and $H_2S_{(G)}$ are the dominant species, as shown in Table 22.8 for iteration $m = 4$. Therefore, the system is now assumed to be heterogeneous, consisting of graphite ($C_{(S)}$) coexisting with an ideal gas phase.

The Gibbs energies of the system are further adjusted using Eq. (22.12) to satisfy the mass balances of the system, similar to the previous example for a homogeneous system. Adjustments made to the elemental Gibbs energies are constrained by the relative Gibbs energy of $C_{(S)}$ when it is assumed to precipitate. That is to say that the hyperplane representing adjustments made to the elemental Gibbs energies of the system intersects the point corresponding to the relative Gibbs energy of $C_{(S)}$. The hyperplane pivots about this point and the intercepts correspond to adjustments made to the Gibbs energies of the pure elements.

The mass constraints imposed on the gas (χ'_{gas}) differ from that of the system (χ^*) in regard to a nonzero number of estimated moles of $C_{(S)}$. The number of moles of $C_{(S)}$ is added

[a] The leveling method ($m=4$) provides initial estimates for the computation of the final equilibrium state ($m=10$). The computation of this system is made in reference to Table 21.1 in Chapter 21.

or withdrawn from the system every iteration in a systematic manner. An initial estimate of the number of moles of the pure condensed phase can be computed from the mass balance of the dominant species produced by the leveling algorithm at $m=4$.

The final equilibrium composition is shown on the extreme right column in Table 22.8, which is referenced to Table 21.1 in Chapter 21. A predominance diagram can be constructed using the methodologies discussed in this chapter by systematically adjusting the partial pressures of two components while maintaining constant temperature, pressure, and activities of the remaining elements. These diagrams are convenient methods to graphically identify the predominant corrosion products over a range of partial pressures of two gaseous species. Figure 22.3 reproduces a predominance diagram from Chapter 21 for the system shown in Tables 22.7 and 22.8. The coordinates corresponding to the partial pressures of $CO_{(G)}$ and $CO_{2(G)}$ in the extreme right column of Table 22.8 determines that $Ni_3S_{2(S)}$ is a stable phase coexisting with $Cr_2O_{3(S)}$.

D. CONCLUSION

The application of computational thermodynamics in determining the equilibrium gas composition and various condensed phases may be utilized for predictive characterization of system speciation and phase behavior. The methodologies described herein are particularly valuable as they do not rely on any prior knowledge of the coexistence of

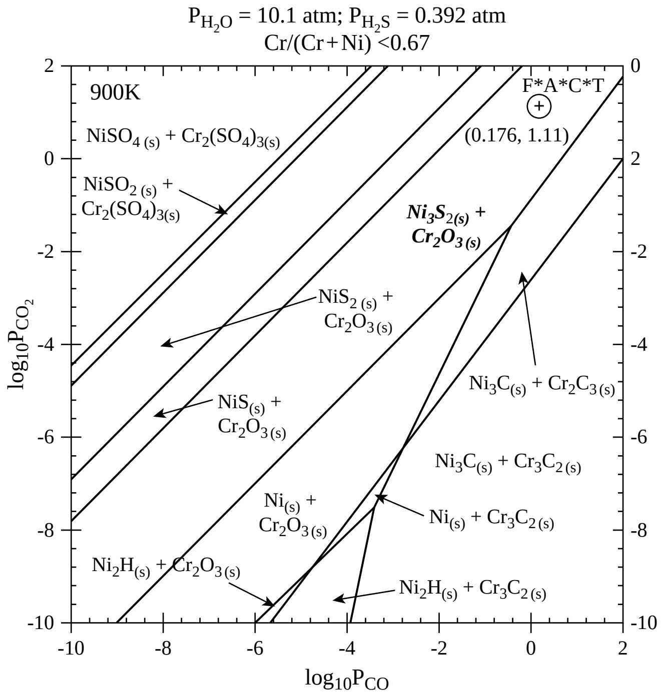

FIGURE 22.3. Predominance diagram of the Ni, Cr–H, O, S, C system at 900 K and 30 atm (see Chapter 21). The coordinate ⊕ is consistent with computed partial pressures of $CO_{(G)}$ and $CO_{2(G)}$ in Table 22.8.

phases at equilibrium. In this way, it is unnecessary to resort to clumsy empirical correlations of independently generated phase diagram computations with the loss in fidelity from which the empirical approach inherently suffers. This process allows for the capability of dealing in a fundamentally correct manner with a wide range of applications associated with corrosion phenomena.

A. INTRODUCTION

Atmospheric corrosion generally refers to corrosion processes occurring in outdoor or indoor environments. Such a broad definition is associated with very high visibility, for example, rusty bridges, flag poles, buildings (Fig. 23.1) and outdoor monuments (Fig. 23.2) [1]. Many of the parameters used to describe the phenomena associated with atmospheric corrosion are inherited from climatology and describe variables such as rainfalls, wind speeds, pollution level, humidity, and aerosol transport.

Atmospheric corrosion thus refers specifically to the situation of exposure of a component or a structure and, therefore, does not relate to any particular form or type of corrosion that may be developing in such situations. Consider, for example, what has been called brass season cracking. At the turn of the twentieth century, much trouble was caused by the cracking of brass cartridge cases stored in British army depots in India, where the air was hot and contained ammonia from animal waste (horses).

The metallurgical cracking susceptibility of brass in such circumstances was traced down to internal stresses left after fabrication, which were largely tensional in the surface layers of the parts affected, although balanced by compressive stresses in the central zone. The chemical action of ammonia at the grain boundaries allowed the grains, initially in tension, to contract, leaving definite fissures between one and another. This case was studied in many countries, but the extensive work of Moore and Beckinsale in 1920–1923 not only established the conditions favorable to intergranular cracking but also indicated the means of avoiding the trouble by annealing [2].

A more recent example concerned the case of the swimming pool stress corrosion cracking (SCC) of stainless steel supports. In 1985, 12 people were killed in Uster, Switzerland, when the concrete roof of a swimming pool collapsed. The roof was supported by stainless steel rods in tension, which failed due to SCC. A few years later, the suspended ceiling of a municipal swimming pool in the

FIGURE 23.1. Noticeable rust on Willow stem plant in downtown Philadelphia. (Courtesy of Kingston Technical Software.)

Netherlands collapsed due to a similar cause. There have been other incidents associated with the use of stainless steel in safety-critical load-bearing applications in the environment created by modern indoor swimming pools and leisure centers [3]. While chloride-induced SCC damage is recognized as a common failure mechanism in stainless steels, a somewhat surprising element of these failures is that they occurred at room temperature. As a general rule of thumb, it had often been assumed that chloride-induced SCC in these alloys was not a practical concern at temperatures below 60°C.

Another incident that has received a high level of attention, particularly by the aircraft industry, was the Aloha incident in 1988, when a Boeing 737 lost a major portion of the upper fuselage in full flight at 7300 m (Fig. 23.3) [4]. This case baffled investigators until it was recognized that the deformation due to the corrosion of aluminum in lap joints of commercial airlines was accompanied by a bulging ("pillowing") between rivets, due to the increased volume of the corrosion products over the original material. The prevalent corrosion product in corroded fuselage joints was found to be hydrated alumina [$Al(OH)_3$], an aluminum corrosion product very stable at low temperatures with a particularly high volume expansion relative to aluminum [5]. The buildup of voluminous corrosion products when hydrated alumina is formed can produce an undesirable increase in stress levels near critical fastener holes (Fig. 23.4) and

FIGURE 23.2. Galvanic corrosion induced on military monument exposed to environments in front of Halifax Citadel. (Courtesy of Kingston Technical Software.)

FIGURE 23.3. Boeing 737 operated by Aloha airlines after it lost major portion of upper fuselage in 1988.

subsequent fracture due to the high tensile stresses resulting from the pillowing.

A similar corrosion situation, described by civil engineers as "pack rust", occurs when wetting and drying cycles produce a manyfold expansion of iron corrosion products within the crevices formed between riveted steel plates (Fig. 23.5). The expanded rust products may eventually build up enough pressure to break rivets used in steel bridge construction. Pack rust can also cause freezing of expansion joints and contribute to an increase in fatigue stress of primary structural components as was noted in the investigative report requested by the Minnesota legislature following the I-35W bridge collapse on August 1, 2007 [6].

The expansion of iron corrosion products is also responsible for spalling of concrete cover on many reinforced concrete structures. An equivalent volume expansion ratio of 3.0–3.2 has been measured in such situations due to the formation of corrosion products on steel bars embedded in concrete [7]. The pressure thus created may be high enough to cause cracks and the degradation of the reinforced concrete material (Fig. 23.6).

B. OUTDOOR ATMOSPHERES

The corrosivity of an atmospheric environment is an important consideration for designing and maintaining systems that are to be exposed to such environments. A widely accepted scheme for the classification of outdoor environments has been developed by a working group (WG 4) of the International Organization for standardization (ISO) corrosion technical committee (TC 156) [8].

In the program nicknamed ISO CORRAG specially prepared coupons of steel, copper, zinc, and aluminum were exposed for 1, 2, 4, and 8 years at 51 sites located in 14 nations in order to generate the necessary data for predicting atmospheric corrosivity from commonly available weather data [9]. Triplicate specimens were used for each exposure. The program was initiated in 1986 and closed in 1998. After a planned exposure, each specimen was sent to the laboratory that had done the initial weighing for cleaning and evaluation. Based on these data, a simple classification scheme of five corrosivity classes was established for each metal (Table 23.1). The environmental and weather data gathered in this program are based on SO_2 and Cl^- deposition rates combined with time of wetness (TOW) measurements at each site.

These five corrosivity categories can be roughly translated into five outdoor situations listed here in decreasing order of corrosivity, that is, industrial, tropical marine, temperate marine, urban, and rural. These outdoor situations have also been used to estimate the zinc coating thickness required to achieve a certain service life with galvanizing (Fig. 23.7) [10]. Service life in Figure 23.7 is defined as the time to 5% rusting of the steel surface.

This graphical method is applicable to zinc-coated steel produced by batch or continuous galvanizing, including hot-dip, electrogalvanized, and thermal sprayed coatings. However, it does not apply to coatings containing more than 1% alloying elements. The method also assumes that the galvanized product is free of significant defects that could accelerate corrosion. Additionally, the service life prediction does not consider issues of water entrapment that can create severe crevice chemistry and degrade a zinc coating very aggressively (Fig. 23.8).

In fact, this last consideration applies generally to most atmospheric corrosion categories since these are usually based on general descriptors that do not consider local variations that can drastically alter the corrosion reactions at an exposed surface. Even the most benign environments may thus become locally extremely corrosive in certain

TABLE 23.1. ISO 9223 Corrosion Rates after One Year of Exposure Predicted for Different Corrosivity Classes

Corrosion Category	Steel (g/m^2 year)	Copper (g/m^2 year)	Aluminum (g/m^2 year)	Zinc (g/m^2 year)
C1	≤10	=0.9	negligible	=0.7
C2	11–200	0.9–5	=0.6	0.7–5
C3	201–400	5–12	0.6–2	5–15
C4	401–650	12–25	2–5	15–30
C5	651–1500	25–50	5–10	30–60

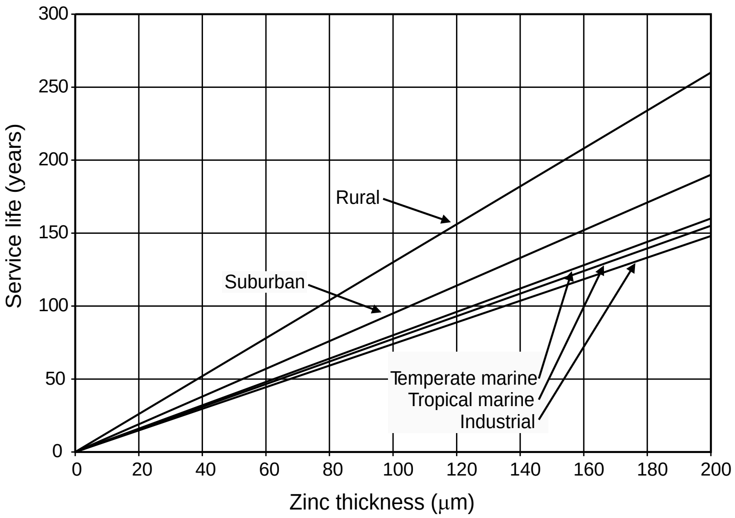

FIGURE 23.7. Service life of hot-dip galvanized coatings as function of zinc thickness and specific environments.

circumstances or conditions, as shown in Figure 23.9 where the statue head may occasionally serve as a perching platform for passing birds, a common situation in many parks where such monuments are erected.

Industrial atmospheres are typically rich in various polluting gases composed mainly of sulfur compounds such as sulfur dioxide (SO_2), a precursor to acid rain, and nitrogen oxides (NO_x), the backbone of smog in modern cities. Sulfur dioxide from burning coal or other fossil fuels is picked up by moisture on dust particles as sulfurous acid. This is oxidized by some catalytic process on the dust particles to sulfuric acid, which settles in microscopic droplets and fall as acid rain on exposed surfaces. Other corrosive pollutants may also be present such as various forms of chloride, which may be much more corrosive than the acid sulfates. The reactivity of acid chlorides with most metals is more pronounced than the reactivity of other pollutants such as phosphates and nitrates.

Marine atmospheres are laden with fine particles of sea mist carried by the wind to settle on exposed surfaces as salt crystals. The quantity of salt deposited may vary greatly with wind velocity, and it may, in extreme weather conditions, even form a very corrosive salt crust. The quantity of salt contamination decreases with distance from the ocean and is greatly affected by wind currents. In the Tropics, in addition

FIGURE 23.8. Galvanized bolting assembly after 10 years of exposure to deicing salt environment. (Courtesy of Kingston Technical Software.)

FIGURE 23.9. Jesus Breaking Bread statue serving as perching platform. (Courtesy of Kingston Technical Software.)

to the high average temperature, the daily cycle includes a high relative humidity, intense sunlight, and long periods of condensation during the night. In sheltered areas, the wetness from condensation may persist long after sunrise. Such conditions may produce a highly corrosive environment.

The corrosivity of urban and suburban environments is in great part related to the air quality in these environments, which can vary greatly from city to city and from country to country. For more than a century, severe air pollution incidents in cities such as London have shown that breathing dirty air can be dangerous and, at times, deadly. However, it was only in the late 1940s and early 1950s when air pollution disasters on two continents raised an alarm. Both the 1948 "killer fog" in the small town of Denora, Pennsylvania, that killed 50, and the particularly virulent London "fog" of 1952 in which some 4000 died, were associated with widespread use of dirty fuels and were catalysts for government efforts to tackle urban air pollution.

Since then, many nations have adopted ambient air quality standards to safeguard the public against the most common and damaging pollutants. These include sulfur dioxide, suspended particulate matter, ground-level ozone, nitrogen dioxide, carbon monoxide, and lead, all of which are tied directly or indirectly to the combustion of fossil fuels. Although substantial investments in pollution control in some industrialized countries have lowered the levels of these pollutants in many cities, poor air quality is still a major concern throughout the industrialized world.

Rural atmospheres are, typically, considered to be the most benign from a corrosion standpoint since these atmospheres are free of industrial pollutants, which is usually the case unless one is close to a farm operation where by-products made of various waste materials or the handling of concentrated chemicals such as fertilizers can be extremely corrosive to metals.

C. INDOOR ATMOSPHERES

Normal indoor atmospheres are generally considered to be quite mild when ambient humidity and other corrosive components are under control. However, some combinations of conditions may actually cause relatively severe corrosion problems. Even in the absence of any other corrosive agent, the constant condensation on a cold metallic surface may cause an environment similar to constant immersion for which a component may not have been chosen or prepared. Such systems are commonly encountered in confined areas

FIGURE 23.10. Rusted paint can after a few years in a normally humid basement. (Courtesy of Kingston Technical Software.)

close to ground level or, worse, below ground where high humidity may prevail. Home basements are a good example where such conditions prevail most of the time (Fig. 23.10).

Museums around the world contain all sorts of priceless cultural and historical artifacts that have been collected over centuries. Within such protective environments, surprisingly corrosive microclimates can exist. Corrosive pollutants such as ammonia, formaldehyde, acetaldehyde, formic acid, and acetic acid are often found in higher concentrations indoors than outdoors, inducing an array of chemical, electrochemical, and physical corrosion processes [11].

There can be an abundance of corrosive agents within storage cabinets, display cases, and galleries. The materials making up display cases, paint on the walls, or the carpets on the floors may all be the sources of an artifact's demise. Indeed, even the materials that were used in the manufacture, cleaning, or repair of an object can contribute to corrosion. Perhaps slower in pace and smaller in scale but destructive nonetheless, these corrosion processes mimic the more dramatic and extensive processes outdoors.

Another area of growing concern is related to the ubiquitous presence of electronics and microcomputers. The trend toward miniaturization of technology has led to the development of small personal electronic devices that are now present everywhere, such as pagers, cellular phones, and palm-sized personal organizers and computers [12]. According to the U.S. Census Bureau, the American electronic manufacturing industries alone shipped \$336 billion worth of electronic components in 1997. As electronic devices become increasingly ubiquitous and robust, the concern over the operating environment seems to lessen, particularly in the personal computer (PC) market.

Materials used in electronic components range from aluminum-based alloys (integrated circuits conductors) to copper contacts electroplated with nickel or gold for improved electrical conductance. Submicron dimensions of electronic circuits, high-voltage gradients, and an extremely high sensitivity to corrosion or corrosion products present a unique set of corrosion-related issues. A major departure from most corrosion situations is the incredibly small volume of the material that can be damaged and lead to a fault. The microchip in an automobile, for example, is not directly subjected to the same environmental hazards as the car body. However, the tolerance for corrosion loss in electronic devices is many orders of magnitude less, that is, on the order of picograms (10^{-12} g). Minimum line width in the state-of-the-art printed circuit boards (PCBs) in 1997 was less than 100 μm. On hybrid integrated circuits (HICs), line spacings may be less than 5 μm [13].

Printed circuit boards can suffer from a variety of problems if the surface is contaminated with electrically conducting materials. When combined with moisture, contamination results in a lowering of the resistance between tracks and pads, which may lead to corrosion of metals. It may also result in the formation of metal filaments or whiskers, which grow between pads, or tracks on rigid or flexible circuits and between oppositely charged metal terminations of components or between the pins of connectors. The essential conditions required for this are a combination of ionic contamination, moisture, and an applied voltage. Not only will the materials degrade, but numerous failure modes may be triggered and become apparent long before any noticeable or detectable changes in the electronic materials themselves. Additionally, these failure modes are quite often intermittent and will only present themselves while exposed to harsh conditions. This makes isolating, identifying, and correcting problems very problematic [14].

Equipment used under dry conditions should not suffer from these problems unless there are large temperature fluctuations that result in condensation occurring on the surface of the circuitry or if the contaminants are hygroscopic and adsorb enough moisture to provide a liquid layer on the surface.

New semiconductor technologies require much more stringent control of the manufacturing environment. From an air quality standpoint, the control of chemical contamination has become as important as the control of particulate contamination for many processes. Levels of airborne molecular contaminants (AMC) in ambient air are high enough to be problematic if introduced into the facility. However, the types and numbers of chemical species used in the

TABLE 23.2. Concentration of Selected Gaseous Air Constituents (ppb) in United States [14]

Gas	Outdoor (ppb)	Indoor (ppb)
O_3	4–42	3–30
H_2O_2	10–30	5

Cl_2	<0.005–0.08	0.001–0.005
HCHO	4–15	10
HCOOH	4–20	20

manufacturing of semiconductor devices also mean that there is a greater chance of chemical contamination from internal sources adversely affecting these sophisticated manufacturing processes [15].

Reactive gases usually have a relatively short life expectancy in the atmosphere and their active presence will last for a few minutes to several days, depending on conditions and type of gas. Many gases combine to form other airborne compounds as well as reacting with or being absorbed by surfaces. Table 23.2 shows a generalized arithmetic mean level of the amount of gaseous pollutants in the air for the United States. Other parts of the world, notably China and Asia, East Central Europe, and large population centers in Latin America have up to four times higher levels of pollutants.

Reactivity monitoring as described in International Society of Automation (ISA) Standard S71.04 has been used for many years to provide accurate environmental assessments to process and control industries. Many of the same types of contaminants that have to be controlled in these industries are those of concern to the semiconductor industry. Because of this, reactivity monitoring has been accepted as a viable environmental monitoring method by a number of semiconductor manufacturers. An air quality classification scheme based on reactivity monitoring has thus been established with wide acceptance throughout the semiconductor industry.

This classification scheme covers airborne contaminants that affect electrical or electronic equipment according to the type of contaminant as shown in Table 23.3. The synergistic effects of all contaminants present are seen in the total thickness of corrosion on the copper reactivity coupons. Then the corrosion damage measured on the reactivity coupons are related to reliability of the electronic equipment in that space.

D. ATMOSPHERIC CORROSIVITY FACTORS AND THEIR MEASUREMENT

As mentioned earlier many of the factors driving atmospheric corrosion are described and monitored as typical meteorological features. The quantity and composition of pollutants in the atmosphere and the variation of these with time are monitored on a regular basis by many governmental organizations for air quality assurance. Temperature, relative humidity (RH), wind direction and velocity, solar radiation, and amount of rainfall are also routinely recorded. Not so easily determined are dwelling time of wetness (TOW) and the surface contamination by corrosive agents such as sulfur dioxide and chlorides. However, methods for these determinations have been developed and are in use at various test stations. By monitoring these factors and relating them to corrosion rates, a better understanding of atmospheric corrosion can be obtained.

Water in the form of rain is not always corrosive. It may even have a beneficial effect by washing away atmospheric pollutants that have settled on exposed surfaces. This effect is particularly noticeable in marine environments. On the other hand levels of humidity causing dew and condensation are always undesirable from a corrosion standpoint if they are not accompanied by frequent rain washing to dilute or eliminate surface contamination.

Temperature plays an important role in atmospheric corrosion in two ways. First, the corrosion activity may double for each 10° increase in temperature. Second, a little

TABLE 23.3. Classification of Reactive Environments [15]

Severity Level	Mild	Moderate	Harsh	Severe
Copper Reactivity Level (in nm)	<30	<100	<200	≥200

SO_2, SO_3	<10	<100	<300	≥300
Cl_2	<1	<2	<10	≥10
NO_x	<50	<125	<1250	≥1250
HF	<1	<2	<10	≥10
NH_3	<500	<10,000	<25,000	≥25,000
O_3	<2	<25	<100	≥100

recognized effect is the temperature lag between metallic objects and ambient air that may follow sudden changes in ambient air temperatures. The period of wetness that may be much longer than the time the ambient air is at or below the dew point is a complex variable that depends on the section thickness and heat capacity of the metal structure and also on air currents, RH, and direct radiation from the sun. This lag may have some dramatic effects in poorly ventilated areas where moisture is trapped during the cold part of a temperature cycle.

As the ambient temperature drops during the evening, for example, metallic surfaces tend to remain warmer than the humid air surrounding them and do not begin to collect condensation until sometime after the dew point has been reached. As the temperature begins to rise in the surrounding air, the lagging temperature of the metal structures will tend to make them act as condensers, maintaining a film of moisture on their surfaces.

Since the dew point of an atmosphere indicates the equilibrium condition of condensation and evaporation from a surface, it is advisable to maintain the temperature some 10–15°C above the dew point to ensure that no corrosion will occur by condensation on a surface that would be colder than the ambient environment.

D1. Relative Humidity, Dew Point, and Time of Wetness

The most important factor in atmospheric corrosion is by far moisture, either in the form of rain, dew, condensation, or high RH. In the absence of moisture, most contaminants would have little or no corrosive effect. A fundamental requirement for atmospheric corrosion processes is the presence of a thin-film electrolyte that may form on metallic surfaces when exposed to a critical level of humidity. While this film is almost invisible, the corrosive contaminants it contains are known to reach relatively high concentrations, especially under conditions of alternate wetting and drying.

In the presence of thin-film electrolytes, atmospheric corrosion proceeds by balanced anodic and cathodic reactions described, respectively, in Eqs. (23.1) and (23.2). The anodic oxidation reaction involves the corrosion attack of the metal, while the cathodic reaction is naturally the oxygen reduction reaction (Fig. 23.11).

$$\text{Anode reaction} \qquad 2Fe \rightarrow 2Fe^{2+} + 4e^- \qquad (23.1)$$

$$\text{Cathode reaction} \qquad O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \qquad (23.2)$$

Relative humidity is defined as the ratio of the quantity of water vapor present in the atmosphere to the saturation quantity at a given temperature, and it is expressed as percent. In absence of any particular surface effects, the dew point corresponds to the temperature at which condensation

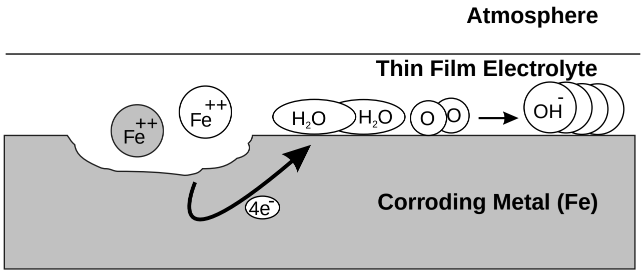

FIGURE 23.11. Schematic description of atmospheric corrosion of iron.

occurs. A high relative humidity would therefore be associated with a dew point close to ambient air temperature. If the relative humidity was 100%, for example, the dew point would be equal to ambient temperature. Given a constant dew point, an increase in temperature will lead to a decrease in relative humidity. Equation (23.3) provides a convenient way to calculate the dew point as a function of temperature to within ±0.4°C [16]:

$$t_d = \frac{B\left(\ln \mathrm{RH} + \dfrac{At}{B+t}\right)}{A - \ln \mathrm{RH} - \dfrac{At}{B+t}} \qquad (23.3)$$

where

$A = 17.625$
$B = 243.04°C$
RH = relative humidity as a fraction (not percent)
t = surface temperature (°C)
t_d = dew point temperature (°C)

Equation (23.3) is valid for $0°C < t < 100°C$, $0.01 < RH < 1.0$, and $0°C < T_d < 50°C$. Figure 23.12 illustrates the relationship between the dew point temperature and relative humidity for selected surface temperatures.

Precise RH measurements can be obtained by comparing the results from wet-bulb and dry-bulb thermometers. The comparison between the two readings provides an indication of water vapor in the air. The readings can be plotted on a chart known as the psychometric chart from where the properties of air vapor mixture such as relative humidity, absolute humidity, and dew point can be directly determined.

The critical humidity level below which there should be no corrosion additionally depends on the nature of the corroding material, the tendency of corrosion products and surface deposits to absorb moisture, and the presence of atmospheric pollutants [17]. It has been shown, for example, that this critical humidity level is 60% for steel when the environment is free of pollutants. In this context, marine environments have typically high RH and are laden with sea salts.

Studies have shown that the thickness of the adsorbed water layer on zinc surface increases with %RH and that corrosion rates increase with the thickness of the adsorbed

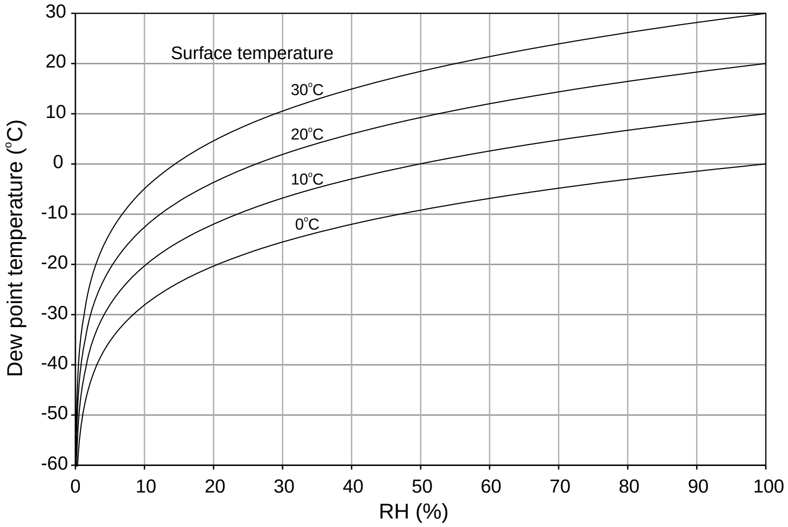

FIGURE 23.12. Relationship between dew point temperature and relative humidity for selected surface temperatures.

layer. There also seems to be a finite thickness to the water layer that, when exceeded, becomes limiting due to oxygen diffusion across the adsorbed water layer [18]. However, when metallic surfaces become contaminated with hygroscopic salts, their surface can be wetted at a lower RH. The presence of magnesium chloride ($MgCl_2$) on a metallic surface can make it wet at 34% RH while sodium chloride (NaCl) on the same surface requires 77% RH to create the same effect [19].

A commonly used compromise between these various observations is the TOW concept, which many corrosion scientists use and report in their studies. TOW is a parameter based on the length of time RH values are greater than 80% at a temperature greater than 0°C. It is commonly reported in hours or days per year or as an annual percentage of time a surface is above this threshold to express the persistence of the wetting water film and its potential consequences.

A method of measuring the TOW has been developed by Sereda and correlated with the corrosion rates encountered in the atmosphere [20]. The moisture-sensing elements in this sensor are manufactured by plating and selective etching of thin films of appropriate anode (copper) and cathode (gold) materials in an interlaced pattern on a thin nonconductive substrate (Fig. 23.13). When moisture condenses on the sensor, it activates the cell, producing a small voltage (0–100 mV) across a 10^7-Ω resistor.

D2. Aerosol Particles

The behavior of aerosol particles in outdoor atmospheres is explained by empirical equations that describe their formation, movement, and capture. These particles are present throughout the planetary boundary layer, and their concentrations depend on a multitude of factors including location, time of day or year, atmospheric conditions, presence of local sources, altitude, and wind velocity.

Aerosols can either be produced by ejection into the atmosphere or by physical and chemical processes within the atmosphere (called primary and secondary aerosol production, respectively). Examples of primary aerosols are sea spray and windblown dust. Secondary aerosols are produced by atmospheric gases reacting and condensing or by cooling vapor condensation. Once an aerosol is suspended in the atmosphere, it can be altered, removed, or destroyed, and average lifetimes are of the order of a few days to a week, depending on the aerosol size and location.

The highest concentrations are usually found in urban areas, reaching up to 10^8 and 10^9 particles per cubic centimeter, with particle size ranging from a few nanometers to around 100 µm. Size is normally used to classify aerosol because it is the most readily measured property and

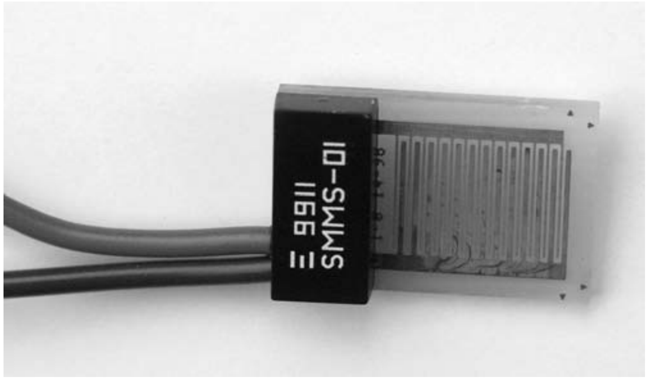

FIGURE 23.13. Interlocking combs of gold and copper electrodes in a Sereda humidity sensor. (Courtesy of Kingston Technical Software.)

other properties can be inferred from size information [21]. The highest mass fraction of particles in an aerosol is characterized by particles having a diameter in the range of 8–80 μm [22]. Some studies have indicated that there is a strong correlation between wind speed and the deposition and capture of aerosols. In such a study of saline winds in Spain, a very good correlation was found between chloride deposition rates and wind speeds above a threshold of 3 m/s or 11 km/h [23].

Aerosol particles have a finite mass and are subject to the influence of gravity, wind resistance, droplet dry-out, and possibilities of impingement on a solid surface. Studies of the migration of aerosols inland of a seacoast have shown that the majority of the aerosol particles are typically deposited close to the shoreline (typically 400–600 m) and consist of large particles (>10 μm diameter), which have a short residence time and are controlled primarily by gravitational forces [22, 23].

Airborne salinity refers to the content of gaseous and suspended salt in the atmosphere. It is measured by the concentration in the air in units of micrograms/cubic meter. Since it is the salt that is deposited on the metal surface that affects the corrosion, it is usually reported in terms of deposition rate in units of milligrams/meter squared/day. Chloride levels can also be measured in terms of the concentration of the dissolved salt in rainwater.

A number of methods have been employed for determining the contamination of the atmosphere by aerosol-transported chlorides, for example, sea salt and road deicing salts. The "wet candle method," for example, is relatively simple [24] but has the disadvantage that it also collects particles of dry salt that might not deposit otherwise. This technique uses a wet wick of a known diameter and surface area to measure aerosol deposition (Fig. 23.14). In this device, the wick is maintained wet, using a reservoir of water or 40% glycol–water solution. Particles of salt or spray are trapped by the wet wick and retained. At intervals, a quantitative determination of the chloride collected by the wick is made and a new wick is exposed.

In reality, the wet candle method gives an indication of the salinity of the atmosphere rather than the contamination of exposed metal surfaces. The technique is considered to measure the total amount of chloride arriving to a vertical surface, and its results may not be truly significant for corrosivity estimates.

Other techniques for measuring surface chlorides in the field are commercially available. The Bresle method, for example, is particularly suited to test for soluble surface contaminants on blasted surfaces. A Bresle patch is attached to the surface where the presence of chlorides is a concern, and distilled water is injected with a syringe in the patch and then extracted and measured with a conductivity meter. An alternate product called CHLOR*TEST, shown in Figure 23.15, uses a proprietary extract solution to retrieve surface chloride contamination. In the field, this special extract is said to enhance retrieval rates, thereby increasing accuracy.

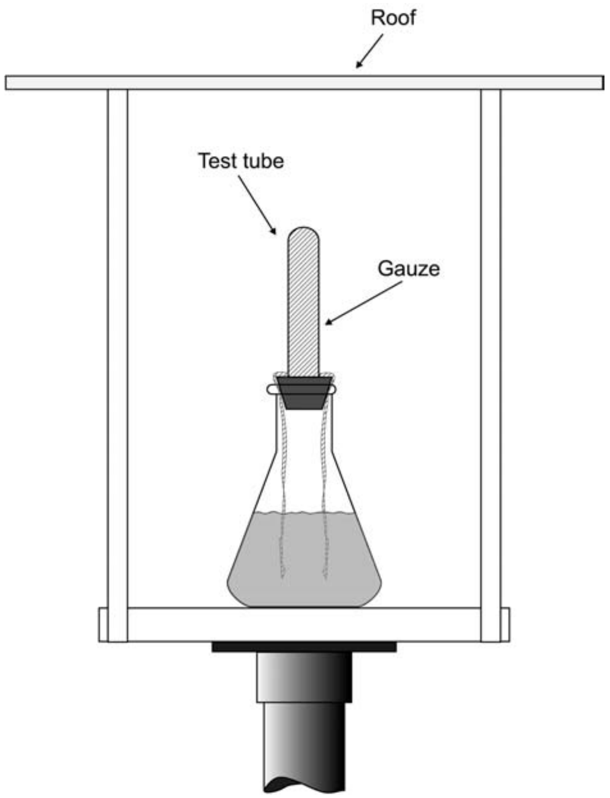

FIGURE 23.14. Schematic of wet candle chloride apparatus.

Another field monitoring technique incorporates a flat sensor to measure the conductivity of a solution from a single drop of sample (Fig. 23.16). Users can either place a sample

(a)

(b)

FIGURE 23.15. (*Continued*)

on the meter's flat sensor or immerse the meter directly in the solution being tested, giving the meter a broad range of applications.

D3. Pollutants

Sulfur dioxide (SO_2), a gaseous product of the combustion of fuels containing sulfur such as coal, diesel, gasoline, and natural gas, has been identified as one of the most important air pollutants that contribute to the corrosion of metals.

Less recognized as corrosion promoters are the nitrogen oxides (NO_x), which are also products of combustion. A major source of NO_x in urban areas is the exhaust fumes from vehicles. Sulfur dioxide, NO_x, and airborne aerosol particles can react with moisture and ultraviolet (UV) light to form new chemicals that can be transported as aerosols. A good example of this is the summertime haze over many large modern cities. Up to 50% of this haze or "smog" is a combination of sulfuric and nitric acids. Sulfur dioxide, NO_x, and other urban pollutants are routinely monitored with sophisticated equipment often housed in mobile units (Fig. 23.17) and typically reported in terms of their concentration in air in units of micrograms/cubic meter.

FIGURE 23.16. Portable conductivity meter. (Courtesy of Kingston Technical Software.)

The pollution levels may also be measured by analyzing rainwater for inorganic salts or by measuring its pH. However, this is only indirectly related to the effect of gaseous pollutants on corrosion since only the actual amount of salt deposited on metal surfaces is important.

There are two widely used methods for determining the deposition of SO_2 concentration in the atmosphere of interest. Both employ the affinity of lead oxide to react with gaseous SO_2 to form lead sulfate. The most common method used in corrosion work is the sulfation plate method. It consists of exposing small disks of lead oxide facing the ground under a small shelter to prevent the reactive paste from being removed by the elements [25]. The disk surface is thus exposed only to gaseous SO_2 and protected from particulates. The American Society for Testing and Materials (ASTM) procedure suggests a 30-day exposure, followed by a standard sulfate analysis [26].

The other method sometimes used is the peroxide candle, similar in its function to the chloride candle. In this method, a lead peroxide paste is applied to a paper thimble in the laboratory and allowed to dry thoroughly before exposure. The thimble is then exposed in an instrument shelter to the test yard environment. In both methods, the SO_2 deposited results are appropriately reported in terms of deposition rate on the surface in units of milligrams/square meter/day.

D4. Atmospheric Corrosivity

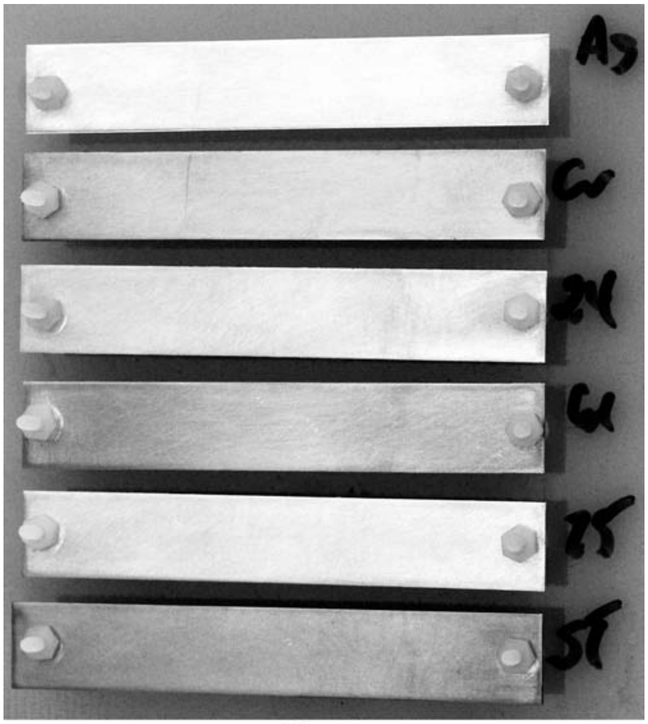
The simplest form of direct atmospheric corrosion measurement is by coupon exposures. Subsequent to their exposure, coupons can be subjected to weight loss measurements, pit density, and depth measurements as well as other types of examination.

FIGURE 23.17. Deployable air quality monitoring unit on Montreal Island. (Courtesy of Kingston Technical Software.)

Battelle Institute has used such coupon exposure as a passive method to monitor the atmospheric corrosivity of Air Force and other sites [27]. The database describing the relative corrosive severity levels of different locations and actual corrosion rates of a variety of metals has now grown to more than 100 sites worldwide. The metals included in that study are three aluminum alloys (A92024, A96061, and A97075), copper, silver, and steel. Figure 23.18(a) shows a closeup view of the coupons before exposure. Once exposed to the environment for a given period of time, the corroded metal strips [Fig. 23.18(b)] are sent back to the laboratory for mass loss measurements following standard methods [28] and further analysis.

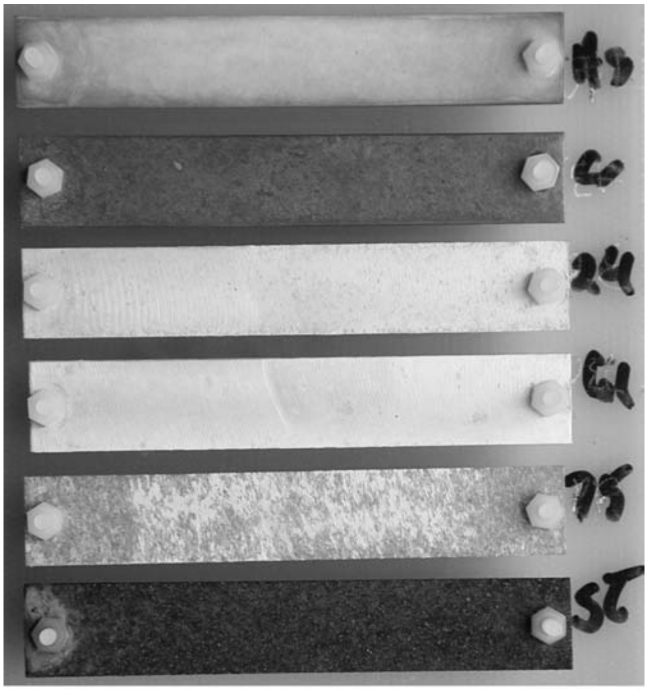
Another type of coupon has been developed to provide rapid material/corrosivity evaluations [29]. The helical coil adopted in the ISO 9226 methodology is a high surface area/weight ratio coupon that gives a higher sensitivity than panel coupons of the same material. The use of bimetallic specimens in which a helical A91100 aluminum wire is wrapped around a coarsely threaded bolt enhances further the sensitivity of the device has been described as the Classify Industrial and Marine Atmospheres (CLIMAT) coupon [29, 30].

The mass loss of the aluminum wire of a CLIMAT coupon after 90 days of exposure is considered to be a relative measure of atmospheric corrosivity. However, the results vary greatly between the various combinations of materials suggested in the ASTM standard [30]. The aluminum wire on copper bolts has been found by many to be the most sensitive of the three proposed arrangements in the ASTM standard. The use of triplicate coupons on a single holder additionally provides an indication of the reproducibility of the measurements, and the use of vertical rods can reveal directional information on the corrosive agents as will be illustrated in the following examples.



(a)

FIGURE 23.18. Metal coupons (a) before exposure to the environment and (b) after a 3-month exposure in a rural environment. (Courtesy of Battelle.)



(b)

FIGURE 23.18. (*Continued*)

A CLIMAT coupon with three copper rods installed at the NASA Kennedy Space Center (KSC) beach corrosion test site (Fig. 23.19) is shown immediately after it had been installed [Fig. 23.20(a)], after 30 days [Fig. 23.20(b)], and after 60 days [Fig. 23.20(c)]. KSC having the highest corrosivity of any test site in the continental United States [31], the mass loss recorded even after a shorter exposure than usual can be very high. In the present example it was already 16% of the original aluminum wire after 60 days. The base support of these CLIMATs were purposefully installed parallel to the sea coast, and the directional effect of the marine salts may be illustrated by comparing the front and back of the exposed CLIMATs [Fig. 23.21(a) and (b)].

E. ATMOSPHERIC CORROSION MODELS

One of the principal goals of scientific discovery is the development of a theory or model that can be used to provide explanations and predictions for a specific domain of knowledge. Theory development is a complex process involving three principal activities: theory formation, theory revision, and paradigm shift, as illustrated in Figure 23.22 [32]. A theory is first developed from a collection of known

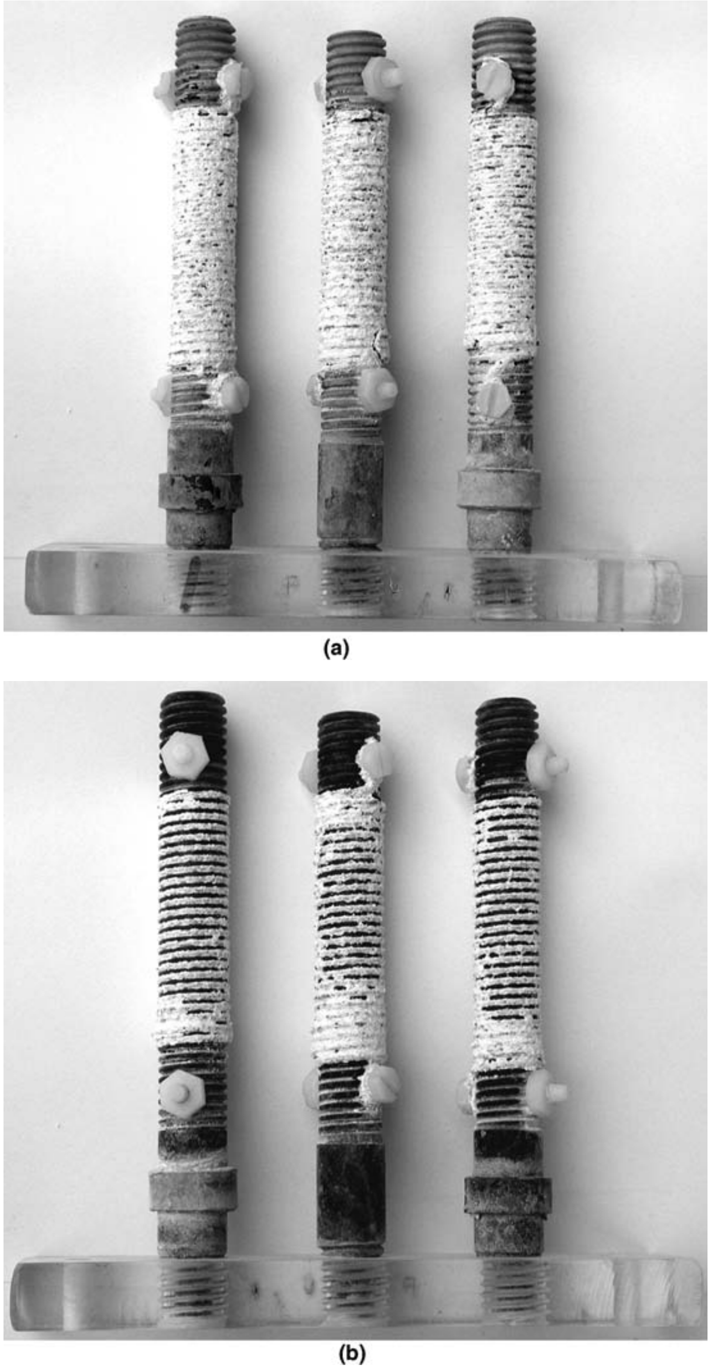

FIGURE 23.21. Close-up pictures of CLIMAT coupon exposed at KSC for 2 months: (a) seaside and (b) backside.

observations. It then goes through a series of revisions aimed at reducing the shortcomings of the initial model that are often realized when new facts and data become available.

The concept now universally accepted that rusting of iron and other metals in normal atmospheres requires the simultaneous presence of oxygen and water was seriously debated by scientists during the first decades of the twentieth century. Though the view presented by Dunstan in 1905 was supported by much experimental evidence, many still believed and argued then that the presence of carbon dioxide was required for an atmosphere to be really corrosive [33]. The first models to describe atmospheric corrosion processes and their rates were, however, proposed much later by W.H.J. Vernon following his extensive experimental work with

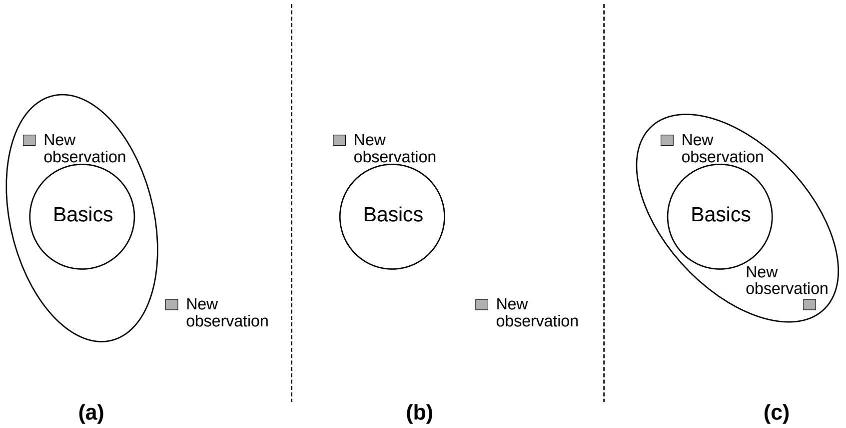

FIGURE 23.22. Theory revision using abduction for hypothesis formation.

copper [34] and iron [35] specimens that had been diligently exposed to various levels of sulfur dioxide, carbon dioxide, and suspended particles [36, 37].

E1. Statistical Models

E1.1. Corrosion Damage Functions. Corrosion damage functions for aluminum, zinc, and steel were developed based on experiments related to measuring the effects of acid rain during the 1980s [38]. The statistical model described in Eq. (23.4) was presented as a correlation of corrosion damage for aluminum and the environmental variables that were measured:

$$M = 0.206t^{0.987}(0.099 + 0.139f_{90}SO_2 + 0.0925Cl + 0.0164H^+ - 0.0013DUST) \quad (23.4)$$

where

- M = cumulative mass loss of aluminum per unit area, g/m^2
- t = time, years
- SO_2 = average SO_2 concentration, μg/m^3
- Cl = chloride deposition rate, mg/m^2 day
- H^+ = hydrogen ion deposition rate in precipitation, μeq/m^2 day
- f_{90} = fraction of time where relative humidity >90% and temperature >0°C
- DUST = dustfall deposition rate, mg/m^2 day

The reason for combining the time of wetness term, f_{90}, with the sulfur dioxide term, SO_2, in this equation is that sulfur dioxide requires a water film for absorption and will not deposit onto a dry surface.

E1.2. ISO Corrag. As mentioned previously, ISO technical committee TC 156 initiated a coupon exposure program that became known as ISO CORRAG. Exposures of flat plates and helixes of mild steel, copper, aluminum, and zinc involved 51 sites in mostly Europe and the United States. The program began in 1986 and ended in 1998. The relative humidity, temperature, salt deposition rate as measured by salt candles, and sulfur dioxide deposition rate as measured by sulfation plates were logged at each site. Statistical correlations between the environmental variables and corrosion rates for these metals have been developed [39, 40]. An example of the regression results for one-year log corrosion rates with aluminum plates are shown in Eq. (23.5):

$$\log(\text{rate}) = -0.739 + 3.26(\text{TOW}) + 5.02(SO_2) + 6.71(\text{Cl}) \quad (23.5)$$

where TOW is the time-of-wetness factor, SO_2 is the sulfation rate, and Cl is the chloride deposition rate. This expression was based on data from 32 sites and had an F statistic for regression of 5.9.

E1.3. International Cooperative Program on Effects on Materials. The International Cooperative Program on Effects on Materials (ICP Materials) was started in September 1987 and involved 39 exposure sites in 14 countries of Europe and North America. The meteorological variables recorded in the data set are listed in Table 23.4 [41]. The first approximation of a corrosion rate, K in Eq. (23.6), consisted of a linear summation of these three contributing factors [42]:

$$K = f(SO_2) + f(Cl^-) + f(H^+) \quad (23.6)$$

where $f(SO_2)$ is the sulfur dioxide factor, $f(Cl^-)$ is the chloride deposition factor, and $f(H^+)$ is a measure of the acidity of the rain. The sulfur dioxide factor was expanded by multiplying the concentration of sulfur dioxide by the TOW, as expressed in Eq. (23.7):

$$f(SO_2) = A(SO_2)^B(\text{TOW})^C \quad (23.7)$$

TABLE 23.4. Average Annual Ranges Used for ICP Materials Dose–Response Functions

Description	Range	Unit
Time	1–8	Year
Temperature	2–19	°C
Relative humidity	56–86	%
SO_2 concentration	1–83	$\mu g/m^{-3}$
Ozone concentration	14–82	$\mu g/m^{-3}$
Rainfall	33–215	cm
Acid concentration	0.6–130	$\mu g\ (H^+)\ L^{-1}$

The model fitting also revealed the complicated effect of temperature on atmospheric corrosion. In low-temperature regions, the corrosion rate increased with increasing mean temperature. In warm or hot regions a negative temperature effect was observed in the absence of chlorides, which is due to a reduced time of wetness. In marine atmospheres a positive temperature effect was observed also in warm/hot regions due to the presence of hygroscopic salts at the metal surface that prolong the TOW. As the temperature increased the corrosive effect of chloride, the corrosivity in tropical marine atmospheres with high deposition of chlorides can be extremely high.

E1.4. Iberoamerican Atmospheric Corrosion Map Project. The Iberoamerican Atmospheric Corrosion Map Project (MICAT—Mapa Iberoamericano de Corrosion Atmosferica) was initiated in 1988 with three objectives: (i) construct a corrosion map for Iberoamerica, (ii) provide a better understanding of atmospheric corrosion phenomena, and (iii) identify mathematical models that could predict the corrosion rate of metals as a function of meteorological and pollution variables [43, 44]. Plates of zinc, mild steel, aluminum, and copper were exposed. The environmental variables logged were relative humidity, temperature, number of rainy days per year, sulfur dioxide deposition rate, and chloride deposition rate. One approach was to assume that corrosion rate changes with time according to the parabolic relationship expressed in Eq. (23.8):

$$C = At^n \tag{23.8}$$

where C is the corrosion rate and t is time. The coefficients A and n were obtained by a statistically fit to the measured environmental variables. The regression equations accounted for 83, 62, 59 and 41% of the variance in the annual corrosion data for zinc, steel, aluminum, and copper, respectively. The goodness of fits of data from rural atmospheres was considerably lower. The same data sets were also analyzed with neural networks [45]. This later technique exhibited superior performance in terms of goodness of fit when compared to the classical regression models and reproduced some well-known nonlinear interactions among the variables of interest. The linear regression model obtained for the corrosion of iron is shown in Eq. (23.9):

$$\mathrm{Fe} = b_0 + \mathrm{Cl}^-(b_1 + b_2 \times P + b_3 \times \mathrm{RH}) + b_4 \times \mathrm{TOW} \times \mathrm{SO_2} \tag{23.9}$$

where $b_0 = 6.8124$, $b_1 = -1.6907$, $b_2 = 0.0004$, $b_3 = 0.0242$, and $b_4 = 2.2817$.

E1.5. Topographical Effects on Wind Velocity. Wind speed, wind direction, and distance from the sea are the most important factors influencing the transport and deposition rate of marine aerosols. A mapping method, based on grids with topographic factors, was developed to assess the influence of various factors on average wind speed at locations near a seacoast [46]. Basically, there are three steps in this method:

- Identify the topographic factors that can affect the flow of wind between a site of interest and the seacoast.
- Determine the topographic factors for each grid and then regress against measured wind speeds.
- Estimate the integrated sea wind for each site.

The concept integrates the geographical texture of the environment in all directions (16 sector resolution) with its effect on airflow. For example, the results of a multiple regression analysis for the annual average wind velocity for sites on the Miura Peninsula (Japan) are expressed in Eq. (23.10):

$$Y = 1.432x_1 + 0.002x_2 - 3.45x_3 - 0.058x_4 - 0.009x_5 - 0.34x_6 + 3.573 \tag{23.10}$$

where
Y = annual average wind velocity, m/s
x_1 = ratio of land to sea per unit area
x_2 = corrugation (effect of height variation within a grid)
x_3 = degree of shielding
x_4 = wind convergence over 2–7 km
x_5 = difference in wind direction
x_6 = wind convergence over 1–2 km

It is interesting to note the least significant factors in the regression analysis (low coefficients) are the corrugation and wind direction effects, possibly due to the presence of important local geographic features. However, the negative values give an indication of the reduction of wind velocity, due to shielding, convergence of wind, and the direction of the wind on the peninsula. The most significant factor affecting sea wind was the degree of shielding.

E2. Mechanistic Models of Corrosivity Factors

E2.1. Pollutant Mass Transfer to a Surface. In a study on the corrosion of plates of galvanized steel, the pollutant mass transfer rate to the plates was modeled as the product of the pollutant concentration and the deposition velocity. The deposition velocity was modeled from an analogy from momentum transport in Eq. (23.11) [47]:

$$u = \frac{V^{*2}}{V} \tag{23.11}$$

where u is the deposition velocity, V is the average upstream wind velocity, and V^* is the friction velocity. The friction velocity is itself described in Eq. (23.12):

$$V^* = \sqrt{\frac{f}{2}} \tag{23.12}$$

where f is the friction factor, which from boundary layer theory for smooth flat plates is defined in Eq. (23.13):

$$f = \frac{0.03}{(\mathrm{Re}_L)^{1/7}} \tag{23.13}$$

where Re_L is the Reynolds number for the plate as described in Eq. (23.14):

$$\mathrm{Re}_L = \frac{LV}{\nu} \tag{23.14}$$

where L is the length of surface over which the air flows and ν is the kinematic viscosity of air.

E2.2. Marine Aerosol Transport. A model was developed that accounted for a steady source of marine aerosol particles and their transport fairly near the ground, well within the planetary boundary layer. Aerosol particles were assumed to be transported by convection and turbulent diffusion, while they would be deposited on the ground by turbulent diffusion. The predicted aerosol concentration as a function of distance for 1500 m from a source was consistent with published data on steel corrosion and salinity rates near an ocean [48].

The chloride concentration as aerosol particles was modeled as a function of distance from a source such as a salt-water body [22]. The main assumption was that as wind carries chloride particles from the sea there is a deposition to the ground due to turbulent diffusion. This deposition rate is characterized by a deposition velocity, v_d. The deposition velocity depends upon particle size, ground surface roughness (open terrain, presence of vegetation, vertical projections such as hills, mountains, buildings, etc.), and wind speed. A mass balance of the chloride concentration within a height h above the ground at a distance x from a source of salt aerosols is described in Eq. (23.15):

$$S = S_0^{(-v_d x)/hV} \tag{23.15}$$

where

S = average concentration of chloride in air within a height h above the ground
S_0 = initial chloride conc. at shoreline
x = distance from shoreline
v_d = deposition velocity at ground
V = wind speed
h = height of air layer above ground

This equation was shown to be applicable for the first few hundred meters from a source, but other factors were found to greatly complicate the phenomenon as distance increases:

- The change of particle size distribution with distance as largest particles settle first and therefore changes in v_d.
- A nonuniform vertical profile of salt concentration.
- Decrease of wind speed with downwind distance caused by friction of the ground surface.
- The effect of rainout or even low cloud levels, which reduces the chloride present in the air, is not accounted for.

It was also noted in that study that a minimum wind speed or threshold of approximately 11 km/h is required for the entrainment of marine aerosols over a salt-water body [23].

E2.3. Corrosion under a Droplet. A detailed model of the corrosion processes within a droplet on a surface was developed [49]. The typical day and night cycle drives changes in condensation and evaporation on metallic surfaces. The model assumed the surface under the droplet functioned as an anode, and the surface at the droplet periphery functioned as a cathode. The effects of changing droplet size and electrolyte concentration at the limiting oxygen reduction current were simulated. The model predicted that there is no significant resistive control in an evaporating droplet under these conditions. However, in a condensate or absorbate of uniform thickness, resistive effects may become significant in layers less than 10 μm thick. In atmospheric corrosion, this has relevance with respect to repeated evaporation and condensation during wetting and drying, to the effects of rainwater washing and surface cleaning.

E2.4. Wind Speed Factor. In a study focused on the shielding effects of buildings in a marine environment, the directional impact of marine aerosols was revealed by comparing the level of patina on CLIMAT's copper rod exposed for three winter months at facilities on the Pacific coast [50, 51]. What

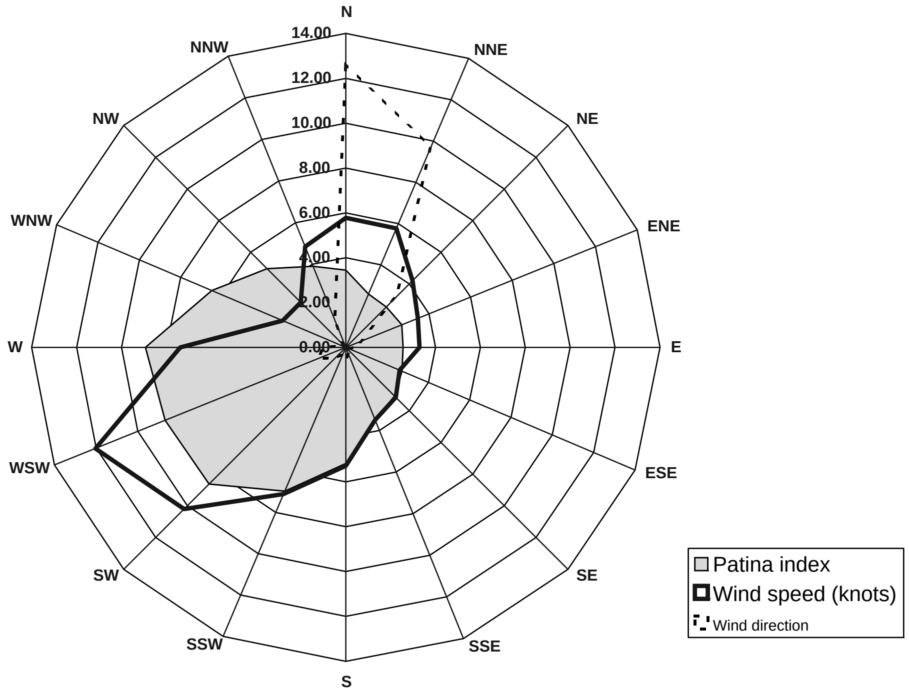

FIGURE 23.23. Average corrosion index for copper rods exposed on rooftop and average wind speed recorded at the local weather station as a function of 16 points of compass.

became evident in that study was that the pattern of the bluish-green patina attributed to the corrosion product $CuCl_2 \cdot 2H_2O$ was not uniformly distributed around the circumference of each copper rod.

A template with the 16 points of the compass was placed onto the outside of each copper rod that was on the most boldly exposed coupons in order to visually quantify the intensity of the bluish-green color. The relative degree of corrosion for each compass point was assessed by assigning a number between 0 and 10 with 0 corresponding to 0 bluish-green patina and 10 corresponding to 100% coverage of the colored corrosion product. The average corrosion index for each of the 16 points of the compass for the copper rods is shown in Figure 23.23.

One attempt to correlate the directional corrosivity observed on the copper rods with weather data was to plot the fraction of time that winds came from the 16 points of the compass during the 3-month exposure period. The dominant direction was the north to northeast. However, the pattern of corrosion product did not correspond to the most frequent wind direction but did correspond to the direction with the highest wind speeds, which were in the west-to-south quadrant at this particular site (Fig. 23.23).

E3. Maps of Atmospheric Corrosivity

Maps are powerful tools for communicating information related to geographical landscapes, and corrosivity maps of various countries have been drawn to illustrate the corrosion severity of regions of these countries [52]. One of the very first atmospheric corrosivity maps was produced to summarize many years of results obtained by exposing bare steel coupons attached to different vehicles in the northeastern United States and Canada (Fig. 23.24) [53]. The results presented in this figure reveal the corrosive effects of using deicing salts since this is the main factor that can explain the higher level of vehicle corrosion in the Snowbelt region when compared to adjacent nonmarine regions.

Similar corrosivity maps have been created from data available in the literature such as the corrosivity map for China (Fig. 23.25), Cuba (Fig. 23.26), and Great Britain (Fig. 23.27) adapted, respectively, from [54], [55], and [56].

F. PREVENTION AND CONTROL

The following sections contain a brief description of methods commonly used to prevent and control the damage due to atmospheric corrosion.

F1. Materials Selection

Only a few metals and alloys are usually boldly exposed to outdoor environments. Among these are all the bronzes and other copper alloys that have been used for centuries for the production of monuments and artifacts. The long life

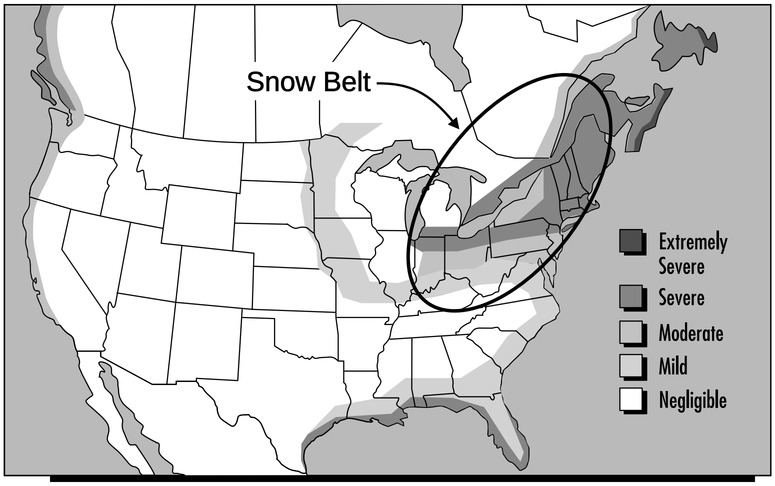

FIGURE 23.24. Corrosivity map of North America showing the particular aggressiveness of Snowbelt region.

provided by copper roofing is another example where the practical usage of such metal also produces a pleasant patina that has become the trademark of many touristic cities. However, most structural metals need some sort of shielding from direct contact with the environment. Aluminum, for example, will typically be anodized and often coated before being put in service. Similarly, steel is typically coated with protective coatings mostly based on organic coatings or galvanized for added protection. There are, of course, some exceptions to this general statement.

Iron, in its various forms, tends to be highly reactive because of its natural tendency to form iron oxide. When it does resist corrosion, it is due to the formation of a thin film of protective iron oxide on its surface by reaction with oxygen of the air. This film can prevent rusting in air at 99% RH, but a contaminant such as acid rain may destroy the effectiveness of the film and permit continued corrosion. Thicker films of iron oxide may act as protective coatings and, after the first year or so, could reduce the corrosion rate, as shown in Figure 23.28.

The Cor-ten high-strength low-alloy (HSLA) weathering steel in Figure 23.28 has shown to be more than 10 times corrosion resistant than carbon steel when freely exposed to mild environments [57]. This is why weathering steel has

FIGURE 23.25. Corrosivity map of China.

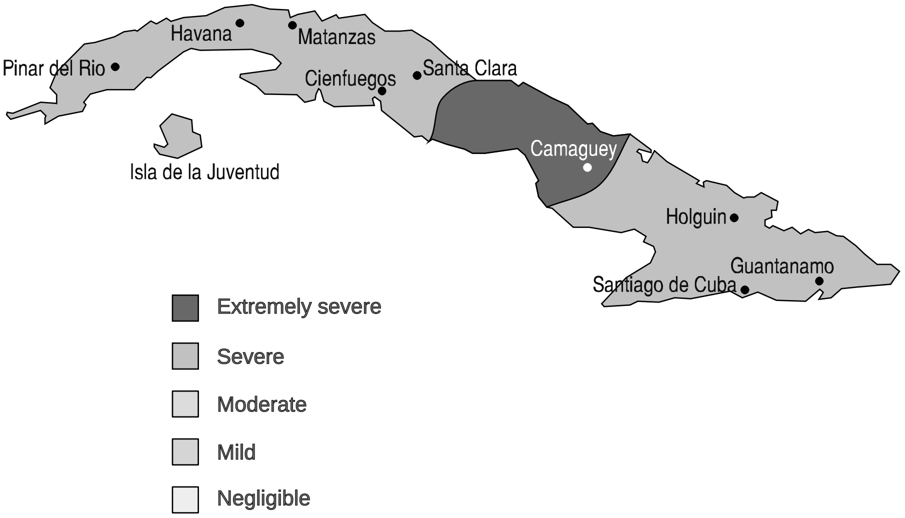

FIGURE 23.26. Corrosivity map of Cuba.

been the choice of many designers for the construction of boldly exposed surfaces, from buildings to utility poles (Fig. 23.29). The formation of a protective rust on weathering steels results from a combination of certain alloying elements, generally totaling <3%, which include Cr, Cu, Ni, Si, and P. Two commonly used weathering steels used for structural purposes are K11430 or Cor-ten B and K12043.

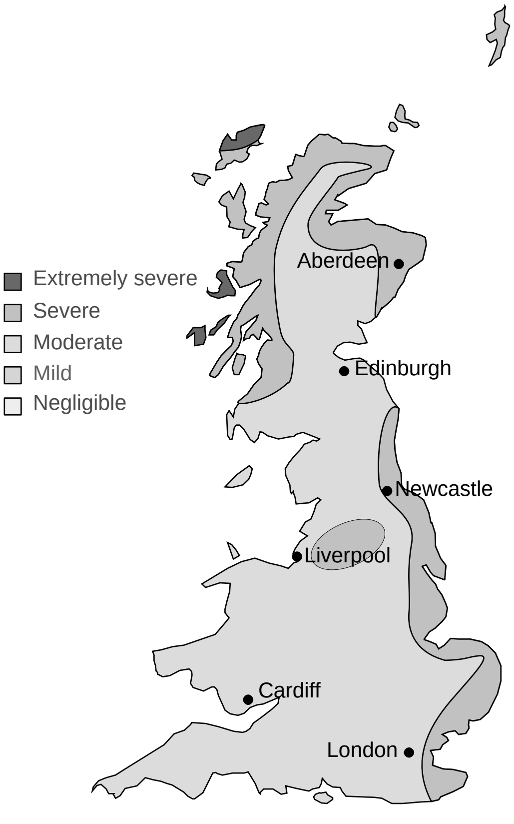

FIGURE 23.27. Corrosivity map of Great Britain.

The alloying additions also add strength to weathering steels, thereby enabling further cost and weight savings compared to ordinary structural steels. Regression analyses of long-term atmospheric corrosion tests of hundreds of steels that were conducted at 3 industrial environments lead to conclusions about the effects of 15 elements on corrosion resistance [58]:

- In order of decreasing effect, P, Si, Cr, C, Cu, Ni, Sn, and Mo are beneficial.
- S has a very large and detrimental effect.
- V, Mn, Al, Co, As, and W have no significant effect.

While weathering steels do not require any particular care once installed, it may suffer surprising corrosion attack in crevice areas. As the severity or the physical conditions of exposure change, these weathering steels will show less superiority. In crevices or on the backside of structural forms in a corrosive atmosphere, weathering steel will in fact not perform better than plain carbon steel.

Austenitic stainless steels have become the material of choice of many architects in recent history since they can keep their shiny aspect without tarnishing for many decades as illustrated in The Triad, a tall sculpture erected in the busy part of Toronto in 1984 (Fig. 23.30). Stainless steel has also been used to great advantages in more notorious buildings and monuments as early as 1930.

The Chrysler Building completed in New York City in 1930 was the first high-profile stainless steel application in the world. Type 302 stainless steel was used for the production of six rows of arches topped with a stainless steel spire. Stainless steel gargoyles were installed on the 31st and 61st floors. The present-day condition is estimated to be very good. The exterior of the Empire State Building, completed one year later (1931), was made of stainless steel, gray limestone, and dark gray aluminum. Over 300 metric tons

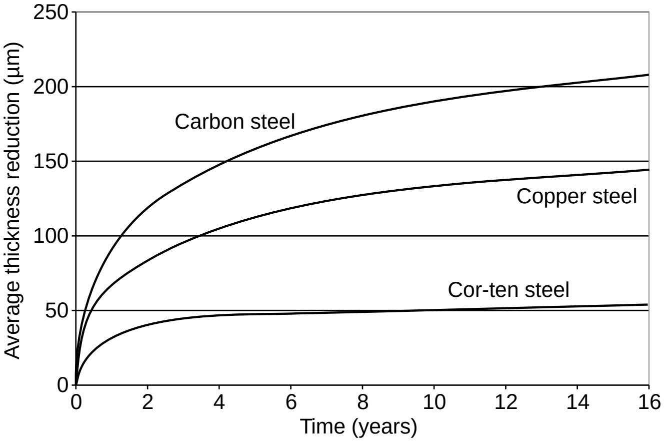

FIGURE 23.28. Time–corrosion curves of three steels in industrial atmosphere, Kearny, NJ: (1) ordinary steel, (2) Custeel, and (3) Cor-ten.

of 1.3-mm-thick Type 302 stainless steel was used for its construction. This historic landmark with a height of 282 m was the world's tallest building for 41 years. The stainless steel was estimated to be in excellent condition 70 years after the construction of this historical landmark. Many other buildings have since then incorporated large amounts of stainless steels in their facades and roofs.

F2. Protective Coatings

The large segment of the paint industry committed to the manufacture and application of products for the protection of metals, as well as the large-scale operations of the galvanizing industry, attest to the importance of controlling atmospheric corrosion. The general subject of protective coatings for the prevention and control of corrosion is the focus of many technical books and much beyond the scope of the present chapter in which only the breakdown of organic coatings exposed to the atmosphere will be discussed.

What happens when moisture and oxygen penetrate the coating? Perhaps nothing, if a truly good bond has been achieved, but a number of reactions may occur. Where the moisture contacts the steel, for example, a corrosion cell comparable to that in a pit on freely exposed iron may then develop. If ionic contaminants such as chlorides and other soluble salts are present at the interface between the coating and the steel, the electrolyte would be more conductive and thus favor a more vigorous cell action.

The rate at which diffusion of water and contaminants is occurring through a coating is largely controlled by its thickness and formulation. The thickness of a coating necessary to resist moisture permeation from the atmosphere and otherwise resist deterioration is approximately 125 μm. If good flowout is not obtained during application, thin spots (particularly at the edges) or actual holidays (holes) may exist in the film and reduce the effective thickness of the coating barrier.

Due to the presence of these imperfections in the coating, the steel substrate is directly exposed to its surroundings and may start corroding as described in Eq. (23.16). In order to maintain electroneutrality within the system, this reaction is balanced by at least one cathodic reaction. In most naturally occurring situations, this reaction will be the reduction of oxygen from ambient air, as illustrated in Eq. (23.17). These two reactions initially take place adjacent to each other but soon separate as the process continues with the cathode moving under the coating.

$$Fe_{(s)} \rightarrow Fe^{2+} + 2e^- \qquad (23.16)$$

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \qquad (23.17)$$

In given conditions of humidity and oxygen permeation, the initial corrosion site may begin to move in a random manner as the corrosion product reduces the oxygen content at the surface and the area becomes highly anodic to the surrounding cathode area of oxygen saturation. The worm track of corrosion that then occurs is termed filiform corrosion (Fig. 23.31).

The ferrous ions produced in Eq. (23.16) carry a positive charge, while the cathode is producing hydroxyl ions (OH^-), resulting in an excess of negative charge. These local charge imbalances are unstable. Additionally, the ferrous ions produced by the corrosion reaction in Eq. (23.16) are not stable in the presence of oxygen and soon react with water to form what is called rust, or $Fe(OH)_3$, following the combination of oxidation and hydrolysis reaction described in Eq. (23.18):

$$Fe^{2+} + 3H_2O \rightarrow Fe(OH)_3 + 3H^+ + 1e^- \qquad (23.18)$$

The electrons produced in Eq. (23.18) are also consumed by the reduction of oxygen. The path from the exposure environment to these initial corrosion sites may be either restricted or blocked completely when the coating adheres well to the substrate. In such cases the corrosion process would be relatively stifled after the initial attack.

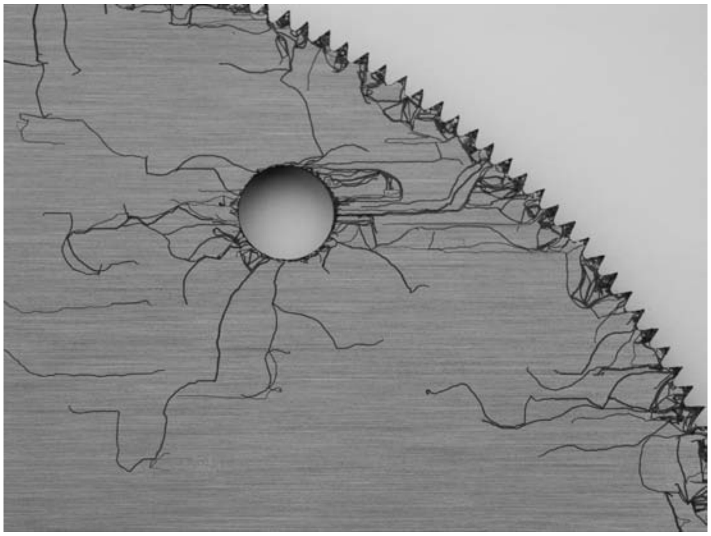

FIGURE 23.31. Filiform corrosion under lacquer protecting surface of new handsaw. (Courtesy Kingston Technical Software.)

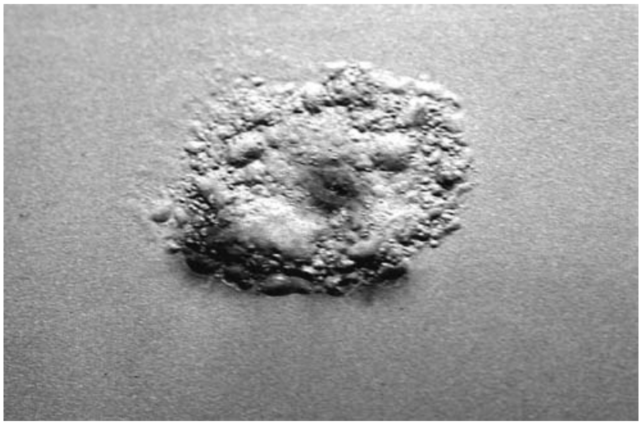

FIGURE 23.32. Corrosion blister formed on a car door months after impact caused break in coating. (Courtesy of Kingston Technical Software.)

For less adherent coatings, much less restrictive pathways such as micronic dust, coating porosity, and holidays are available for counter ions, and the corrosion reaction would be allowed to proceed at a much faster pace. When this happens, a second cathodic reaction may be triggered by the increased acidity at the anodic site, leading to the production of gaseous hydrogen as described in Eq. (23.19) and pry the coating loose (Fig. 23.32):

$$2H^+ + 2e^- \rightarrow H_2 \qquad (23.19)$$

Another aggravating factor is that organic coatings are generally poorly resistant to alkaline conditions and may be attacked by the hydroxyl ion, causing a serious loss of surface adhesion. The reason this alkalinity causes such failure has been variously attributed to either saponification of the coating, dissolution of the oxide layer at the interface, or simply alteration of the ionic resistance of the film [59]. External cathodic currents provided by cathodic protection or internal currents produced by inorganic zinc additives during immersion service, for example, would increase the possibility of failure by the hydrogen or hydroxyl formation because much greater quantities of these cathodic reaction products would be created.

F3. Dehumidification

Corrosion may also be prevented or controlled by modification of the corrosive environment. One method commonly used consists in reducing the water content of the environment by dehumidification to prevent the formation of a continuous film of moisture on metal surfaces. There are a number of different types of dehumidification systems available, and each proposed installation needs to be assessed to determine the most suitable type. Where the item to be protected is in a vapor-sealed enclosure, desiccant beads such as silica gel may be used successfully. However, if external air is allowed to enter, then the moisture load will soon exceed a desiccant capacity. More efficient dehumidification methods will therefore be required as the complexity and size of the applications increase.

Dehumidification by heating works on the principle that if the air within an enclosed space is heated, then the relative humidity of the air will be reduced. In order for this method to be fully effective, all items in the space, as well as the air itself, need to be heated as humid zones may occur at cold spots on metal surfaces.

Another method commonly employed is the reduction of moisture by passing air through an evaporator coil where it is cooled below its dew point, forcing water to condense on the outside of the coil from where it is drained. The air is then often heated back to ambient temperature. However, cooling to very low temperature makes the refrigeration process impractical, as it requires a great deal of subsequent reheating. The reduction in air temperature is also limited by the freezing point of water condensing on the cooling coil, which in some designs may be offset by the use of a complicated brine spray or a liquid lithium chloride type of system that works on a combination of refrigeration and adsorbent liquid.

The static or dynamic use of desiccants through absorption or adsorption processes also provides a wide spectrum of dehumidification techniques. In the case of absorption processes, desiccants change physically, chemically, or both during the sorption process. Lithium chloride crystals are an example of a solid absorbent. When water is absorbed by this material, it changes to a hydrated state. In liquid sorption dehumidification systems, air is passed through sprays of a liquid sorbent such as lithium chloride or glycol solution. The sorbent in an active state has a vapor pressure below that of the air to be dehumidified and absorbs moisture from the airstream. The desiccant solution, which becomes diluted with moisture during the process of absorption, is regenerated when the solution is subsequently heated.

In the case of adsorption processes the desiccant does not change physically or chemically during the sorption process. Adsorbents such as silica gel, molecular sieve, and activated alumina are normally granular beads or solids with porous structures making these capable of holding large amounts of water on their surface. The principle behind desiccant dehumidification is that the desiccant is exposed to moisture-laden air, from which moisture is extracted. During regeneration, the saturated desiccant is heated and the collected moisture is driven off into the exhaust airstream. Thus a continuous cycle of sorption and regeneration can be set up providing an atmosphere with very low dew point.

F4. Corrosion Prevention Compounds

Corrosion prevention compounds (CPCs) are widely used as a temporary measure to provide cost-effective corrosion

FIGURE 23.33. Fogging of aircraft with commercial CPC. (Courtesy Mike Dahlager Pacific Corrosion Control Corp.)

protection on most metals. CPCs are applied as fluids by wiping, brushing, spraying, or dipping. These compounds are usually immiscible with water but may contain some water displacing components to remove water from surfaces and crevices.

Corrosion prevention compounds are commercially available in a wide range of products. A number of these fluids are based on lanolin and contain various solvents and inhibitors. The evaporation of the solvents leaves either thin soft films, semihard films, or hard resin films that provide varying degrees of short-term protection. The exact compositions of these CPCs are not published for obvious reasons. However, information contained in the Materials Safety Data Sheets (MSDSs) reveal that they may include [60]:

- An oil, grease, or resin-based film former
- A volatile, low surface tension carrier solvent
- A nonvolatile hydrophobic additive
- Various corrosion inhibitors, for example, sulphonates, or surface-active agents

Water-displacing CPCs act by spreading across surfaces, into cracks and crevices where they displace moisture, leaving behind a residue to act as a further barrier after the carrier solvent has evaporated. The hard film CPCs dry to a waxy or hard resinlike finish after application and provide a barrier film to corrosive environments.

Corrosion prevention compounds have been used in many applications where corrosion is a concern. In the aircraft industry, for example, these products are often recommended by the manufacturer in the maintenance manuals as a way to help prevent the onset of corrosion in specific aircraft locations. The application of a CPC is relatively easy by using specially designed high-pressure pump systems to convert it into a dense fog and literally fog the area or cavity that needs protection (Fig. 23.33).

These products are also extensively used on road vehicles to reduce the severity of corrosion, particularly in cold-weather areas where deicing salts are used to break down snow and ice. There are plenty of locations in road vehicles where water can accumulate and accelerate corrosion, leading to premature failure of the equipment or perforation of the sheet metal. The underside of cars is especially vulnerable to rust and corrosion due to the exposure to high levels of moisture.

Since the 1970s, hot-melt wax thermoplastic CPCs have been used extensively during the construction of new vehicles to protect underbody structural components against corrosion and enhance vehicle durability. Hot-melt waxes are usually applied through a dipping process. The wax is preheated to a temperature between 125 and 195°C. Following an alkali cleaning and water rinsing operation, parts are immersed in the molten wax. The thickness of the wax deposited on the parts is controlled through a preheat of the parts prior to dipping and the actual time of immersion in the hot-melt wax.

Thin fluid film CPCs are typically used on road vehicles as a yearly maintenance application for added corrosion protection. The CPC treatment using air-powered spray units is relatively inexpensive and can be provided by various rust-proofing centers (Fig. 23.34). No particular preparation is required. For outdoor spraying a NIOSH-approved oil mist mask, as worn when spraying indoors, is recommended. Gloves are worn for comfort, as the aerosol cans or air-powered spray guns quickly get cold. After treatment, any excess fluid may be wiped up with a cloth or paper towel.

F5. Volatile Corrosion Inhibitors

Volatile corrosion inhibitors (VCIs), also called vapor-phase inhibitors (VPIs) are used in close environments where they saturate the ambient atmosphere. In boilers, volatile basic compounds, such as morpholine or hydrazine, are transported with steam to prevent corrosion in condenser tubes by neutralizing acidic carbon dioxide or by shifting surface pH toward less acidic and corrosive values. In closed vapor spaces, such as shipping containers, volatile solids such as salts of dicyclohexylamine, cyclohexylamine, and hexamethylene-amine are used. On contact with the metal surface, the vapor of these salts condenses and reacts with moisture to provide protective ions.

It is desirable, for an efficient VCI, to provide inhibition rapidly and to last for long periods. Both qualities depend on the volatility of these compounds, fast action wanting high volatility, whereas enduring protection requires low volatility. A convenient partial vapor pressure for closed spaces VCIs will lie between 10^{-3} and 10 Pa (Table 23.5) [61].

It is significant that the most effective volatile corrosion inhibitors are the products of the reaction of a weak volatile base with a weak volatile acid. Such substances, although ionized in aqueous solutions, undergo substantial hydrolysis, the extent of which is almost independent of concentration. In the case of the amine nitrites and amine carboxylates, the net result may be expressed by the following reaction:

$$H_2O + R_2NH_2NO_2 \rightarrow (R_2NH_2)^+ : OH^- + H^+ : (NO_2^-) \tag{23.20}$$

The nature of the adsorbed film formed at a metal–water interface is an important factor controlling the efficiency of VCIs. Metal surfaces exposed to vapors from VCIs in closed

TABLE 23.5. Saturated Vapor Pressures of Some VCIs

Substance	Temperature (°C)	Vapor Pressure (mm Hg)	Vapor Pressure (Pa)	Melting Point (°C)
Morpholine	20	8.0	1070	
Benzylamine	29	1.0	130	
Cyclohexylamine carbonate	25.3	0.397	53	
Diisopropylamine nitrite	21	4.84×10^{-3}	0.65	139
Morpholine nitrite	21	3×10^{-3}	0.40	
Dicyclohexylamine nitrite	21	1.3×10^{-4}	0.017	179
Cyclohexylamine benzoate	21	8×10^{-5}	0.010	
Dicyclohexylamine caprylate	21	5.5×10^{-4}	0.073	
Guanadine chromate	21	1×10^{-5}	0.0013	
Hexamethyleneimine benzoate	41	8×10^{-4}	0.110	64
Hexamethyleneamine nitrobenzoate	41	1×10^{-6}	0.00013	136
Dicyclohexylamine benzoate	41	1.2×10^{-6}	0.00016	210

containers typically become covered by a hydrophobic-adsorbed layer as evidenced by an increase of the contact angle of distilled water on treated surfaces with time of exposure.

A. INTRODUCTION

Atmospheric corrosion is an electrochemical process, and moisture must be present on the corroding surface for it to proceed. This can be in the form of a visible liquid layer (rain, dew) or as a thin film formed by condensation at the surface. It has been accepted that such moisture films can form at critical relative humidities, which are determined by the nature of the corroding surface and the chemical species that are present on it. The time that a surface remains "wet" by either of these processes has been defined as the time of wetness (TOW) in the International Standard on Corrosivity of Atmospheres ISO 9223 [1], and it is the critical factor in determining the extent of atmospheric corrosion, together with die presence of pollutants that can be natural (e.g., airborne sea salt) or man-made (SO_x, NO_x). The ISO standard also uses the length of time when the relative humidity exceeds 80% at a temperature greater than 0°C as an estimate of TOW. However, evidence gathered by several researchers in coastal regions of the Antarctic continent has shown this definition to be inadequate.

There has been a common assumption that there is no corrosion in Antarctica because of the "dry cold," and this myth has persisted even among people with Antarctic experience. Remarkable preservation of metal can be observed in Antarctica, and the excavation of uncorroded metal artifacts from the ice inside the Scott expedition huts in New Zealands's Ross Dependency in the early 1960s probably reinforced the myth. Removal of the ice and snow radically changed the microenvironment and resulted in rapid corrosion of metal items [2]. Notwithstanding the low temperatures, the environment at several historic Antarctic sites was perceived to be severely corrosive and erosive, with very strong winds frequently blowing salt-laden snow off the sea ice and depositing it on huts and equipment. Measurements of corrosivity were made at Cape Evans (the site of Scott's hut) using a standard copper-bearing steel, and the result of 10.8 μm/year (0.43 mil/year) was much higher than expected, considering the site is 77°S, is surrounded by sea ice for 10 months of the year, and has air temperatures rarely above 0°C [3]. At nearby Scott Base (Ross Island), the mean monthly temperature for the coldest month (July) is −29°C, for the warmest month (January) is −5°C, and annually it is −20°C. The precipitation is 150–200 mm of water equiv/year [3].

The myth that corrosion in very cold regions is always low is dispelled. This chapter discusses issues relating to cold climate corrosivity and gives references to studies conducted in these regions.

B. INFLUENCE OF TEMPERATURE AND SOLUBLE SALTS

Experimental and theoretical work in the former Soviet Union [4] demonstrated that no significant reduction in corrosion rates occurs until the temperature falls below $-25°C$; it then falls sharply and approaches zero at $-45°C$. This was attributed to a retardation of the electrochemical processes at the surface. Laboratory studies in Canada [5] using the potential developed between platinum and zinc electrodes to indicate the presence of an electrolyte showed measured potentials at $-20°C$, and the conclusion drawn was that there was no freezing point at which corrosion would cease. Furthermore, as discussed above, salt deposition is significant in coastal regions of Antarctica. Rain is very rare and wind-deposited salt is not washed off surfaces. The phenomenon of depression of the freezing point of salt solutions is well established [6], and with appropriate salt compositions involving chlorides of calcium and sodium, the freezing point could be depressed to as low as $-50°C$. Given the salt deposition regime in coastal regions of the Arctic/Antarctic and the absence of rain washing, a scenario of a saturated salt solution at the surface is definitely feasible in such environments. It is possible also that the long hours of sunlight in the polar summers could raise the surface temperature of dark objects considerably above the surrounding air temperatures, but this temperature rise is inadequate to totally volatilize the electrolyte layer.

C. DEFINITION OF COLD CLIMATE REGIONS

The issue of defining which geographic regions of the world have climates with low temperatures that can significantly influence corrosivity has been addressed by Perrigo et al. [7, 8]. They state that the regions designated Arctic and Antarctic above and below $66°33'$ latitude norm and south do not cover this adequately. Neither does the inclusion of the subarctic and subantarctic defined by some as the regions between 60° latitude and the polar circles. In the Northern Hemisphere, Perrigo suggests two regions defined by the U.S. Army Cold Regions Research and Engineering Laboratory (CRREL) [9] in which the average temperature of the coldest winter month is $-18°C$ or less, or between 0 and $-18°C$. Nonetheless, part of these regions can have "normal" summer temperatures (>20°C) and rainfall, and at these times corrosion proceeds unchecked.

In the Southern Hemisphere, Perrigo has similarly identified two global lines to define the limits of cold climates. The northern most is an isotherm where the mean temperature of the warmest month is 10°C (50°F) [7], and to the south is the Polar Front (previously known as the Antarctic Convergence [10]), which is a temperature boundary between the near-freezing waters surrounding Antarctica and the warmer waters of the subantarctic. Only the southern tip of the South American continent, the subantarctic islands, and of course Antarctica itself fall within these regions. Heginbottom et al. draw attention to the distribution of permafrost [11] as being another indicator of a cold climate and a factor that will significantly influence cold climate corrosion.

D. ARCTIC CLIMATE AND CORROSIVITY STUDIES

The general pattern of corrosivity in the regions traditionally designated as the Arctic and subarctic can be expected to differ from the cold regions in the Southern Hemisphere, namely, the Antarctic and subantarctic, since the Arctic comprises continental land masses surrounding the North Pole, which is in the middle of the Arctic Ocean and in summer has large areas of open water. Subarctic regions include prairies and forests that can be expected to have low corrosivity, but there are also areas with substantial industrial and mining activity in North America, Scandinavia, and Russia, where higher corrosivity will occur. There are many islands and coastal regions with maritime climates (e.g., Aleutian Islands and Alaska) where marine salts will influence corrosivity. Extensive use is made of deicing salts in North American and Scandinavian cities, which have a profound local effect on corrosivity.

A Canadian site, Norman Wells, some 450 km from the sea in the Northwest Territories has been a benchmark for a site with low corrosivity. The 1-year corrosion rate of cold rolled steel was measured as part of ongoing American Society for Testing and Materials (ASTM) programs and the average rate (for 6 years) was 0.7 μm/year (0.03 mil/year) [12]. This is a surprisingly low result considering that the mean monthly temperature ranges from $+6$ to $+16°C$ for 5 months of the year with significant summer precipitation and relative humidity (RH) consistently >85% [13].

Divine and Perrigo [14] exposed a range of metals in Anchorage, Alaska, and report a 1-year corrosion rate for carbon steel of 8.1 μm/year (0.32 mil/year). Biefer [15] exposed mild steel wire-on-nylon bolt specimens for a period of 1 year at sites in the Canadian Arctic and subarctic. Corrosion rates as low as 2–5 μm/year (0.08–0.2 mil/year) were obtained at 10 inland sites on the mainland of the western Arctic and the northwest Arctic Islands. At 7 other northern sites, usually within 1 km of the sea, corrosion rates ranged from 21 to 34 μm/year (0.83–1.34 mils/year), comparable to rates measured in southern Canada.

Mikhailov et al. [16] studied corrosivity in eastern Siberia including severe cold climates both on the coast (annual temperatures -6 to $-13°C$) and inland (-11 to

$-17°C$). They provided corrosivity data for carbon steel and zinc for 29 sites, and this was correlated against TOW, annual average temperatures and relative humidities, and atmospheric pollutants (SO_2, Cl^-). Measured steel corrosion rates ranged from 0.7 to 32 µm/year (0.03–1.26 mils/year). Thirteen references are provided.

There have been a number of studies in Scandinavia concerned with the classification of corrosivity. Kucera et al. [17] exposed specimens of steel and zinc at 32 sites, of which all but one were described as being in a temperate climatic zone. The subarctic station with a yearly average temperature of 1.3°C showed a steel corrosion rate of 6 µm/year (0.24 mil/year). Hakkarainen and Yläsaari [18] measured corrosion with steel and zinc at five sites in southern Finland and correlated the data with TOW and SO_2 levels. Corrosion rates of steel were from 20 to 50 µm/year (0.79–1.97 mils/year). In Norway, a series of exposure programs was reviewed by Atteraas and Haagenrud [19]. Materials included steels, zinc, and aluminum exposed at up to 38 sites mostly close to the coast Measured corrosion rates were generally quite high (e.g., for carbon steel 1-year exposure 17–70 µm/year) (0.67–2.76 mils/year). Seventeen references were provided.

E. SUBANTARCTTC CLIMATIC VARIATION AND CORROSIVITY

Isolated subantarctic islands surround the Antarctic continent. Subantarctic climates are very different from those of Antarctica itself. Characteristically, temperatures are cool, with summer temperatures rarely above $+10°C$ and winter temperatures rarely below 0°C. Formation of sea ice is rare. Winds are characteristically gusty and strong. Being isolated by long sea distances from any industrial activity, pollution is very low. All of the islands have historic sites, and metal artifacts show extensive corrosion. Macquarie Island (an Australian territory at latitude 54°S) was the subject of a small survey (6 sites) to obtain corrosivity data that could assist in conservation measures [20]. The environment is severe marine with annual rainfall of 901 mm, and mean relative humidity at 0900 h is 85–90% throughout the year [21]. Standard low-alloy copper-bearing steel coupons were used, and 1-year corrosion rates were found to be on average 122 µm/year (4.80 mils/year), with a maximum rate of 219 µm/year (8.62 mils/year). Twenty-two references are provided.

F. ANTARCTIC CLIMATE AND CORROSIVITY STUDIES

Corrosion studies conducted in Antarctica and aspects of the Antarctic climate have been reviewed in a paper that also describes a corrosivity survey conducted at nine sites on the continent, including the South Pole [22], Thirty-nine references were provided.

The Antarctic is generally characterized by severe cold, with average temperatures in summer being significantly lower than those in the Arctic [10]. The Antarctic Peninsula is the warmest region of continental Antarctica, but summer air temperatures are still rarely above $+5°C$. Summer temperatures in the high Arctic are considerably warmer and can exceed $+20°C$, and dwarf Arctic willow trees grow even at 75°N. Antarctic climates are so cold that there are no trees and even grass only grows in the warmest parts of the Antarctic Peninsula.

The authors of the review recognized that standardized measurements of corrosivity could assist in conservation strategies at historic sites, and clarification was needed to establish why corrosion rates are higher than expected given presumed low TOWs. The 1-year corrosion rate of low-alloy copper steel showed an exceptional range from 27.1 µm/year (1.07 mils/year) at Rothera (Antarctic Peninsula, 67°34′S, on the coast) to 3.4 µm/year (0.13 mil/year) at Mawson (67°36′S, on the coast), 0.87 µm/year (0.03 mil/year) at Vanda (77°35′S, 80 km from the coast [3]), and 0.05 µm/year (0.002 mil/year) at Vostok (78°28′S, 1200 km from the coast). This variation on the Antarctic continent itself represents a factor >500. The influence of TOW, salt deposition, and wind direction on the results was discussed.

Mikhailov et al. [23] studied the corrosion of steel, copper, cadmium, and an aluminum alloy at a Russian coastal station, Mirnyi (66°33′S). A corrosion rate for steel of 7.7 µm/year (0.30 mil/year) was measured and described as comparable with the rate on Ayon Island in the Russian Far East (above the Arctic Circle) and an order of magnitude higher than the corrosion rates measured at two other Russian sites, namely Bilibino and Oimyakon [24]. Climatic parameters and salt levels were measured and the ISO TOW was only 93 h/year in contrast to the range described in the standard [1] of 250–2500 h/year (category τ_3) for dry cold climates and some temperate climates. The authors concluded that in the presence of airborne sea salt, corrosion could proceed at temperatures significantly lower than $-1°C$.

Fahy [25] studied corrosion of aluminum coupons with different surface treatments including mill and anodized finishes. He experienced problems with conducting the exposures since he was unable to travel to Antarctica himself, and some plates were exposed next to diesel generators at Scott Base and pollutants affected results. Exposures were later repeated at unpolluted Arrival Heights that resulted in considerably less pitting of sample coupons.

Rievero et al. [26] used Mössbauer spectroscopy to study the corrosion products on low-alloy steel exposed at a Uruguayan Antarctic island site (Artigas, 62°10′S). The

mean temperatures for the coldest month, hottest month, and annual were, respectively, −6.4, 2.2, and −2.3°C, and steel corrosion rates (1 year) were 40–66 μm/year (1.57–2.60 mils/year).

Resales et al. [27] measured corrosion rates for steel, zinc, copper, and aluminum at Jubany, an Argentinean Antarctic base. The TOW was directly measured using Pd/Ag electrodes on an alumina substrate and compared with the ISO-estimated TOW using climatic data. High corrosion rates were measured for all metals (steel 1-year rates, 36–41 μm/year) (1.42–1.61 mils/year) and measured TOW (always higher than the ISO estimate) was 24 h/day continuously for 7 months of the year. The minimum values in the coldest months (−3°C) still gave a daily mean TOW of 6 h. The authors concluded that in the presence of marine salt, liquid water monolayers could form under ice layers resulting in high corrosion rates at temperatures well below 0°C

G. CONCLUSIONS

Extensive evidence has now shown that atmospheric corrosion rates can be high in cold regions of the world especially in proximity to the sea. Whereas very low corrosion rates can occur in cold continental climates (especially inland Antarctica), in coastal regions the influence of chloride ion from marine sea salt can enable liquid layers to form at temperatures well below 0°C and corrosion proceeds unimpeded. Actual surface temperature in conjunction with the presence of chloride ion determines the rates of corrosion.

A. INTRODUCTION

In the original Uhlig *Corrosion Handbook*, Logan [1] was given the task of describing the state of knowledge regarding the corrosion of metals in soils. Much of the data presented in this study remains pertinent today. Other useful references include Starkey and Wight [2], Booth et al. [3–5] and Flitton and Escalante [6]. Romanoff [7] describes a National Bureau of Standards study in which 37,000 specimens were exposed to 95 types of soil for exposure periods of up to 17 years! Specimens included ferrous and nonferrous metals as well as a selection of coating materials. In 1979, Escalante [8] edited an Amercican Society for Testing and Materials (ASTM) symposium that focused on underground corrosion. Specific articles covered soil surveys, soil corrosivity, soil testing, and mitigation of corrosion in soils. The ASTM *Corrosion and Standards: Application and Interpretation* [9] handbook also contains several sections related to corrosion in soil.

The reason for the abundance of reference material in this area is the economic significance of material degradation in soils. The method of choice for transportation of water, natural gas, oil, and refined hydrocarbons remains that of buried pipelines. In Canada, there are ~580,000 km of buried pipelines, which contribute billions of dollars to the economy. In the United States there are about 2 million km of buried natural gas pipeline and ~280,000 km of petroleum products pipelines. The replacement value for such facilities represents billions of dollars. This mode of transportation remains by far the safest way to ship oil and gas, but deterioration of line pipe steels whether as the result of external corrosion or environmentally assisted cracking

(EAC) can result in failures [10]. Concern over failures has resulted in the development of new direct assessment protocols for external corrosion [11] and stress corrosion cracking [12] that depend in part on characterization of the soil environment [13].

Traditionally, discussions of soil corrosivity have been based on studies where materials including steel were placed in direct contact with the soil environment. Easily measured characteristics such as soil resistivity or moisture content were then correlated with the occurrence of material degradation problems. Such general correlations continue to provide guidance for materials selection, location of structures, route selection, and overall system design but are often too general to allow the accurate prediction or interpretation of damage in specific sites. Soil is a complex material and the many parameters, which affect corrosion by soils, are still not fully understood. Simple models based on the general interpretation of two or three parameters that ignore the specifics of a given situation are not likely to provide a satisfactory explanation of corrosion and EAC processes at specific sites [11, 12]. More sophisticated models are under development. Figure 25.1 shows two scenarios that provide a framework for discussion in this chapter.

Figure 25.1(a) shows the case where a buried steel pipe is in direct contact with the soil environment. The overall system includes the exchange of soil gas with the overlying atmosphere as well as the potential influx of surface water and precipitation to the water table through the unsaturated soil zone. In the unsaturated zone, gas forms the continuous phase between particles in the soil matrix. In Figure 25.1(a), the buried pipe lies partly above the local water table. The steel surface in the unsaturated zone may see a different environment than that lying in the water-saturated soil. Disturbed soil around the buried structure may also lead to a unique environment at the steel surface [6].

Both corrosion and EAC involve local electrochemical processes sustained by a water phase acting as an electrolyte at the metal surface. Soil sets the stage for these processes by controlling the access of agents such as atmospheric oxygen to the steel surface, fostering biological activity, or otherwise altering the chemical composition of the water phase in contact with the metal.

Figure 25.1(b) shows a second situation where the buried steel is shielded from the soil environment by a protective coating or rock shield. Where a protective coating remains effective, corrosion or EAC problems do not occur; however, in situations where water reaches the steel surface, attack on the metal can proceed. In this situation, changes in composition due to Corrosion, microbial activity, cathodic protection, or the incursion of O_2 or CO_2 [14–16] can significantly alter the chemistry of the trapped water.

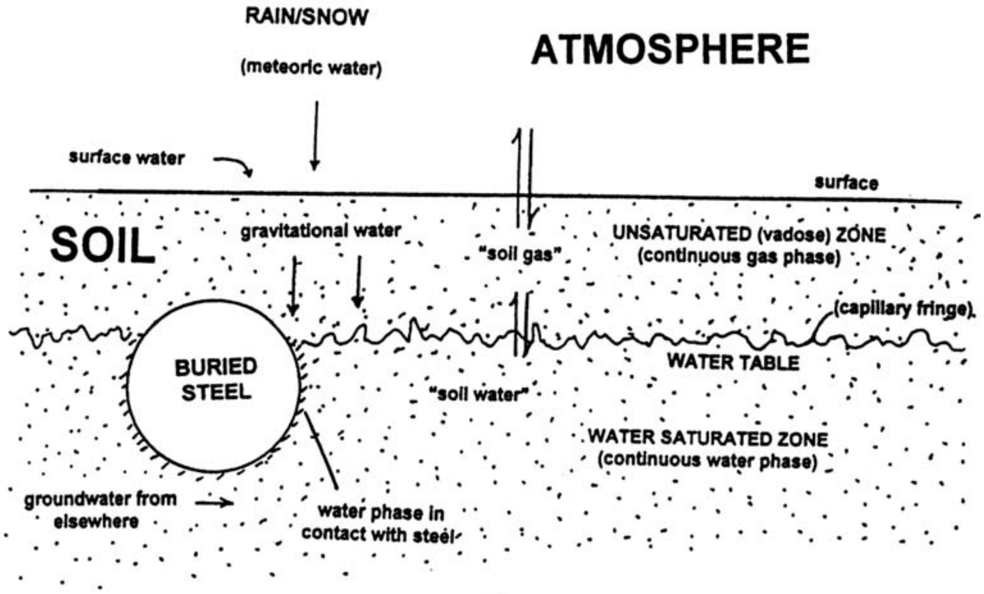
Cathodic protection is routinely used to protect buried steel structures [17]. This involves installation of a system to impress a negative electrical charge on the steel surface, effectively preventing dissolution of the metal for thermodynamic reasons. Application of cathodic protection to the two scenarios shown in Figures 25.1(a and b) can lead to different effects. Where bare steel is exposed directly to the soil environment, Figure 25.1(a), protection potentials can be achieved by a properly designed and maintained cathodic protection system. Where effective potentials are not achieved or maintained, corrosion can proceed according to the corrosivity of the local soil environment at pipe depth. Corrosion cells can develop where bare pipe passes through saturated and unsaturated soil zones along its length or where different parts of the pipe surface lie in different soil environments. For the situation shown in Figure 25.1(a), corrosion could result from a differential aeration cell between the top and the bottom of the pipe due to the difference in water saturation of the soil matrix. For steel surfaces exposed to water under disbonded coating, Figure 25.1(b), a very different scenario occurs. If the disbonded coating remains electrically insulating, the underlying pipe surface can be shielded from cathodic protection (CP). Where effective CP potentials are not achieved, corrosion and environmentally assisted cracking (notably stress corrosion cracking) can proceed [18, 19]. Unfortunately, shielding disbondments have proven difficult to detect by surface inspection methods that depend on anomalies in current or potential to identify coating damage [20, 21].

The development of risk models to improve the long-term maintenance of buried structures is an area that has advanced significantly as integrity management plans become a required element for operating pipeline companies.

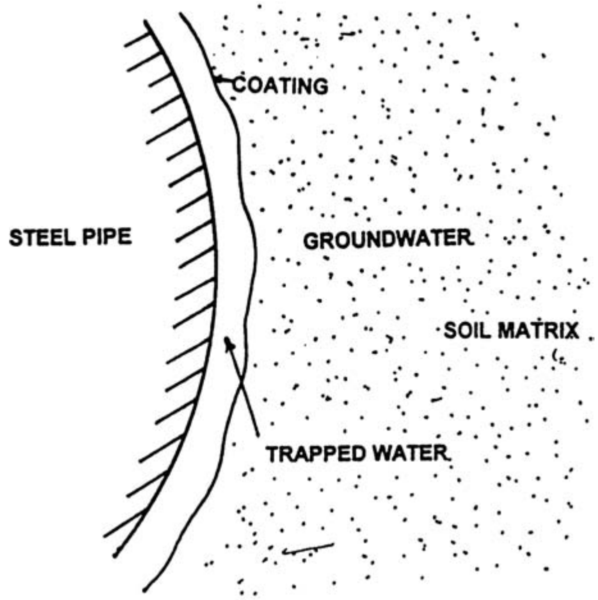
B. WHAT IS SOIL?

Various schemes have been proposed to categorize soils, but no single scheme spans the diversity of soil environments seen by buried metal structures. Muskegs, peat bogs, and swamps consist primarily of water-saturated decaying organic matter mixed with minor amounts of inorganic material. Thus peat bogs are typically 95% water with more than 17% of the dry weight being carbon [22]. Soils with 20% or more organic content such as those found in the Florida everglades are classed as histosols [23]. In contrast other soils are almost devoid of humic or organic matter, consisting largely of inorganic materials broken and weathered to various particle sizes. The organic matter in a highly weathered sandy soil is only ~0.5%, while poorly drained prairie soils contain ~6% organic matter [23]. Soluble salts precipitated from ancient lakes or oceans dominate the behavior of evaporites. Such large variations in soil environments can support a wide range of potential corrosion mechanisms and influence rates in various ways.

Soils are an admixture of rock disintegrated by physical action and modified by weathering (clastic sediments),



(a)



(b)

FIGURE 25.1. (a). Exposure of buried line pipe to soil environment. (b). Failure of protective coating can allow water to reach metal surface. Water trapped beneath the coating can develop a composition which is different than groundwater.

materials precipitated chemically from aqueous solution (nonclastic sediments and evaporites), and organic matter (humus). Relative proportions depend on the specific history of soil formation in a location. As much as one half of the volume of a dry soil can be made up of pore spaces between particles. This space is shared by interstitial water and soil gas. Some water is tightly associated with mineral surfaces and cannot be readily removed. Bulk water can flow through the porous matrix as a continuous phase in water-saturated zones and by drainage in unsaturated ones, Figure 25.1(a). In comparison, gas diffuses through unsaturated zones as the continuous phase but must proceed through the saturated zone dissolved in the water phase. Where biological activity by soil organisms is supported by sufficient nutrients, oxygen is removed in the pore space and carbon dioxide builds to concentrations a hundredfold higher than found in the

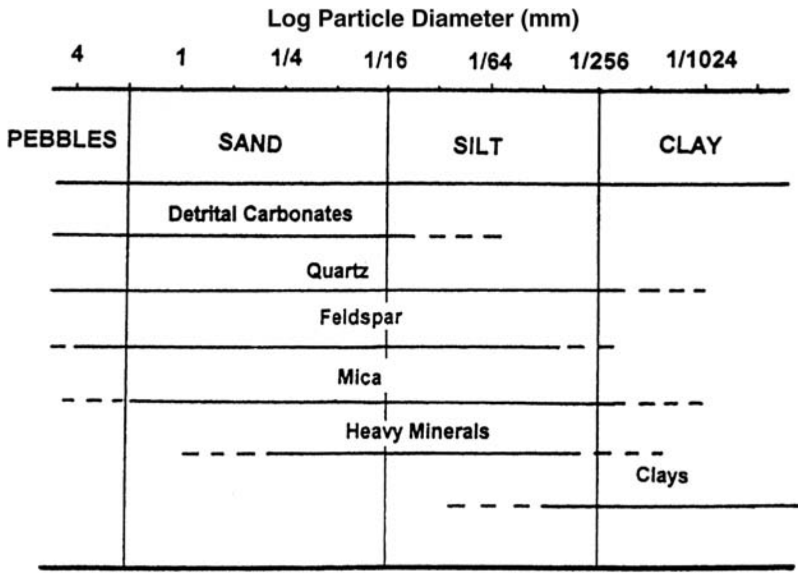


FIGURE 25.2. Classification of sand, silt, and clay based on particle size along with size ranges for various types of minerals commonly found in clastic sediments.

overlying atmosphere [23]. Important transformations also occur as part of the nitrogen and sulfur cycles in a biologically active soil environment.

B1. Textural Classification

Inorganic soil components have been traditionally classified by particle size (Fig. 25.2). The distribution of particle sizes in a given soil matrix can be very broad or surprisingly narrow depending on the manner in which the soil developed.

For example, sand originally laid down as a dune by wind action can be finely sorted with a very narrow range of particle size while soils formed by weathering of rock outcroppings can contain - particle sizes ranging from large boulders to finely divided clays. The particle size distribution along with the shape, orientation, and packing of soil particles determines soil texture.

B2. Permeability

The permeability of a soil matrix is strongly influenced by the particle size distribution.

Figure 25.3 shows how the permeability of well-sorted unconsolidated sand decreases rapidly as the average particle size gets smaller. Permeability is higher in well-sorted sands

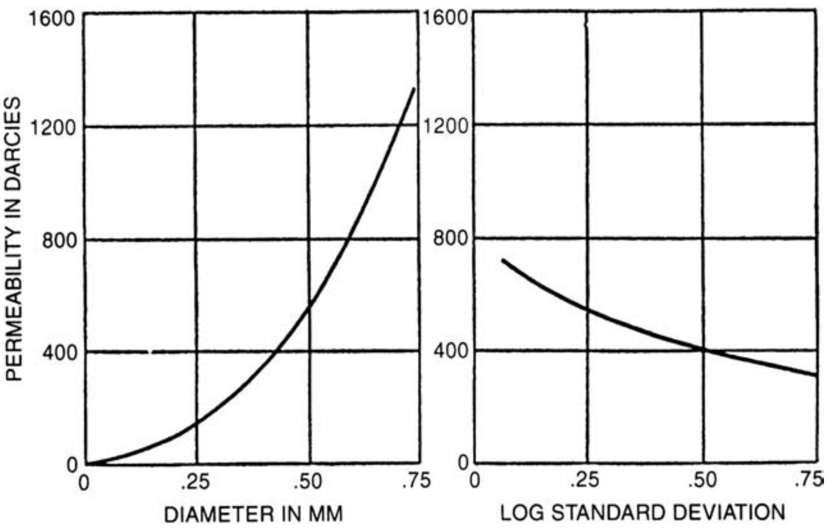

FIGURE 25.3. Variation of sand permeability with average particle size and with breadth of particle size distribution [27].

with a narrow distribution of particular sizes while sands with wider particle size distributions show reduced permeability (Fig. 25.3).

Permeability plays an important role in setting the stage for electrochemical events on a buried steel surface because it controls the relative ease or rate of fluid flow through the soil matrix. Coarse-grained sands allow good drainage and easy access of atmospheric oxygen to structure depth. Fine-grained soils rich in clay are more restrictive. Capillary forces in fine-grained matrices can also draw water up and keep a soil water saturated even during relatively dry conditions by preventing drainage and retarding evaporation [24].

Waterlogged soils are particularly effective at slowing the rate of oxygen ingress from the overlying atmosphere. Consequently, waterlogged soils are often anaerobic at even very modest depths. Control of oxygen access can dictate the basic corrosion scenario seen at a buried steel surface.

Association of inorganic soil particles with organic material can lead to aggregate formation. This influences soil structure and can alter the soil permeability. A well-developed soil structure can enhance water and air movement through the affected soil zone [23].

B3. Soil Color

Soil color can be used to diagnose oxygen permeation. Good drainage and warm temperatures encourage extensive weathering and the formation of iron(III) oxides that give the soil a characteristic red tint. This might be expected in a well-drained sandy soil that is gritty to the touch. Brown and reddish brown hues indicate the presence of organic matter. Yellow or rust colors occur in soils that are slightly wetter due to the iron(III) oxides being left in a hydrated form. This might be expected in silt where a relatively small particle size lowers the permeability of matrix and retains water. Anaerobic soils where iron has not been oxidized to ferric ions are bluish gray, which is characteristic of waterlogged low-permeability clay soils or gley.

Particle size can be roughly correlated with the mineralogy of soils (Fig. 25.2). Techniques such as X-ray diffraction can identify the mineral composition. The diffraction pattern is a fingerprint for the crystal structure of each mineral. Organic material and some inorganic components such as noncrystalline iron sulfide formed by anaerobic microbial action do not show up in this analysis.

B4. Mineralogical Composition

Mineral composition is a key to understanding how a soil can influence the corrosion of buried steel.

B4.1. Clays. Clays are among the most common minerals on earth, constituting perhaps one third of all sedimentary materials [25]. They form through the weathering of parent materials; the chemical transformation of feldspars being one of the most common processes [22, 26]. Clay formation is accelerated where conditions favor weathering and leaching of minerals. In the extreme case, only the most stable clays (e.g., kaolinite) are found. Other clays, being intermediates in the weathering process, dominate the composition where soil has developed under less extreme conditions.

Most clays have notable plasticity when wet and a marked ability to adhere to surfaces. Owing to their small particle size and structure, clays have exceptionally high surface areas and show great surface activity relative to other types of minerals. The surface area of a clay can be 10,000 times that of an equivalent weight of sand [23]. Cations required to charge balance the hydrous aluminum silicate framework in clay minerals provide opportunity for ion exchange and redox chemistry.

In an extensive survey of prairie soils in western Canada, the Alberta Research Council found that the clay content correlated inversely with percent sand present. Concentration of metals including iron, copper, boron, and perhaps cobalt and zinc present in the soil correlated directly with the clay content but calcium, magnesium, and the pH showed no correlation with clay content The plasticity index and liquid limit (% moisture) were also a function of clay content.

Four families of clay minerals are described in Table 25.1.

Characteristics shown in Table 25.1 suggest that the montmorillonite group will have an important influence on the corrosion of buried steel structures. High concentrations of montmorillonite (or smectite) clays are responsible for the sticky yet slippery nature of so-called gumbo soils. Their small particle size leads to very low permeability, extraordinary water uptake and retention, low fluid flow, slow exchange of interstitial water, limited gas migration, and extensive ion exchange with the electrolyte as well as high capacity buffering of pH and poising of the oxidation reduction potential in the soil–water system [26].

Physically, clays of the montmorillonite group such as bentonite can radically change volume through either dehydration/rehydration or ion exchange. This shrinking and swelling can exert force on structures buried in montmorillonite-rich soils leading to potentially detrimental consequences. For example, coating damage and disbondment can occur when a montmorillonite clay adhering to the protective coating on a buried structure changes volume. The ability of clay-rich soils to adhere to surfaces can also aggravate coating damage caused by soil settling around the structure. In extreme cases, shrinkage due to drying can lead to the formation of large-scale cracks through the soil matrix in soils known as vertisols [23]. Swelling conditions can also compromise the permeability of a soil through both the increase in particle volume and the release of particles into fluid flow, resulting in an irreversible plugging of pore throats in the soil matrix [24].

TABLE 25.1. Properties of Major Groups of Clay Minerals[a]

Characteristic	Kaolinite Group	Illite Group	Chlorite Group	Montmorillonite Group
Occurrence	Common	Abundant	Common	Common
Structural type	2 Layer	3 Layer, nonexpandable	3 Layer, nonexpandable	3 Layer expandable
Particle size (μm)	4.0–0.3	0.3–0.1	0.3–0.1	0.2–0.02
Permeability	Large	Moderate	Moderate	Small
Water absorption	Slight	Moderate	Moderate	Very large
Surface area (m^2/g)	5–20	100–200		700–800
Cation exchange	Slight	Moderate	Moderate	Large
capacity (meq/100 g)	2.3	16		81
	7–12	18–24	25–30	90–100
Anion exchange capacity (meq/100 g)	7–20	4–17	5–20	20–30
Plasticity	Slight	Moderate	Moderate	Large

[a]This table is generally based on [27]. Cation exchange capacities are from [26] and [25], respectively, anion exchange capacity based on phosphate exchange is from [28], and surface areas are from [29].

B4.2. Sand. Relative to clays, coarse silica sands tend to be relatively permeable, well drained, and inert.

B4.3. Carbonates. Even modest amounts of limestone or dolomite in soils will dissolve over time to saturate associated groundwater. Dissolved carbonate will buffer the solution in the neutral to alkaline pH range [30]. Exposure of this saturated solution to steel surfaces rendered alkaline by electrochemical reactions induced by an effective cathodic protection system will precipitate hard white carbonate scales (e.g., calcite or dolomite) on the metal surface. These scales are strongly adherent and form an impermeable protective layer that indicates both effective cathodic protection and negligible corrosion problems.

B4.4. Evaporites. Evaporation of ancient lakes and oceans has left massive deposits of precipitated salts in some geographic regions. While construction directly in salt beds is a special situation, high salinity salt seeps formed by dissolution of soluble salts into mobile groundwater affect soils more broadly. Consequent increases in the electrical conductivity of the water in the soil system can accelerate electrochemical reactions causing corrosion of steel directly exposed to the soil environment [Fig. 25.1(a)]. In contrast, the increased conductivity for electrolyte under failed coatings can improve the penetration of effective cathodic protection potentials to the underlying steel surface [31] minimizing corrosion or EAC damage in the scenario shown in Figure 25.1(b).

B5. Soil Profiles

Recent geological deposits or those just beginning to develop as soils lack a vertical profile and are called entisols or inceptisols, respectively.

Mature mineral soils are vertically differentiated between the soil surface and underlying strata or bedrock. Three general horizons can often be seen in the vertical profile [25]. At the top is the A or eluvial horizon. The A horizon is in contact with the atmosphere and receives rainfall, nutrients, and so on, from the surface environment. Biological activity and formation of humus arc generally focused here. Leaching by gravitational water removes soluble minerals from this zone, concentrating less soluble, more stable minerals in this layer. The underlying B or illuvial horizon is an intermediate zone that is often low in organics but is enriched by deposition of soluble minerals and secondary transformation products from weathering reactions in the overlying layer. The C horizon at the bottom of the sequence is largely composed of parent material unaltered by weathering and hosts little biological activity. Each of these horizons can be further differentiated into subzones or can be entirely missing from the sequence depending on local conditions and climatic factors.

The principal factors affecting the soil profile are temperature and rainfall. Increased temperature can accelerate biodegradation of organic material, chemical reactions associated with weathering and leaching of soluble minerals. Increased rainfall accelerates the leaching of soluble minerals from the upper horizons in the soil profile. Carbonic acid dissolved in meteoric water drives the conversion of key primary minerals into secondary ones, for example, the conversion of feldspars to clays. The order of decreasing stability of common minerals under weathering conditions is iron oxides, aluminum oxides, quartz, clays (kaolinites being more stable than illites, chlorites, or montmorillonites), muscovite, potassium feldspar, biotite, sodium feldspar, amphibole, pyroxene, calcium feldspar, and olivine [25].

B6. Soils in Various Climates

Soil profiles are developed from parent materials in response to factors associated with climate. The following selected cases illustrate some of the principles and processes outlined above.

B6.1. Arid Regions. In desert regions, low rainfall results in minimal leaching of soluble minerals and low organic loading. Such soils, known as aridisols, tend to be light in color and rich in soluble salts. In general corrosion rates for unprotected steel are very low in these dry soils. Flitton et al. [32] reported corrosion rates less than 12 μm/year and pit depths less than 170 μm for carbon steel 1018 coupons buried in an arid vadose zone for up to 3 years. Where interstitial water is retained in the soil matrix, it can be strongly saline. This can create very aggressive soil conditions locally even in arid regions. Clays tend to be loaded with sodium that is released by ion exchange when water is introduced to yield a solution that ranges from near neutral pH when the prevalent anion is sulfate or chloride to strongly alkaline if carbonate salts prevail [23, 25].

B6.2. Tropical Climates. In contrast tropical or semitropical climates with high rainfalls leach soluble minerals extensively from soil horizons. Warm temperatures promote the degradation of organics thinning the top zone. The result is a red lateritic soil rich in iron and aluminum oxides underlying a thin veneer of humic material. These soils tend to be very acidic and are called oxisols [23, 25].

B6.3. Temperate Zones. In temperate zones, a range of soil profiles can be found that depend in part on the extent of rainfall experienced. Mollisols occur where rainfall is modest, thick top soils accumulate, prairie grasslands being typical. Alfisols are slightly wetter, more acidic soils that occur on the wetter borders of grasslands, while ultisols in even wetter, warmer regions show more clay accumulation in the B horizon.

B6.4. Arctic Conditions. Arctic regions are represented by vast areas of tundra. Freeze–thaw cycles result in the mechanical weathering or disintegration of parent rock. These cycles can also alter soil structure and sort soil components. Low temperatures result in the accumulation of thick organic layers.

Heaving during freeze and thaw cycles can displace buried steel structures. One study has reported effects seen on a length of pipe buried in sand and in silt under controlled conditions [33]. During freezing in silt, ice formed beneath the pipe left a cavity running along the length of the pipe on thawing. This would generate a discrete channel for groundwater flow in the field. In such a situation, the composition of water in contact with exposed steel surfaces might be different to that expected for the local soil environment [Fig. 25.1(a)].

Permafrost found in arctic and antarctic regions underlies up to one quarter of the earth's land area. Permafrost is ground remaining at or below 0°C. It may consist of cold dry earth, cold wet saline zones (called talik), and icy lenses or ice-cemented earth and rock. Unfrozen saline zones may be of special interest in terms of corrosion scenarios seen on buried steel structures. These arise by exclusion of soluble salts from ice as crystals form. This concentrates salts in the remaining unfrozen solution [22, 33]. In coarse soils where migration of soil water is relatively easy, unfrozen, high-salinity zones can appear as thick layers (called cryopegs). In fine-grained matrices where transport is more constrained, near microscopic pockets of unfrozen saline water are often found.

C. INSTALLATION SCENARIOS

The manner in which steel structures are constructed can lead to different scenarios even in similar soil. For example, steel structures can be

- Driven into ground (e.g., piles)
- Installed in excavations and then buried with backfill (e.g., most pipeline construction)
- Inserted into predrilled shafts or horizontal tunnels (e.g., pipeline river crossings)

In the case of driven piles, the soil profile is left largely undisturbed except for compaction around the structural unit being pounded into the ground. This can reduce the permeability of the soil matrix adjacent to the steel, slowing the ingress of oxygen from the atmosphere and forcing an intimate contact between the steel and soil. Romanoff [34] concluded from a study of 19 installations in service for 7–40 years that corrosion on steel pilings driven into undisturbed soil was insufficient to affect the strength or useful life of the load-bearing structures. Soil conditions aggressive to steel buried under disturbed conditions were not corrosive to steel pilings in undisturbed soil. Corrosion was found to be variable but not serious above the water table [34, 35] and negligible below the water table. Correlations between soil properties and corrosion developed for buried steel structures were of no practical value in predicting the corrosion of pilings. Flitton et al. [6] in a review of simulated service testing in soils noted that corrosion in undisturbed soil is always low, regardless of soil conditions, because of the low availability of the oxygen. Recent inspection of facilities that had been in service for decades in very different climates gave a maximum corrosion rate of <19 μm/year for nonaggressive soils and <48 μm/year for

an aggressive soil environment with high chloride concentration [36, 37].

In the second installation method, the backfill used to bury the structure can be a jumble of various soil horizons and debris that requires extended periods of time to settle and resume development of a normal vertical profile. Flitton et al. [6] indicated that corrosion of unprotected steel in disturbed soils is strongly affected by soil conditions. This is very relevant to buried pipelines and other structures that are constructed or placed in excavated sites and then buried with backfill. Even after many years, Harris [38] found that only the surface zone of the backfill came to resemble adjacent undisturbed soil. The zone above the pipe remained more permeable, more biologically active, and more heterogeneous than adjacent soil at the same depth. The increased permeability allowed increased oxygen penetration into the soil matrix and provided drainage paths for gravitational water. At and below pipe depth, moisture content in the backfilled trench exceeded that of adjacent soil with free water being found in some cases. This could make measurement of bulk soil properties deceptive in terms of predicting the chemistry occurring at the steel surface. For pipeline construction today, top soils are purposely separated from other horizons during excavation and are restored as the covering layer after burial. This minimizes burial of organic rich soil at pipe depth and allows rapid revegetation of the soil surface. Burial of organic materials can promote bacterial activity in the soil adjacent to buried structures, fostering microbially assisted corrosion scenarios in a zone that would be otherwise deprived of organic nutrients [39]:

The third installation method can leave gaps between the steel surface and soil matrix. The influx of meteoric water or surface water and direct interaction with the atmosphere become possible. In this situation, bulk soil properties again may not reflect conditions at the metal surface.

D. FACTORS THAT INFLUENCE CORROSION IN SOIL

Attempts to correlate soil characteristics with the corrosion damage seen for unprotected buried steel initially relied on generic soil classification schemes developed for agriculture or based on the % clay and silt present in the soil matrix [1]. These schemes were generally based on the A horizon of undisturbed soil in a local area and may or may not have reflected conditions in the backfilled trench around a buried pipe, Fig. 25.1(a). The intent was to extrapolate corrosion information developed for a specific location to areas of similar soil classification within a region to inform design decisions related to setting a corrosion allowance or applying protective coatings in new pipeline construction. An extensive database was developed by the National Bureau of Standards (now the National Institute of Standards and Technology) in the United States using buried test coupons buried in a wide range of soils for many years for this purpose [7]. A recent attempt to reassess data from these studies using modern statistical techniques [40] concluded that only general trends between soil composition and properties could be supported due to a number of issues with the data. Ricker [40] concluded that more complete, statistically designed data sets based on measurements that reflected properties of the soil and groundwater directly in contact with the exposed steel sample would be needed to enable the useful prediction of corrosion rates and distribution. Numerous factors can affect the corrosion of buried steel.

D1. Soil Type

Many potential consequences of soil properties have already been noted in the foregoing discussion, of soil particle size distribution, organic content, mineralogy, and structure.

In general, the soil structure and particle size distribution determine the physical properties of the matrix such as its permeability. Permeability in turn controls the rate of movement of fluids or gases through the matrix. Hence, soils made up of a broad distribution of small size particles such as clay are restrictive white well-sorted coarse sands allow much greater flux and exchange. Capillary forces in low permeability soils also draw groundwater in to form a water-saturated zone. This effectively raises the local water table and creates an effective barrier to the movement of gases that must dissolve and travel in the continuous water phase. One key consequence is the restriction of oxygen access from the atmosphere to a buried structure. Exchange of water in contact with the buried steel surface with gravitational water or groundwater [Fig. 25.1(a)] can also be limited, allowing the local environment to develop its own composition as events on the steel surface proceed.

Clays of the montmorillonitc or smectite group can exert physical force on underground structures by their ability to adhere to coating or steel surfaces and through volume changes related to the swelling and shrinking caused by hydration effects or ion exchange [26]. As noted previously consequent coating damage can allow water to reach the steel surface [Fig. 25.1(b)], providing the opportunity for corrosion or EAC to develop.

Soil mineralogy plays a key role in the chemistry of associated groundwater. Clays, especially montmoriltonites, support the adsorption and exchange of both cations and anions (notably phosphate). These clays also buffer groundwater pH and poise the oxidation-reduction potential (ORP) of the soil–water system. A detailed discussion of how soil influences groundwater composition can be found in Stumm and Morgan [26].

Soil type and the position of a buried structure in the soil profile influences biological activity. Arid soils, low in water

and organic matter, support little microbial activity relative to moist organic rich soils. In the latter case, aerobic microbiological activity is focused in the decaying organic matter on top of the soil and in the rhizosphere around plant roots. Other microbiological processes that use nitrate, snlfate, carbon dioxide, or various metal cations (Fe^{3+}, Mn^{4+}) in place of oxygen are found in more reducing conditions [41]. These tend to develop deeper down in the soil as aerobic processes in overlying zones consume oxygen. Certain microorganisms active in the sulfur cycle, such as the anaerobic sulfate reducing bacteria can be especially important in the corrosion of steel. In mineral soils, organic nutrients become limiting and microbial numbers fall off rapidly with depth [29]. Organic matter mixed in the backfill around a buried structure or even organic components of a protective coating system can become the focal point for microbiological activity [42].

D2. Moisture Content and the Position of the Water Table

The presence of moisture in the soil is an essential requirement for corrosion [43], The position of the water table also influences the nature of the corrosion process as it can determine rates of oxygen transport in the soil [44, 45]. The position of the water table may also vary seasonally, and this in turn may influence the nature of the corrosion process occurring on the buried structure. There are essentially three sources of water in soil [Fig. 25.1(a)]. Gravitational water in soil is derived from precipitation (rainfall or snow), capillary water is held within the capillaries of soil particles, and groundwater, which is the result of accumulation of gravitational water at the water table [43].

The water table is the top of a water-saturated zone where water forms the continuous phase in the soil matrix. It rises and falls seasonally with precipitation. Capillary effects in the soil matrix also influence the height of the water table. High capillary forces associated with low permeability silts and clays draw the water table up nearer to the surface of the soil. Local variations in soil composition mean that the top of the water table is not flat but rises and falls through a zone sometimes referred to as the capillary fringe [Fig. 25.1(a)].

As the soil moisture content increases from 0 to 25%, dramatic changes can be expected in a number of factors that influence corrosion rates. These include an exponential decrease in soil resistivity [7, 46] and the freely corroding potential [46, 47] and polarization resistance [46] for exposed steel. In terms of corrosion Booth et al. [3–5] determined that a soil moisture content of >20% can be potentially aggressive toward corrosion of carbon steel and was likely to result in general corrosion. Moisture contents of <20% would often result in pitting corrosion, while dry soils were not of concern with respect to corrosion.

These observations may be explained as a result of differential aeration process [46, 47]. The moisture content and position of the water table will influence the diffusion of oxygen into the soil. In saturated stagnant soils, anaerobic conditions may become established, oxygen transport will be low, and the corrosion rate of a buried metal (in the absence of microbial influence) will be low.

Terrain surrounding a site of interest can influence conditions in the underground environment. For example, a distant impermeable barrier could block the drainage through a permeable zone creating a perched water table and water-saturated conditions not normally expected for the local soil type. Topography must be considered in assessing a particular location regardless of soil type.

D3. Soil Resistivity

In general, it is believed that as soil resistivity becomes lower (i.e., groundwater becomes saltier and more conductive) corrosion of a buried metal becomes faster. However, this dependency is only true for metals that are not subject to cathodic protection. Cathodic protection also becomes more effective as the resistivity of the soil becomes lower. In the case of buried pipelines coated with polyolefin tape products, it has been shown [31] that penetration of effective cathodic protection potentials under a shielding disbondment is limited in part due to the conductivity of the water trapped under the coating [Fig. 25.1(b)]. As the conductivity of the trapped water increases, cathodic protection will penetrate further under the coating and arrest corrosion on the steel surface.

For unprotected steel exposed to soil, Booth et al. [3–5] suggested that a soil was corrosive if the soil resistivity was less than 2000 Ωcm and noncorrosive if the resistivity was >2000 Ωcm. Palmer [48], as shown in Table 25.2, gave a more refined classification of soil corrosion based on soil resistivity.

Miller et al. [49], Kulman [50], and others [43] proposed similar classifications to those presented in Table 25.2. while all agree that lower resistivity leads to accelerated corrosion, the actual values used to categorize soil corrosivity differ. Others suggest that corrosion by soil can be divided into

TABLE 25.2. Classification of Soil Corrosivity Based on Resistivity[a]

Resistivity Range (Ω cm)	Corrosivity
0–1000	Very severe
1001–2000	Severe
2001–5000	Moderate
5001–10,000	Mild
10,001 +	Very mild

[a]See [48].

microgalvanic cell corrosion leading to general corrosion and macrogalvanic cell corrosion leading to localized corrosion. Low resistivity leads to acceleration of the latter type of corrosion but it does not affect the former type of corrosion.

Resistivity varies with soil texture. For sand and gravel, resistivity varies from 10,000 to 500,000 Ωcm depending largely on how well drained the soil is, while soils rich in silt or clay generally show resistivities in the range from 1000 to 2000 Ωcm or from 500 to 2000 Ωcm respectively, depending on moisture content [46, 51]. Resistivity is also a function of the groundwater conductivity and temperature [46]. Soluble ion content of the soil has a direct impact on the resistivity of the soil. An increased soluble ion content will decrease the soil resistivity, which in turn for unprotected metals will increase the corrosion rate. In some locations, salt seeps can be encountered that can be highly concentrated in sodium, chloride, and sulfate ions. Such locations have very low resistivity and can be potentially very aggressive with respect to metallic corrosion on unprotected steel surfaces.

D4. Water Chemistry

Specific ions and organics dissolved in the groundwater can influence the corrosivity of the soil environment. For example, calcium and magnesium ions can mitigate corrosion by forming protective carbonate deposits on exposed pipe where dissolution of limestone or dolomite minerals has saturated local groundwater. Formation of protective hard white calcareous scale is particularly evident where effective cathodic protection has increased the pH at the metal surface. High levels of soluble chloride can increase the corrosivity of the soil environment by preventing the formation of passivating films on the steel surface so that any disruption will lead to unmitigated pitting. Sulfates are not considered to be directly corrosive to pipeline steel but can support the activity of sulfate-reducing bacteria in anaerobic environments where degradable organics are present [13]. These bacteria reduce the sulfate to sulfide, an anion that can participate in various corrosion and cracking scenarios. Soluble high-molecular-weight organic acids darken the color of groundwater in organic soils such as peat. Dick and Rodrigues [52] have reported that the lower-molecular-weight fulvic acids improved passivation by promoting the formation of surface deposits on the metal surface of API 5LSX65 line pipe steel exposed to test solutions while humic acids promoted pitting, an activity the authors attributed to the formation of soluble iron/humic acid complexes.

D5. Soil pH

The pH of soil will generally fall within the range 3.5–10. Soils containing well-humified organic matter tend to be acidic. Mineral soils can become acidic due to leaching of basic cations (Ca^{2+}, Mg^{2+}, Na^{+}, and K^{+}) by rainwater and as the result of dissolving of carbon dioxide into the groundwater.

The corrosion of iron as a function of pH increases considerably at pH values <4, but passivation occurs at high pH values [53]. In contrast to iron, amphoteric metals, such as aluminum, which are protected by oxide films, can be rapidly corroded in alkaline soils with high pH values as well as in acidic environments.

King [54] developed a nomogram that combined the influence of resistivity and pH on the corrosion of steel (Fig. 25.4) but cautioned that the figure should only be used as a guide. The nomogram ignores the influence of both oxidation–reduction potential and microbial activity, key parameters in underground corrosion. It may be best applied to the prediction of corrosion rates in aerobic conditions.

Where acidity is the controlling factor in determining the aggessiveness of a soil environment, the percentage of pipeline failures attributed to corrosion can be correlated to the total acidity of the soil [1].

D6. Oxidation–Reduction Potential

The oxidation–reduction potential (ORP) of soil is the potential of an inert electrode such as platinum, with respect to a reference electrode such as copper/copper sulfate or saturated calomel. It is not a measure of the oxygen concentration but rather an indication of the oxidizing or reducing capacity of the soil. Under aerobic conditions oxygen content of the soil will be high and the ORP will be more positive than that measured for an anaerobic soil. In an anaerobic soil, electron acceptors other than oxygen determine the ORP of the soil. The ORP is somewhat of an abstract value but research and field evidence have indicated that it can be used with some success to help in prediction of soil corrosivity.

Starkey and Wight [2] determined a classification of soil corrosivity based on redox potentials as shown in Table 25.3.

Booth et al. [3–5] developed a similar classification scheme. In this work, soils were considered aggressive if the ORP reading was <0.4 V (NHE at pH 7.0) and nonaggressive if the ORP was >0.4V(NHE at pH 7.0).

The general conclusion made in these systems is that aerobic soil conditions are relatively benign. More severe damage is seen under anaerobic conditions. This observation is at least partly explained by the potential for anaerobic microbial activity in soils with a low ORP.

D7. Role of Microbes in Soil Corrosion

Microbiologically influenced corrosion of iron-based materials in soils has been well documented [55]. While numerous scenarios have been described, two are particularly associated with the corrosion of buried line pipe.

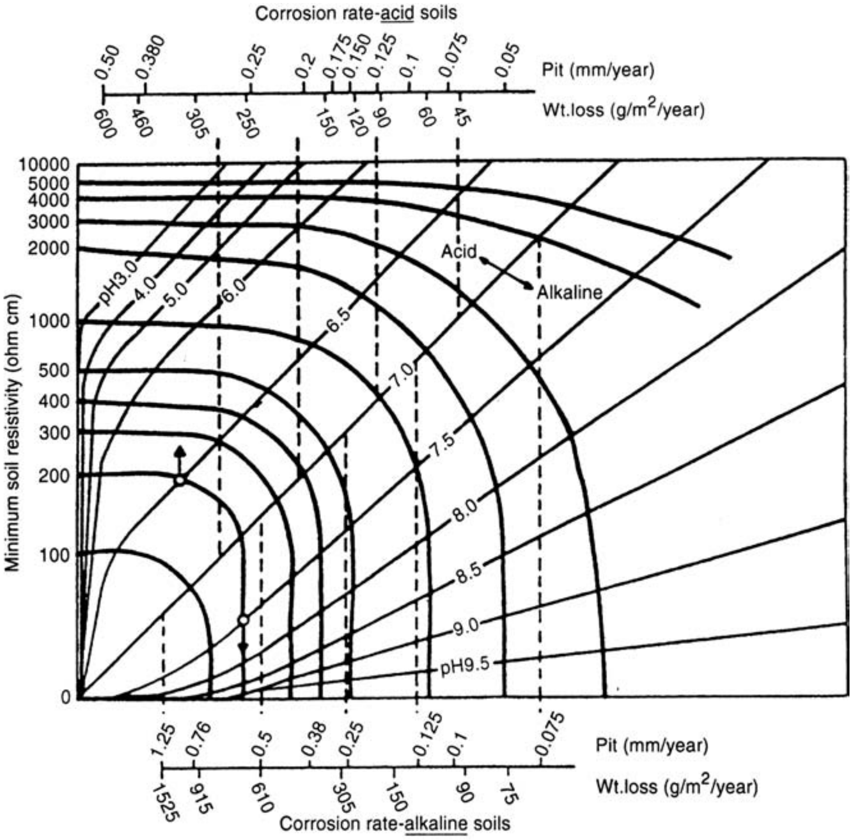

FIGURE 25.4. Nomogram relating soil resistivity, pH, and corrosion rate for steel pipe in soil [54].

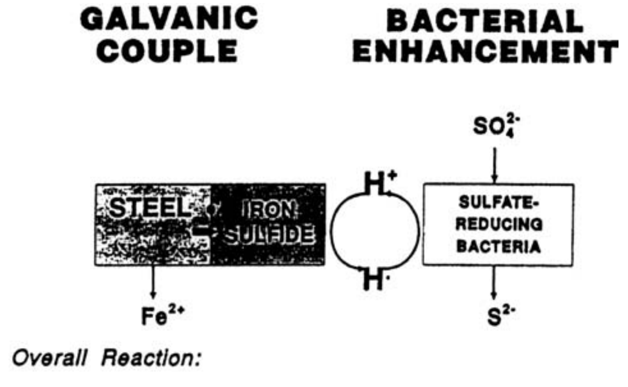
As long ago as 1934, sulfate-reducing bacteria were identified as being responsible for severe corrosion damage observed under anaerobic conditions in wet, black soil [56]. These organisms reduce groundwater sulfate to sulfide as part of their anaerobic metabolism and cause the precipitation of black iron sulfides associated with severe corrosion on pipeline systems. These bacteria can derive energy for growth and metabolism by coupling the oxidation of molecular hydrogen to sulfate reduction [57]. Hardy [58] has shown that sulfate reduction can be stimulated by catbodic hydrogen formed on metal surfaces.

A scheme for the corrosion mechanism is shown in Figure 25.5. A galvanic couple formed between steel and microbially produced iron sulfide is sustained by the removal of electrons possibly in the form of cathodic hydrogen from the iron sulfide matrix by these bacteria. This prevents saturation of the iron sulfide with electrons and leads to further iron sulfide production, which in turn further extends the corrosion cell [20, 59] The amount of iron sulfide present determines the rate of corrosion observed in the lab

TABLE 25.3 Classification of Soil Corrosivity Based on Oxidation–Reduction Potential[a]

ORP Range (mV)[b]	Degree of Corrosion
<100	Severe
100–200	Moderate
200–400	Slight
>400	Noncorrosive

[a]See [2].
[b]The ORP value is corrected to the normal hydrogen electrode (NHE) scale at a pH 7.0.



$$8H^+ + 4Fe + SO_4^{2-} \rightarrow \text{"FeS"} + 3Fe^{2+} + 4H_2O$$

FIGURE 25.5. Corrosion mechanism for microbially influenced corrosion involving anaerobic sulfate-reducing bacteria [20, 59].

experiments [60]. Field observations reported as early as 1940 support an increasing pitting rate corrected to the amount of iron sulfide present [61] consistent with this mechanism.

This scenario is anticipated in anaerobic environments with pH and ORP favorable to the development of sulfate-reducing populations [29, 41, 57]. Water-saturated clay-rich soils provide suitable conditions [43]. Organic coating components and the availability of catbodic hydrogen derived from the steel surface can foster microbial growth and activity [42, 58].

Pope et al. [62] identified a second biologically influenced corrosion scenario with the discovery of high concentrations of organic acids in corrosion products taken from damaged pipe surfaces in the field. These are generated by so-called acid-producing bacteria (APB). Unlike sulfate-reducing microbes, anaerobic conditions are not a prerequisite for activity of these bacteria.

TABLE 25.4. Corrosion Scenarios Identified on Pipelines in Soils in Alberta[a]

Corrosion Scenario (% of sites examined)	Typical Corrosion Deposits
Primary aerobic corrosion (3%)	Various iron(III) oxides including: Fe_3O_4 (magnetite), α-FeOOH (goethite), γ-FeOOH (lepidocrocite), γ-Fe_2O_3, (maghemite), Fe_2O_3 (hematite)
Primary anaerobic corrosion (29%)	$FeCO_3$ (siderite)
Primary anaerobic microbial corrosion (SRB) (27%)	Siderite + amorphous "FeS," mackinawite (FeS), greigite (FeS)
Aerobic site becomes a secondary anaerobic microbial (SRB) site (3%)	Mackinawite (FeS), pyrite (FeS_2;), marcasite (FeS_2 + iron(III) oxides
Primary anaerobic site becomes aerobic (21%)	Siderite + various iron(III) oxides
Anaerobic microbial (SRB) site becomes aerobic (17%)	α-FeOOH (goethite), γ-FeOOH (lepidocrocite) + elemental sulfur

[a]See [63].

E. FIELD OBSERVATIONS

Kulman [50] compared 5 years of leak data for New York City gas mains with the seasonal variation in soil parameters. Increased soil moisture, decreased aeration, and an increase in the proportion of anaerobic soil bacteria were found to correlate with the maximum monthly frequency for leaks caused by the underground corrosion cycle. In a program of 472 excavations carried out through the 1940s, severe corrosion was found at 185 sites. Of these excavations, 103 of them were in clay soil and ferrous sulfide was found in 81% of the sites. In contrast, soil properties including the concentration of soluble sulfate, the number of sulfate-reducing bacteria, and the soil pH failed to show any correlation with corrosion behavior.

Jack et al. [63] studied the corrosion of line pipe steels over a number of years in a variety of prairie soil in Alberta, Canada. At least six scenarios could be identified from the analysis of indicator minerals present in the corrosion products (Table 25.4), Primary sites were those that showed evidence of only one corrosion scenario. Secondary corrosion sites showed evidence that a change in conditions had altered the corrosion scenario. Sites where sulfate-reducing bacteria (SRB) were involved in either the primary or secondary scenario suffered the most severe damage. Laboratory studies for these six scenarios showed that corrosion rates ranged from 0.01 mm/year in sustained anaerobic conditions to rates of 1 mm/year where secondary oxidation of an anaerobic SRB scenario occurred [64].

F. CHARACTERIZING SOILS

Recently released Recommended and Standard Practices to assess the extent of stress corrosion cracking (SCC) and to assess and reduce the impact of external corrosion on pipeline systems [11, 12] review methods for assessing key characteristics of the soil environment associated with these problems. Specific standard methods have long been available for measuring traditional factors such as soil resistivity (e.g., ASTM G57 and G187) and soil pH (e.g., ASTM G51), but methods in this area are currently in a state of active review and continuous improvement [65, 66]. Task Group 369 of the National Association of Corrosion Engineers International has been assigned to develop a report on aboveground techniques used to identify areas on a pipeline at risk for external corrosion based on the corrosiveness of the environment, but this is likely to be a benchmark report for further development.

F1. Soil Probes

Attention has increasingly shifted over the years from surface observations to measuring key soil characteristics at pipe depth through the use of portable probes that can be inserted directly into the soil to depths of a meter or more.

Starkey and Wight [67] and Deuber and Deuber [68], in association with the American Gas Association, developed the first probes for field measurement of redox potential along pipeline right of ways. Costanzo and McVey [69] developed this probe further. Their probe consisted of two platinum electrodes coupled to a saturated calomel reference

electrode. A similar probe for field determination of redox potentials was developed by Booth et al. [3–5]. A more comprehensive probe was patented in Japan [70].

In 1992, Wilmott et al. [71] reported the development of a soil probe that could be used to determine soil pH, resistivity, redox potential, temperature, and pipe to soil potentials. This probe was used in the characterization of buried pipeline environments associated with external corrosion, stress corrosion cracking, and external hydrogen-induced cracking. In most cases, it was found that the soil redox potential and resistivity are important parameters in determining the nature of the scenario that is found at a given location [72].

The seasonal variation in soil parameters can be significant. Soil readings for resistivity, ORP, and moisture content were monitored monthly for 87 sites in the United Kingdom. These readings were then used to classify the sites as aggressive or nonaggressive according to the scheme of Booth et al. [5]. In only about one-half of the sites did the monthly readings consistently result in the same diagnosis. In 5–9% of the sites, an individual monthly reading had a 50% or more chance of giving an incorrect diagnosis relative to long-term site behavior. These observations led to a recognized need to take as many measurements as possible and to use seasonally averaged values to predict the soil corrosivity [5].

One way of characterizing a site more reliably over its seasonal variations is to use permanent soil probes. Gabrys and Van Boven [73] reported such a study. The probe used was based on the principles of that reported by Wilmott et al. [72] but was designed to be permanently buried and can be used in conjunction with corrosion coupons to monitor seasonal variations in cathodic protection, environmental parameters, and associated corrosion rates for pipeline steels, A second approach to soil corrosivity mapping was reported by Wilson [74] in New Zealand who developed a probe, which can be used for measuring corrosion potential, corrosion rate and soil resistivity as a function of time and probe depth. One aim of this research was to monitor seasonal variations in parameters associated with corrosion of buried metals. In 2001, Li et al. [75] reported development of a probe to measure corrosion current density and corrosion potential of metals in soil along with soil resistivity, ORP, and temperature. The last parameter can influence the corrosion rate, ion exchange kinetics with soil components such as clays and coating degradation. Dedicated probes for soil resistivity and corrosion rate measurement (based on linear polarization resistance with compensation for high solution resistance) are available commercially. Electrical resistance probes can be used to measure corrosion rates in very high resistivity soil environments. One application has been the assessment of cathodic protection effectiveness in desert soils where extremely high infrared (IR) drop frustrates other methods of assessment [76]. A review of corrosion rate probes is available [77] and the U.S. PHMSA has set a research contract [78] to validate their use.

Geotechnical engineers have also developed a number of tools that can be useful in characterizing soil corrosivity. These probes are commonly called cone penetrometers and were initially designed to measure soil mechanical properties. Adaptations of such devices have allowed determination of resistivity, pH, and redox potentials [79–82].

Soil probes provide an essential insight into local conditions adjacent to a buried structure. Disturbed soil, perched water tables, groundwater flow through gaps generated by installation, or freeze–thaw cycles as well as other local effects can preclude the reliable correlation of local soil type with the probability of corrosion behavior at a specific site. Soil probes can characterize the environment at the buried metal surface where the bare metal is in direct contact with the soil [Fig. 25.1(a)] and provide the data needed to assess likely corrosion rates without excavation. Characterization of environments under defective coatings in the scenario illustrated in Figure 25.1(b) is more problematic and will require further research effort to understand how this environment evolves based on background soil and groundwater characteristics.

G. MODELS

Having assayed parameters that can influence corrosion and cracking scenarios on buried structures the question arises as to what to do with the information that is gathered? The goal of soil corrosivity mapping should be to enable development of models that can ultimately be used to identify specific sites that would be susceptible to a given corrosion or cracking scenario.

Traditionally, simple soils models have been used to rank various soil environments in terms of corrosion severity based on the factors described in this chapter [1, 40] with the aim of informing decisions on pipeline design (route selection, corrosion allowance, coating application, remedial backfill, etc.) or prioritizing inspection and maintenance activities. The simple models employed assign a degree of corrosion severity to ranges of values for each factor and then consider the cumulative effect. The approach recommended in ANSI/AWWA C105/A21.5, for example, is to assign points to ranges of values for soil resistivity, pH, ORP, and moisture content and the presence of sulfide. The points assigned to the various factors are then summed to decide whether special action such as the application of a protective coating to the pipe is warranted. The direct measurement of corrosion rates at pipe depth enabled by the new generation of soil probes can be used to prioritize the location and frequency of inspection and maintenance activities, but the cost of collecting such data is sufficient that simple models

that rank soil environments along the pipeline right of way may find use in targeting this more sophisticated approach to data collection.

Risk assessment and risk management processes are used in the pipeline industry as a means of prioritizing pipeline hazards and identifying cost-effective maintenance actions. There are a number of components to this process.

- Identification of all likely hazards
- Determination of the probability of failure from each hazard
- Prioritization of pipeline segments based on risk (including consideration of consequences)
- Optimization of maintenance activities to reduce overall risk

Recognized protocols are now available to guide this process for external corrosion and stress corrosion cracking [11, 12].

In the case of SCC, Marr and Associates, in conjunction with TransCanada Pipelines, developed a predictive model to identify and rank areas along a pipeline that are most likely to develop SCC [83, 84]. Wilmott and Sutherby [85] reported on a fault tree analysis that can also be used to identify locations of high SCC susceptibility. The factors employed in SCC models [12] include the following;

- Type of coating
- Year of pipeline construction
- Pipeline operating conditions
- Soil type, drainage, and topography

In terms of external corrosion of pipelines, risk management has been addressed in a number of articles [86, 87] and a textbook has been written by Muhlbauer [88]. The processes employed in such analyses range from indexing methods [88] through to more complex decision analysis frameworks based on influence diagrams [86].

H. SOIL EFFECTS ON CATHODIC PROTECTION AND COATINGS

Cathodic protection and protective coatings are used to prevent the external corrosion and EAC of buried steel structures [17]. Either method on its own can effectively protect steel in the underground environment. Used together the coating can reduce the cost of cathodic protection while the cathodic protection system can protect steel surfaces exposed to the soil environment through coating damage or defects.

Occasionally, soil conditions can compromise the performance of cathodic protection. For example, the electrical conductivity of the soil is a key factor in the design of an appropriate cathodic protection system. Poor design or an unexpected increase in soil resistivity brought on by drought or other factors can result in a loss of effective protection at buried steel surfaces.

Coating damage or defects can create the opportunity for corrosion or EAC on buried steel surfaces by allowing water to reach the steel surface [Fig. 25.1(b)] in the absence of effective cathodic protection. One example of this occurs where soil stress has pulled a polyolefin tape wrap coating off the steel surface. The electrical insulating ability of the disbonded tape effectively shields the underlying steel surface from effective cathodic protection, allowing metal damage to proceed at essentially the freely corroding potential [31]. This scenario is most common in high clay soils and in locations where soil movement or extensive settling occurs. High temperatures or excessive cathodic protection potentials can accelerate coating disbondment. In another scenario, coating materials including polyvinyl chloride, asphalt, or coal tar can suffer a loss of integrity in service through removal of coating components by water leaching, oxidation, or biodegradation. High temperatures can again accelerate coating deterioration. The resulting increase in coating permeability allows water access to the underlying steel surface. If the permeable coating holds water on the steel surface during dry spells when the surrounding backfill dries out and cuts off effective cathodic protection, corrosion and EAC can occur. Examples of both these scenarios have been seen in the field.

I. SUMMARY

Early work correlating readily measured soil parameters with the degradation of buried materials has provided simple models for soil aggressivity. These models provide general guidance for materials selection and for the location and design of underground systems.

As scientists and engineers learn more about the role of soil in corrosion and environmentally assisted cracking processes it becomes apparent that, while useful generalizations regarding the corrosivity of various types of soil can be made, the underground environment can be complex. A simple, unified theory describing all soil conditions and the resulting corrosion processes is unlikely. Corrosion in soils is a multivariate problem that requires an understanding of chemistry, geology, and materials science to name but a few topics. No single unified process for assessing soil corrosivity has been or is likely to be developed. Direct measurement of soil parameters in disturbed soil adjacent to buried steel structures can improve understanding of site-specific conditions; however, a better understanding of corrosion and EAC mechanisms is needed to refine the linkage between conditions in the surrounding soil and events

on a buried steel surface. Where protective coatings have failed in a way that allows water to access the underlying steel surface in the absence of effective cathodic protection, it becomes even more difficult to make this link. An understanding of how coatings fail and the consequences in terms of conditions developed at the steel surface in various soil environments remains a key issue for futurework.

The ability to predict the probability of corrosion or cracking damage on a site-specific basis is important for the ongoing maintenance of a reliable pipeline infrastructure. Risk management tools play a key role in prioritizing effort in both the maintenance and inspection of aging systems to ensure their safety and reliability cost effectively.

A. INTRODUCTION

Microorganisms play a very active and an important role in the biosphere, mediating the decomposition of natural organic materials and recycling essential nutrients. They also have a less recognized negative role to human society, damaging a wide range of natural and engineering materials, including metals [1–4], polymeric materials [4–7], and inorganic minerals and stone [8–12]. Under natural conditions, corrosion of metals is a result of both electrochemical and biological processes operating at the interface between metal surfaces and microorganisms, which can be initiated and accelerated by the presence and the active metabolism of microorganisms [1, 3, 13–16]. Degradation and deterioration of a wide range of polymeric materials are due to the action of microorganisms and other metabolites followed by physical disintegration and damage of the material structures [4, 6, 7]. Concrete and stone are degraded mostly by acidic metabolite attack by the attached microflora. The processes of corrosion, degradation, and deterioration are ambiguously called microbially influenced (induced) corrosion (MIC) in the corrosion and engineering literature without detailed differentiation.

Microbial adhesion and establishment of a complex community (microfouling) are prerequisites for substantial degradation and physical changes of the underlying materials [15, 17–20]. All surfaces, including both nonliving and living, may act as substrata for attachment and then formation of the biofilms [21–27]. Therefore, subsequent attack of materials by microorganisms can take place either directly or indirectly, depending on a combination of factors [6], including the indigenous microflora, material composition, nature of the surface, and environmental conditions. In

addition, other specific factors affecting the physical environment also influence the extent of bacterial adhesion on surfaces, including ionic strength of the solution, type of cation, hydrodynamic force, and surface properties (e.g., hydrophobicity or hydrophilicity) [26].

Corrosion of metals is closely associated with the formation of complex microbial biofilms on surfaces [1, 3, 4, 14]. The attached microbial cells on metal surfaces induce the formation of differential aeration cells under aerobic conditions because dissolved oxygen is consumed near and within microbial colonies. At the same time, the decrease in oxygen levels provides an opportunity for anaerobic microorganisms to become established within biofilms. In particular, sulfate-reducing bacteria can become established and cause rapid corrosion of underlying metals. Under conditions that promote microbial corrosion, a variety of minerals have been reported to be associated with different processes [14, 28]. Microorganisms are also capable of extracting electrons from metals under both aerobic and anaerobic conditions [1, 29–31]. Aerobic and anaerobic corrosion of metals are discussed elsewhere [3] as well as in Chapter 39 in this book. In addition, hydrogen produced during microbial metabolism may cause corrosion by affecting the mechanical strength of metals through a process called microbial hydrogen embrittlement [2, 15, 32, 33].

Direct utilization of natural polymeric materials by microorganisms can also proceed at a high rate because of their structural similarities to other biological materials [34–41]. Microbial degradation of complex (high-molecular-weight) polymers is most likely mediated by extracellular depolymerases because the molecular sizes of these polymers are too large to penetrate through cellular membranes for effective assimilation. However, extracellular degradation products can be assimilated by microorganisms as a source of carbon and energy when the polymers are depolymerized. The consequences of degradation are the weakening of polymer backbone linkages and a decrease in mechanical properties due to utilization of the backbone carbon and further damage of the internal bonding between different components of the polymer chain [34, 40, 42]. The process in which a material is decomposed and altered significantly in chemical and physical terms by microorganisms is called biological degradation or deterioration. Mineralization is designated strictly for complete breakdown of polymer carbon to simple inorganic compounds, and the end products during mineralization are CO_2 and H_2O under aerobic conditions and CH_4, H_2S, CO_2, and H_2O under a range of anaerobic conditions [6, 41, 43]. Complete degradation of synthetic and engineering polymer is seldom achieved by microorganisms because part of the substrate carbon will be immobilized in new microbial biomass and recalcitrant organic matter. During degradation, the molecular weight of the polymer decreases under both aerobic and anaerobic conditions.

Corrosive metabolic products from microorganisms have also been found to contribute to the deterioration of a wide range of materials, particularly stone [10, 44], concrete [9, 12, 45], and metals [1, 46–50]. Succession of physiologically different groups of microorganisms on surface of materials and their metabolites contribute significantly to the degradation and deterioration of this class of inorganic materials. Indirect damage to materials by exoenzymes, exopolymeric materials of microbial origin, and other microbial products has drawn increasing attention [46, 48].

A fundamental understanding of bacterial interactions with any kind of material surface requires integration of information from several disciplines, including materials science and engineering, microbial ecology, biochemistry and physiology, and electrochemistry. Basic microbiological knowledge is required for a better understanding of the role of microorganisms in corrosion and deterioration. In this chapter we will discuss microbial diversity and the physiological and biochemical properties of microorganisms with an emphasis on processes relevant to corrosion and degradation of materials.

B. DIVERSITY OF MICROORGANISMS

B1. Evolution and Diversity

Microorganisms are the early life forms preceding all other life on Earth. Mutation and genetic recombination and exchange coupled with natural selection contribute to the divergence of life over the 4.6 billion years of history. Natural selection is the key to the survival of individual species and also provides new opportunities for new ones to evolve. For the diverse life forms on Earth, schemes of classification of the invisible microorganisms have always interested biologists. Prior to the 1960s, biological species were classified solely based on their morphology, biochemistry, and physiology [51–53]. Using these approaches, biologists classified all living organisms into two distinctive kingdoms, the prokaryotes and the eukaryotes [54–59].

Modern molecular biology has contributed significantly to the insights of the fundamental relationships between organisms and the possible events during evolution of life by deciphering the genetic codes in the organism genome. In the case of bacteria, 16S ribosomal RNA (rRNA) has been widely used [60]. The 16S rRNA genes, which are ubiquitous in all biological species on our planet, were proposed to be chronometers for measuring evolutionary changes, and as a result evolutionary relationships between different biological species can be reconstructed by analyzing sequences of nucleotides in the rRNA genes [60].

Currently, the biological world is classified as consisting of Eukarya, Archaea, and Bacteria based on their 16S rRNA [60, 61]. The former prokaryotes were further divided

into Bacteria and Archaea as two distinct domains. Since Archaea consists of mostly single cells closely related to early evolutionary life, this domain includes microorganisms thriving in extreme environments, for example, alkaline, acid, high and low temperatures, high pressure, and a range of strictly anaerobic conditions. Further refined classification of Archaea has been made possible by molecular sequencing of 16S rRNA from isolated bacteria and cloned genes from a hot spring pool in Yellowstone National Park. Crenarchaeota, Euryarchaeota and Korarchaeota were proposed for these subdivisions in the phylogenetic tree [62, 63]. As molecular techniques are increasingly used to understand the basic biology and relationships between species, our concept of taxonomic classification and systematics in biology will face constant challenges and revision of the old dogma [64, 65].

B2. Biochemical and Physiological Diversity

Microorganisms also have diverse physiological and biochemical capabilities. For instance, they can be grouped based on their nutritional requirements. While all life forms require certain basic elements, such as nitrogen (N), phosphorus (P), and sulfur (S), they also need a source of carbon and electrons. Microorganisms can be classified based on their sources of carbon and electrons (Table 26.1). An autotroph (lithotroph) is an organism that is capable of utilizing carbon dioxide as the sole source of carbon and obtaining electrons through photosynthesis. At the present time, it is believed that all autotrophs can use organic forms of carbon, but many use carbon dioxide as the primary source. Examples include Fe-oxidizing bacteria. A heterotroph is a microbe that requires reduced forms of carbon for biosynthesis. Carbon dioxide can also be fixed to some extent by heterotrophs, but their primary sources of carbon are more reduced than carbon dioxide, such as glucose, cellulose, and humic materials. This group has probably the largest collection of species.

According to their primary source of energy, electrons and carbon, organisms have a range of nutritional forms (Table 26.1). Early classification schemes used this information exclusively. For example, see the second edition of *The Prokaryotes* [54] and the four-volume set of *Bergey's Manual of Systematic Bacteriology* [55–58]. General microbiology information can be found in a number of textbooks (e.g., Madigan et al. [53] and others [52, 66–68]).

B3. Ecological Diversity

Over the history of life on Earth, microorganisms have left evidence of early life in various unique environments, including deep-ocean thermal vents, hot springs, and sulfate-reducing and methanogenic habitats [59, 69–72]. Based on the environment where a microorganism thrives, microorganisms may be referred to as methanogenic, acetogenic, sulfate reducing (sulfidogenic), alkaliphilic, acidiphilic, barophilic, psychrophilic, and mesophilic. Based on their physiology and biochemistry, these bacteria reflect evolutionary history of life on Earth [73–76].

Contemporary microbiological techniques are incapable of yielding more than approximately 1% of the natural microbial population in laboratory cultures [77]. Difficulties are particularly encountered in isolation of new microorganisms from their natural environments. The majority of the natural microbial community has not been fully explored due to limited understanding of the physiological requirements by the microorganisms. It is commonly accepted that a diverse population of microorganisms is present in the environment, and our inability to culture most microorganisms (~99%) is a direct reflection of our lack of knowledge on the relationship between the microflora of natural habitats and their biochemical, physiological, and nutritional requirements. Corrosion and degradation processes under natural conditions are commonly associated with a mixed population of microorganisms and specific biochemical processes. Molecular cloning and nucleotide probing coupled with the polymerase chain reaction (PCR) provide some advantages in beginning to characaterize nonculturable microorganisms. And, in fact, the emerging field of metagenomics is

TABLE 26.1. Nutritional Types of a Range of Organisms

Nutritional	Organisms	Electron Source	Energy Source	Major Carbon Source
Chemoautotroph (chemoorganotroph)	Most bacteria fungi, protozoa, higher animals	Organic molecules	Electrons from reduced organic molecules	Reduced organic molecules
Chemoautotroph (chemolithotroph)	Hydrogen, iron, Nitrifying, and colorless sulfur bacteria	Reduced inorganic molecules	Electrons from inorganic molecules	Carbon dioxide
Photoautotroph (photolithotroph)	Purple and green sulfur bacteria, blue-green bacteria, algae, higher plants	Reduced inorganic molecules	Light	Carbon dioxide
Photoheterotroph	Purple nonsulfur bacteria, some eukaryotic algae	Organic molecules	Light	Reduced organic molecules

increasingly providing information on the biochemical properties of nonculturable microorganisms [78]. However, a detailed understanding of the physiological and biochemical processes that contribute to biocorrosion and biodegradation remains extremely difficult in the absence of pure cultures of the organisms under study.

C. MICROBIAL BIOFILMS

C1. Fundamental Concepts

Microbial biofilms are a collection of individual bacterial cells and aggregates of cells that are maintained on surfaces by electrostatic forces [26, 79] and/or by adhering exopolymers [21, 48]. Bacteria in planktonic solution are capable of colonizing surfaces of living tissues [80] and inert materials [20, 81, 82]. Formation of bacterial films on surfaces is a result of contact between bacteria and substratum surfaces by short-range forces. The initial contact with a surface is made possible by flagella, Brownian motion of the cells, or hydrodynamic forces. After the initial collision, some cells are freed from the surface by their physical motion or hydrodynamics of the medium, while others will remain on the surface and synthesize expolymeric materials. The production of exopolymers is thought to induce bacterial attachment [83–88]. A pure culture of *Bacillus megaterium* deposited on a membrane filter surface after incubation under laboratory conditions shows extensive space between cells with considerable production of extracellular materials (Fig. 26.1). Results indicate that cell-to-cell signaling molecules, which control the density of bacterial cells in the growth medium, triggers the synthesis of exopolymers when a specific density is reached [89], and more recent information suggests that interspecies communication between bacteria is also possible and may have considerable ecological implications [90].

Signaling between cells under laboratory conditions [89] induces attachment of *Pseudomonas aeruginosa*. Our understanding of how bacteria attach to surfaces and the initiator of the event is limited under natural conditions. Marshall and co-workers sggested that bacterial adhesion could be separated into two categories, reversible attachment and irreversible attachment [91]. Recently, Dalton and coworkers [92] observed that colonization on hydrophobic surfaces was characterized by the formation of tightly packed biofilms, in contrast to hydrophilic surfaces which exhibited sparse colonization and formation of long chains of more than 100 μm in length. Fletcher [93] and Wiencek and Fletcher [94] further proposed a series of models explaining the selectivity of modified monolayer surfaces of different materials on bacterial adhesion. Heterogeneity of biofilms is evident in both space and time [95–97], and multicellular organization may also have some role in biofilm structure and ecological function [98]. However, the fundamental mechanisms of bacterial adhesion and the behavioral response of bacteria to surface selectivity are still not completely known.

C2. Factors Affecting Biofilm Formation

Formation of microbial biofilms in natural and artificial environments follows a sequence of events: the initial adhesion of a conditioning film consisting of organic molecules on surfaces, recruiting of microorganisms to the surfaces, bacterial colony formation, and growth to a mature biofilm. Biofim growth, senescence, and sloughing off is a continuous process [99–103]. Biofilms are interfacial matrices affecting the physical and chemical conditions of the substratum. The initial events of bacterial attachment to a surface were investigated by Marshall et al. [91]. In their pioneering study,

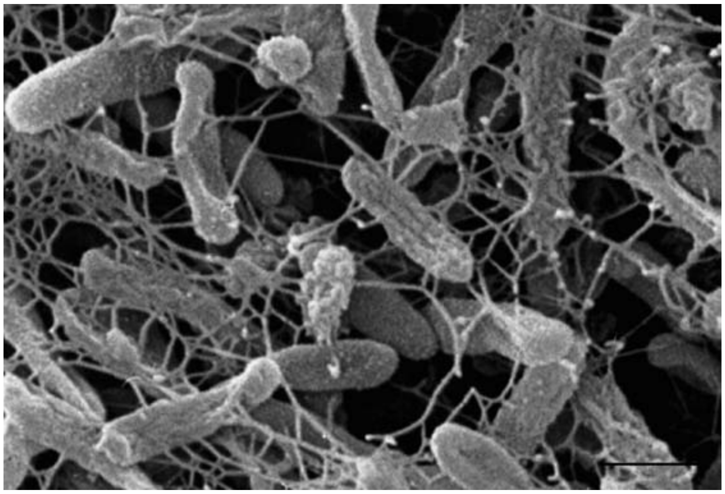

FIGURE 26.1. Scanning electron microphotograph of a pure culture of *Baccilus mageterium* on membrane filter and treated with dehydration and gold-palladium coating before viewing (scale bar, 2 μm).

Pseudomonas sp. adhered to glass slides either reversibly or irreversibly. Flagella promoted irreversible attachment by overcoming the short-range repulsion force between the bacterium and substratum when the distance between the two was very small. Planktonic bacteria may also settle on surfaces due to the presence of molecules that serve as cues for the bacteria [104, 105]. Fletcher [106] concluded that the structure of the surface materials also affects microbial adhesion. Hydrophobicity of a surface favors the formation of biofilms, while hydrophilicity discourages settlement [79, 107–110]. This generalization is not fully understood due to the lack of information about the physical chemistry of interactions between bacteria and surfaces.

A cell-to-cell signal was proposed as a key factor in the development of biofilms [89, 111]. *N*-Acyl homoserine lactone molecules were involved in mediating biofilm formation through a population-dependent process, in which the signaling molecules by bacteria respond to cell density and then induce the synthesis of exopolymers. More recent studies with pure cultures of *Mycobacterium avium* demonstrate that, at least with this organism, addition of the signaling molecule autoinducer-2 triggers an oxidative response mechanism that in turn induces biofilm formation. A similar response was also noted with simple addition of hydrogen peroxide, suggesting that biofilm formation is simply a response to environmental stress [22, 112]. However, bacteria in natural environments differ greatly from those in laboratory studies. Experimental results from the laboratory can be extrapolated only to a limited extent to the natural or artificial environments. After the initial attachment, reproductive growth and colony formation occurs. When the biofilm reaches a maximum thickness, the film may slough off due to hydrodynamic shear forces. The residual cells on surfaces divide and form new colonies; new biofilm will be developed again. During cell division, the daughter cell not attached to the surface may be released into the planktonic phase. The planktonic cells may also settle on newly available surfaces, providing initial colonization for biofilm development.

Physicochemical factors also influence biofilm formation. These include ionic strength, type of cation (valence and charge), concentration of the cation, presence of surfactant, and substratum surface characteristics. Microbiologists largely ignore this information [96, 105, 113]. Marshall discussed the fundamentals associated with this phenomenon [26]. Generally, higher ionic strength, concentration of ions, and higher valence of cations favor the formation of biofilms by decreasing the electric diffuse double layer, which is a barrier against bacterial movement toward a surface. When a bacterium approaches a surface, it must overcome a critical energy level before it can firmly attach. The higher concentrations and valence of cations can compress the diffuse double layer, bringing planktonic bacteria closer to substratum surfaces and facilitating adhesion.

C3. Some Properties of Microbial Biolfilms

C3.1. Biofouling. Biofouling is the undesirable accumulation of microorganisms, their products, and various deposits, including minerals and organic matter, on a substratum surface. The thin film on fouled surfaces usually consists of microorganisms embedded in an organic matrix of biopolymers, which are produced by the microorganisms under natural conditions. Biofilms of various microorganisms can be visible on stone surfaces in tropical climates (Fig. 26.2). In addition, microbial precipitates, minerals, and corrosion products may be present [83, 114]. Industrial fouling is a complex phenomenon involving interactions between chemistry, biology, and materials science. The fouling products may include inorganic particles, crystalline precipitates and scale, and corrosion products. Fouling is common and can be found in purified water systems [115], drinking water filtration and treatment facilities [116], wastewater treatment plants [117, 118], porous media [119–123], and biotechnology processes [124]. In addition, materials immersed in aqueous environments or under high-humidity conditions are also susceptible to biofouling, including both metallic and nonmettalic materials [4, 14, 28, 125–127], urinary catheters [82, 128], water pipes [129], and coatings [125, 130, 131].

C3.2. Changes in Local Environment. Establishment of microbial biofilms on the surface of materials changes the surface chemical properties due to the presence of microbial cells and exopolymeric products. Accumulation of biomass also changes the local environment in terms of water content, which in turn affects expansion/contraction upon heating or cooling [11]. Such physical modifications of the local environment have considerable impacts on the substratum materials and their subsequent susceptibility to further colonization by microorganisms.

C3.3. Heat Transfer Resistance. Biofilms form on a wide range of engineering materials, particularly on equipment used for cooling and transport. They reduce performance and the lifetime of the materials. The thickness of a biofilm may reach between 50 and 100 μm depending on physiochemical conditions of the environment, hydrodynamics of flow, and availability of nutrients. Individual bacterial cells within this layer of gelatinous exopolysaccharides are embedded in the heterogeneous porous matrices, and nutrients may diffuse and be transported in void channels throughout the biofilm matrices [132]. Biofilm establishment on surfaces increases frictional resistance, reduces heat transfer efficiency, and causes pitting corrosion of a variety of alloys. Both aerobic and anaerobic conditions provide opportunities for a metabolically diverse community of microorganisms. When the substratum materials are metals, corrosion may occur, resulting in the buildup of corrosion products on surfaces [133].

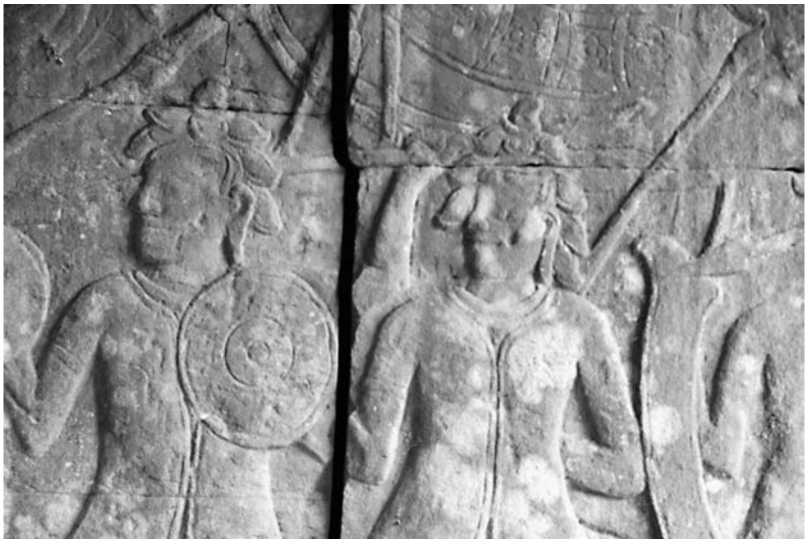

FIGURE 26.2. Photograph of natural biofilm community with different colors on sandstone bas-relief of Bayon Temple in Angkor Thom of Cambodia.

Deposited corrosion products may reach a significant thickness that prevents efficient transfer of heat across the cooling pipes and also a significant increase in friction resistance [28, 31, 134]. These changes in surface characteristics affect system performance.

Biofilms may also serve as crucial chemical cues for recruitment of invertebrates [101, 135–137]. Macrofouling is problematic to the power and water industries due to the blockage of pipes and biomass accumulation on surfaces. For example, the freshwater invertebrate zebra mussel (*Dreissena polymorpha*), an accidentally introduced species, has been a serious problems for both the power and drinking water industries in the Great Lakes region of the United States since the 1980s. The combination of heat transfer reduction and corrosion from macrofouling was estimated to be $5 billions for the power-generating industries by 2000 [138].

C3.4. Clogging of Pipes and Porous Media. Another consequence of microbial growth on surfaces, particularly as a result of MIC, is clogging of water distribution systems by corrosion products [30, 139]. Iron-oxidizing bacteria are partially responsible for the clogging under aerobic and microaerophilic conditions. In porous media, bacterial transport and accumulation generally decrease with distance along the flow path, especially if hydrodynamic and shearing forces are low. Bacteria are not easily transported through a tortuous path, and they become attached after a number of collisions on sediment surfaces [140, 141] and synthetic materials. Exopolymers of bacteria also participate in the corrosion of metals and have been shown to solubilize Cu from pipes under soft water conditions [142, 143]. Clogging may also be observed in wastewater treatment facilities through aggregation of microorganisms in the presence of nucleating agents.

Porous media in subsurface environments are important for bioremediation of contaminated groundwater. Clogging is a common problem in bioremediation. Negatively charged bacteria may readily adhere to surfaces by electrostatic attraction, hydrogen bonding, cation bridging, and/or exopolymers, particularly under low nutrient conditions. Transport of bacteria and collision of bacteria on surfaces are a focus of several recent studies [140, 141]. Bacterial preference for surfaces makes bioremediation *in situ* difficult as exogenous organisms are not readily transported through porous media for effective mobility and bioremediation. In addition, aromatic and polyaromatic pollutants are mostly adsorbed on minerals or organic matter because of their hydrophobicity. Similar problems are also commonly encountered in oil drilling and recovery following seawater injection; clogging may be so severe that the less accessible oil reserves are not recovered. When seawater is introduced, the high ionic strength of the medium promotes microbial production of exopolymeric materials.

C3.5. Corrosion and Deterioration. Activity of microorganisms on surfaces may result in adverse effects on underlying materials, particularly corrosion and deterioration. Corrosion of metals and deterioration of polymers have been reviewed [1, 5, 9, 14, 29]. Corrosion is an electrochemical process induced or accelerated by the presence of microorganisms and their active metabolism [15], while deterioration of polymer is a metabolic process by which microorganisms obtain carbon and energy for their growth. Both corrosion and degradation can take place under aerobic and anaerobic conditions.

Corrosion of metals results in a decrease in tensile strength of the materials and may result in failure of the system. In industrial environments, the consequence of biocorrosion can be catastrophic. Microbial contamination is common even in ultrapure water systems used by pharmaceutical industries and semiconductor manufactures [115]. Several groups of microorganisms have been recognized for their role in corrosion, including the sulfate-reducing bacteria [29, 75], exopolymer-producing bacteria [48], hydrogen-producing and hydrogen-utilizing bacteria [1, 33], acid-producing bacteria, Fe-oxidizing bacteria [144, 145], and fungi [50]. The manganese oxidizing bacterium *Leptothrix discophora* is capable of ennoblement of stainless steel by increasing the open-circuit potential through deposition of MnO_x on surfaces [28, 146]. A correlation between microbial activity and deposition of MnO_x has been established by Dickinson et al. [146], and similar observations have also been reported [147]. Specific mechanisms of corrosion are discussed previously [148] and also in Chapter 39 of this book.

C3.6. Biocide Resistance. Biofilms protect microorganisms from activity of biocides because mass transfer is diffusion limited within the biofilm [149–158]. In order to effectively eradicate biofilms on surfaces, higher concentrations of biocides are often used (Fig. 26.3). Biofilm bacteria are in an environment where gene exchange may occur at high frequency [159–162], and resistance may therefore develop rapidly to a specific chemical, forcing the use of alternative treatments.

Biofilm bacteria respond to biocide concentration levels differently from planktonic bacteria. The efficacy of a biocide should be tested against both planktonic and biofilm bacteria under closely simulated environmental conditions. For example, a biocide for protection of polymeric coatings should be tested in the proposed coating materials and exposed under the relevant conditions [5, 6]. Polymeric materials also contain plasticizers which can be utilized by microorganism as a source of carbon and energy [163, 164]. Such growth-promoting effects of chemicals leaching from these materials can sustain levels of microbial activity and growth not seen in culture solutions. Because of this, extended tests may be needed [165].

D. DIAGNOSIS AND CONFIRMATION

Microbiology as a discipline began when small cells were first observed by Anthonie van Leeuwenhoek under a microscope in 1677 [166, 167]. His observation opened up an unrecognized world. Louis Pasteur investigated microbial contributions to disease in humans and animals and to fermentation of wine and vinegar to improve the quality of these products. Robert Koch advanced the field of medical microbiology and postulated the theory of disease (Koch's postulates) as follows in 1884 [168]:

1. The organism should be present in all animals suffering from the disease and absent from all healthy animals.

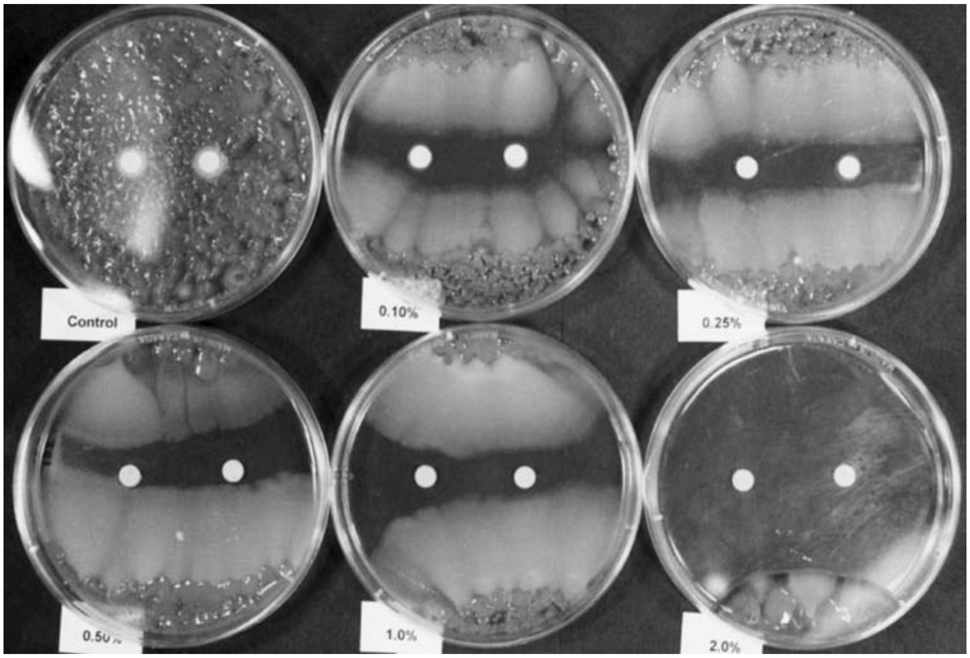

FIGURE 26.3. Photograph showing efficacy of biocide at range of concentrations (0, 0.10, 0.25, 0.50, 1.0, and 2.0%) applied on absorbent filter paper disks on agar plates which were previously inoculated with a testing population of microorganisms on the whole surface.

2. The organisms must be grown in pure culture outside the diseased animal host.
3. When such a culture is inoculated into a healthy, susceptible host, the animal must develop the symptoms of the disease.
4. The organism must be reisolated from the experimentally infected animal and shown to be identical to the original isolate. Today, Koch's postulates remain sound guidelines for medical professionals to prove or disprove the presence of a microbial infection.

Koch's approach can be utilized in research on corrosion and degradation of materials. In this case, organisms should be isolated from the damaged materials to verify their presence. The organisms should be cultured and purified and used to examine corrosion and degradation processes in the laboratory. If corrosion or degradation similar to the initial observation can be duplicated, damage to the material can be linked to the activity of the organisms. Obviously, equipped with molecular fingerprinting techniques and isotope labeling, much higher sensitivity and level of sophistication can be achieved for confirmation of microbial involvement and for understanding the mechanisms.

Uncharacterized mixed cultures have also been used to study degradation and deterioration of polymeric materials [34, 35, 40, 41, 81, 169–171], concrete [45, 172], and metal corrosion [1, 4, 29] and degradation of environmental pollutants [16, 173–175]. Such approaches together with fluorescence *in situ* hybridization (FISH), denaturing gradient gel electrophoresis (DGGE) [176], and stable isotope analysis should allow confirmation of the microorganism's involvement in degradation and deterioration at much higher resolution and sensitivity than currently available with traditional techniques.

E. MATERIAL DEGRADATION PROCESSES

E1. Sources of Carbon and Energy

Organic materials may be utilized by microorganisms as sources of carbon and energy in the presence or absence of molecular oxygen. During degradation, reduced carbon is oxidized, releasing electrons, which are used in bacterial synthesis. Different groups of microorganisms use widely divergent strategies to achieve the goal of decomposition. For example, eukaryotic fungi degrade polymeric materials using extracellular depolymerases. Most bacteria require close proximity to a substratum because the bacteria need to immediately capture the released compounds. This efficient process permits bacteria to maximize their energy conservation. Close proximity allows degradation products to be easily assimilated into cells for further metabolism [5, 6].

Metals can be corroded by bacteria through oxidative processes. Examples are iron- and manganese-oxidizing bacteria [144, 145], which clog drains, water pipes, and wells with deposition of iron oxides and hydroxides [30, 144]. These bacteria are lithoautotrophs utilizing CO_2 from the atmosphere and electrons from metal corrosion for their carbon sources and energy. Most of these bacteria are microaerophilic. Optimal growth is achieved under conditions of reduced oxygen tension/concentrations. *Leptothrix*, *Gallionella*, *Metallogenium*, and *Pedomicrobium* are the most commonly described bacteria [30, 177]. New metal-oxidizing species have been isolated recently [145].

Biological corrosion of metals was described more than 60 years ago [178, 179]. Mechanisms of microbial corrosion are discussed in several reviews [1, 28, 29, 31, 134].

E2. Degradation of Polymers

Some polymers support the growth of microorganisms without structural degradation. Additives to polymers are primarily responsible for the observed results [4, 6, 41, 126, 127]. Because bacteria are capable of cometabolism, polymers that are difficult to degrade can be metabolized when other carbon and energy sources are available for growth, altering the mechanical properties and integrity of the polymer. This phenomenon is particularly important in the degradation of polymers used in the electronic, transportation, and infrastructure industries. For example, a slight alteration of the insulation property of a polymer may result in devastating consequences to the proper functioning of integrated circuitry in storing and transmission of data.

E3. Attack of Metals and Concrete by Microbial Metabolites

Damage to materials is frequently incidental to microbial metabolism. For example, organic acids from fungi were found to corrode aluminum alloys in aircraft fuel tanks [50], and H_2 produced by fermenting bacteria may contribute to hydrogen embrittlement of metals under anaerobic conditions [15, 48]. Hydrogen sulfide (H_2S) from sulfate-reducing bacteria attacks both metals [1, 29, 31, 180] and stone materials [4, 10, 45].

Large quantities of exopolymeric materials can be produced by bacteria on surfaces. These materials may bind metal ions and contribute to galvanic corrosion of metals [47] and concrete [45].

F. PREVENTIVE MEASURES

Microorganisms require minimal quantities of water to survive. Active metabolism requires an appropriate relative humidity and temperature. A combination of low humidity

and low temperature is the simplest way to control bacterial growth [6, 81]. However, fungi are capable of growing under such conditions. Regular cleaning is good practice to prevent biofilm formation and subsequent biodeterioration.

Microbial biocides are commonly used to prevent unfavorable biofilm formation and biofouling. These chemicals are widely incorporated into products, including toys, filtration systems, coatings, and surface-cleaning agents. Because microorganisms are capable of acquiring resistance after exposure to a particular chemical [160–162], no single chemical can be relied on for long-term use. Frequently, effective eradication of microbial populations is achieved by alternating chemicals or increasing the concentrations of a biocide.

In nature, bacteria normally live on surfaces. However, biocide efficacy tests often involve utilization of planktonic bacterial cultures on agar plate (Fig. 26.3). These test data fail to reflect the actual state of bacteria on material surfaces [6, 81]. More rigorous simulation of environmental conditions is highly recommended. For example, several biocides, including diiodomethyl-*p*-tolylsulfone, were excellent biocides in laboratory testing using planktonic cultures, but active growth of microorganisms was observed when the biocide was incorporated into a polyurethane coating [81]. Some biocides may also contain chemicals that support the active growth of environmental microorganisms, because the active ingredient diffuses out of the biocide formulation on test disks much too rapidly, leaving the formulation chemicals to support microbial metabolism (Fig. 26.4). Microbial resistance to biocides is also of concern to public health because of growth of nuisance organisms and pathogens in, for example, air-conditioning systems, drinking water, and water-heating systems.

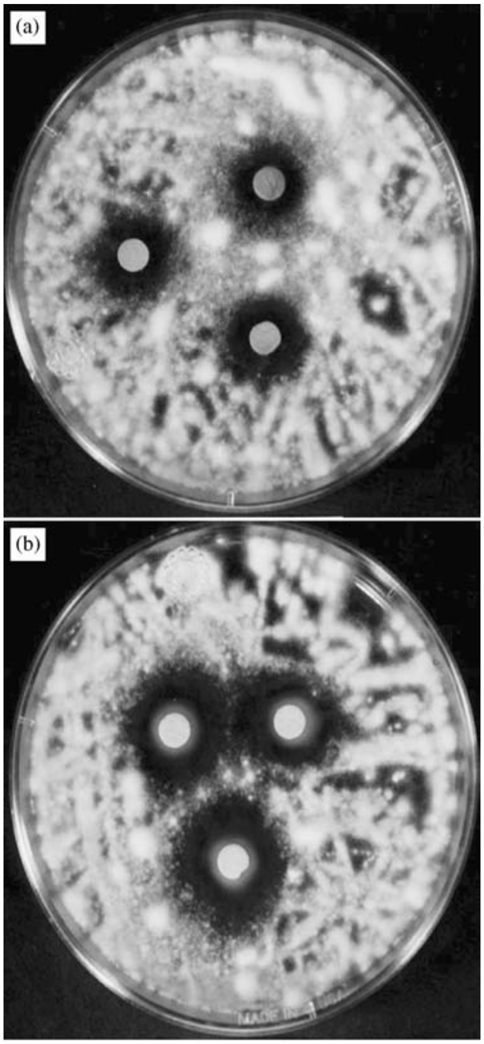

FIGURE 26.4. Photographs showing (a) effective inhibition of test organisms around filter paper disks on surface of agar plate with test chemical embedded in disks and (b) inhibition of test organisms around filter paper disks on surface of agar plate and also active growth of microorganisms on paper disks where test chemical was initially embedded.

G. CONCLUSIONS

Biodegradation of materials is common under both oxic and anoxic conditions. Microorganisms develop strategies to extract electrons and carbon sources from both polymers and metals. During microbial growth on surfaces, metabolites, enzymes, and other exopolymeric materials also affect the underlying materials. Koch's postulates provide an excellent means of associating a degradation process with a causative organism. Degradation may involve the utilization of a polymer for carbon and energy, resulting in mineralization of the materials. Components of a polymer may become substrates for microbial growth, weakening the mechanical properties of the material. Other mechanisms of degradation include corrosive metabolites, for example, H_2S, H_2, organic acids, and exopolymeric materials. Under natural conditions, several of these mechanisms often operate simultaneously. Biofilm formation plays an important role in material degradation, deterioration, and corrosion; microbial films are heterogeneous in both space and time and contain a wide diversity of bacterial species within the gelatinous matrices. Effective eradication of biofilms is difficult because of the phenotypic plasticity and genetic mobility of transferable plasmid genes.

ACKNOWLEDGMENTS

We would like to thank EM Unit at Queen Mary Hospital, The University of Hong Kong, for assistance in taking the scanning electron micrographs used here. We would also like to thank Jessie Lai for helping with the image digitization.

A. INTRODUCTION

Corrosion engineers and scientists are often asked to estimate the corrosion rate of a specific material in a specific environment in order to predict the engineering lifetime. To obtain information to answer such a question, corrosion specialists review all available data in databases accessible to them, as well as in books and in journal literature. Data on general corrosion under commonly encountered conditions, such as steel exposed to the atmosphere, to marine environments, and to soils, are readily available and can be used for lifetime prediction. These data can also be utilized for design purposes, so that the material is made of the thickness required to achieve the desired lifetime, assuming general corrosion is the predominant mode by which degradation will occur during service.

Data on localized corrosion, however, are limited and can be used only for making go–no go decisions on usage of the material in a given environment. For systems that undergo localized corrosion, the corrosion rate cannot be used to predict lifetime. For these systems, the concept of corrosion probability has been introduced for lifetime prediction [1]. The probabilistic concept is essential for quality control, to ensure high-quality products, and in reliability engineering [2], which is a basis for highly efficient production systems in advanced industries.

Corrosion engineering could gain a greater level of confidence if the corrosion probability concept were widely used for estimating lifetime. Probability concepts and statistical procedures, however, can be somewhat difficult for corrosion scientists and engineers to learn, although many textbooks on statistics are available. Although the American Society for Testing and Materials (ASTM) standard G16 [3] is quite helpful in understanding statistical practices for analyzing corrosion data, further insights into corrosion probability, including recent progress, would be very useful. In this chapter, the basic concept of corrosion probability is discussed, along with statistical procedures, based on probability plots, and related topics that have been successfully applied to analysis of corrosion data.

B. CORROSION PROBABILITY

Mears and Evans [4] designed an interesting experiment for demonstrating the concept of corrosion probability. As illustrated in Figure 27.1, wax lines were drawn on the surface of an iron plate, dividing the surface area into N sections, which were then covered with a thin film of water. This procedure was equivalent to preparing N separated specimens exposed to an identical corrosion condition. After exposure for a fixed time under a mixed-gas atmosphere consisting of oxygen and nitrogen, n squares were corroded. The corrosion probability, P, was calculated as

$$P = \frac{n}{N} \tag{27.1}$$

The mean weight loss, Q, for a corroded square could be calculated from the total weight loss, W, divided by n. Then the total weight loss of the specimen, W, is given by

$$W = NPQ \tag{27.2}$$

Mears and Evans [4] demonstrated that both the probability and corrosion rate, equivalent to Q, are functions of the gas composition.

For iron, the corrosion rate increases with increase in the oxygen content in the gas, whereas the corrosion probability changes in the opposite direction, from $P = 1$ to $P = 0$, with increase in the oxygen content, as shown in Figure 27.2. The total weight loss, W, given by Eq. (27.2), shows a maximum at 8% oxygen because of the changes, in opposite directions,

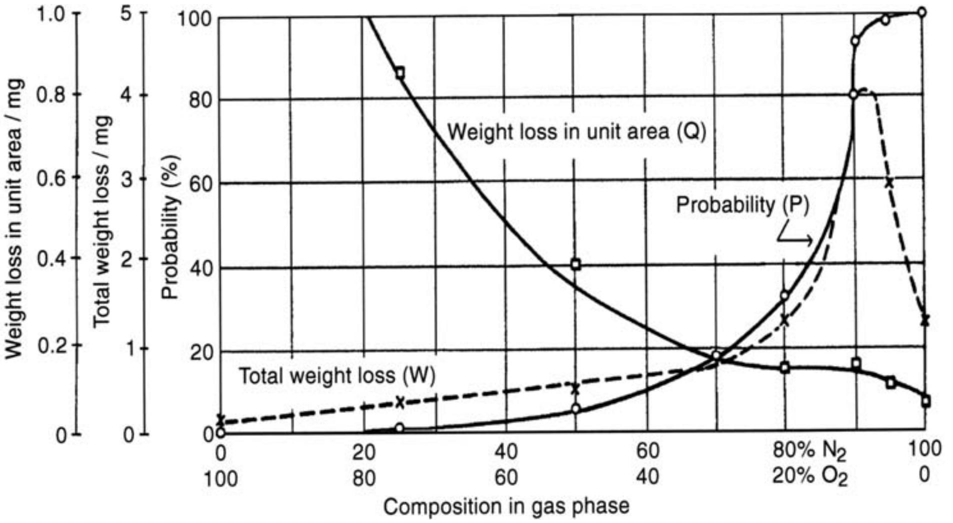

FIGURE 27.2. Corrosion probability, total corrosion loss, and corrosion loss per unit area as function of atmospheric gas composition.

of corrosion probability and corrosion rate with gas composition.

For iron immersed in an aqueous solution of potassium chloride, however, both the corrosion probability and the corrosion rate increase with increase in KCl concentration, resulting in a continuous increase in *W*, with no maximum. Thus, Mears and Evans [4] succeeded in demonstrating that corrosion probability, rather than the corrosion rate, control the overall weight loss.

B1. Corrosion Probability and Rating Number

For coated steel, galvanized steel, and stainless steel, the surface appearance rather than weight loss is important in many engineering applications. Stain, rust spots, and various types of defects, such as debris and scratches, can degrade the surface appearance. Degradation of surface appearance cannot be judged by weight loss because there is usually no significant loss in weight.

A measure called the rating number (RN) is often used for evaluating the degree of surface degradation. A numerical value of RN is estimated by comparing the surface appearance of the specimen with that of a standard figure, which is provided in various industrial standards. Examples of standard figures for assessing RN are shown in Figure 27.3 [5]. As shown in Figure 27.3, an increase in the number of rust spots and/or in the area of spots causes an increase in the total corroded area, the numerical value of which is shown below each figure. Corresponding to the increase in the total corroded area, the RN, indicated above each figure, decreases. The RN is related to the corroded area, *R*, of the specimen as follows;

$$\mathrm{RN} = a - b\log(R) \tag{27.3}$$

where a and b are constants. The correlation is illustrated in Figure 27.4. The total corroded area, or the percentage of the

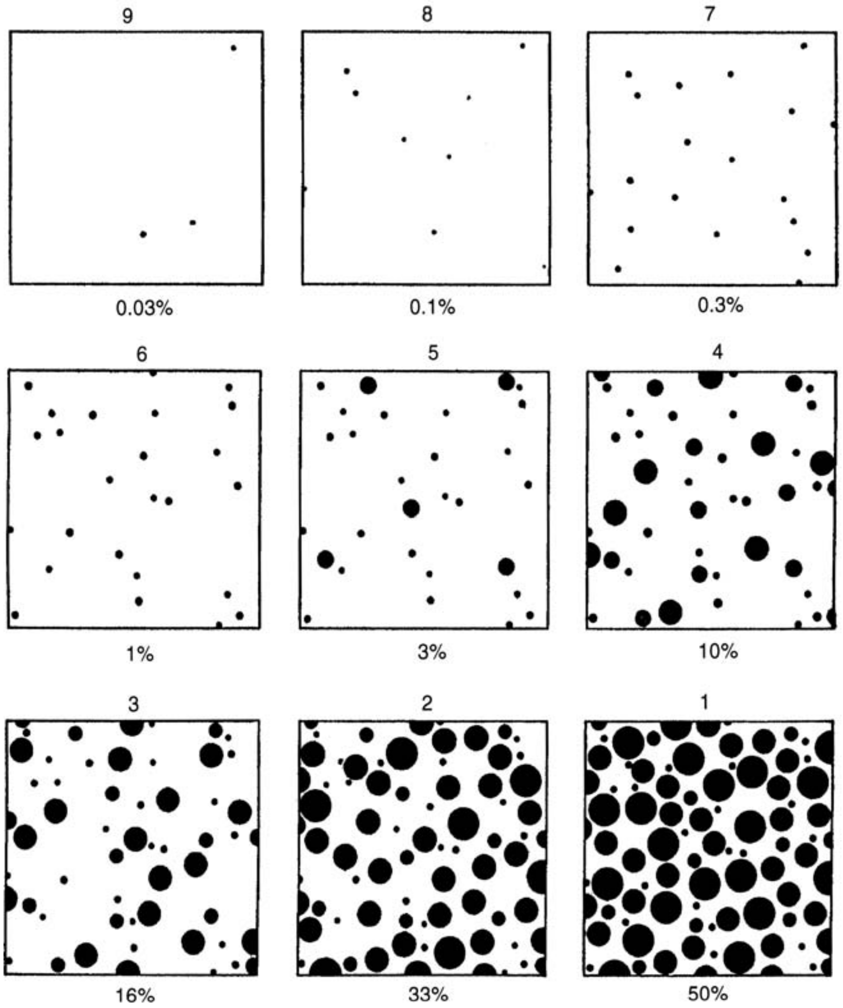

FIGURE 27.3. Examples of model patterns of rust spot distribution with the rating number and total corroded area.

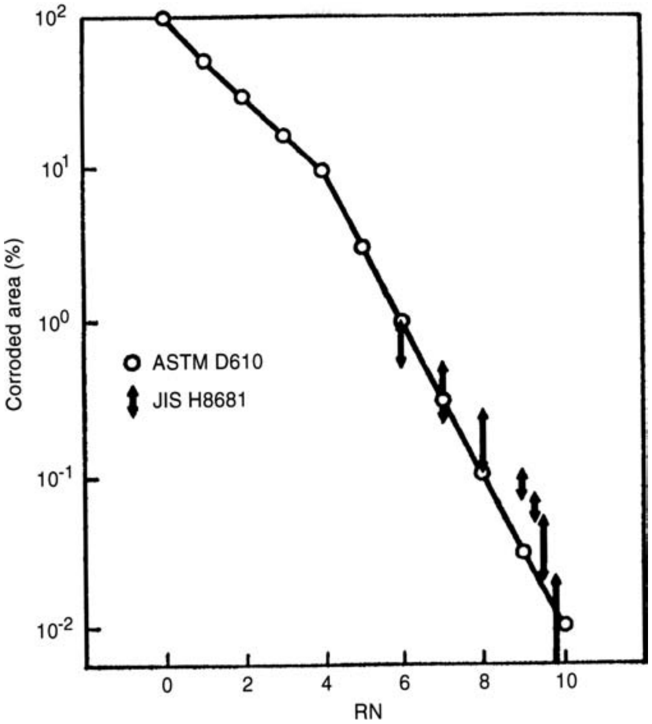

FIGURE 27.4. Total corroded area as function of RN.

total area that is corroded, can be assessed by adding all the areas, a_j, covered by rust spots on the surface:

$$R = \frac{\sum a_j}{A} \quad j = 0, 1, 2, 3, \ldots, n \tag{27.4}$$

where A is the surface area of the specimen, and R is the normalized corroded area. The parameter R is the probability of corrosion occurrence on a two-dimensional (2D) scale and is equivalent to the corrosion probability given by Eq. (27.1).

It is interesting to note that the linear response of RN to $\log(R)$ shows an inflection at RN $= 4$, suggesting a different mechanism on the severely corroded surface (RN < 4) compared with that on the slightly stained surface (RN > 4). In the case of corrosion of stainless steel near the seashore, clustering of the rust spots may be responsible for the change in slope above RN $= 4$, which will be discussed later in this chapter in the section on spatial distribution affecting surface appearance.

C. TYPES OF PROBABILITY DISTRIBUTION OBSERVED IN CORROSION

The distribution of corrosion data can be reduced to several basic probability distributions, which are listed, along with examples, in Table 27.1 [6–14]. Characteristic features of each type of distribution are discussed in the following paragraphs.

TABLE 27.1. Various Probability Distributions Observed in Corrosion

Probability Distribution	Examples in Corrosion	Reference
Normal distribution	Pitting potential	6
Lognormal distribution	SCC[a] failure time	7
Poisson distribution	Two-dimensional distribution of pits	8
Exponential distribution	Induction time for pit generation	9
	SCC and HE[b] failure time	10
Extreme-value distribution		
Gumbel distribution	Maximum pit depth	11
Weibull distribution	SCC failure time	12
Generalized extreme-	Maximum pit depth	13
value distribution	Fatique crack depth	14

[a]Stress corrosion cracking (SCC).
[b]Hydrogen embrittlement (HE).

C1. Normal Distribution

The normal (or Gaussian) distribution is frequently used. The normal distribution is a bell-shaped curve which fits the histogram of most corrosion data. The curve is described by the probability density function, $f(x)$:

$$f(x) = \left(\frac{1}{\sigma\sqrt{2\pi}}\right)\exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] \tag{27.5}$$

where μ and σ are the mean and standard deviation, respectively, which determine the shape of the curve. The area under the curve gives the probability of occurrence, calculated by the cumulative probability function, $f(x)$;

$$F(x) = \int f(x)\,dx = \left(\frac{1}{\sigma\sqrt{2\pi}}\right)\int \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right]dx \tag{27.6}$$

If reduced variate, s, is given by

$$s = \frac{x-\mu}{\sigma} \tag{27.7}$$

then $F(x)$ can be reduced to a standardized cumulative function, $F(s)$;

$$F(s) = \left(\frac{1}{\sqrt{2\pi}}\right) \int \exp\left(-\frac{s^2}{2}\right) ds \qquad (27.8)$$

Numerical values of $F(s)$ can be found in tables of the cumulative normal distribution.

Graphical analysis using normal probability paper to estimate the distribution parameters of μ and α is simple and useful for engineering applications. Normal probability paper is constructed with values of s on one axis and the cumulative probability, $F(s)$, given by Eq. (27.8) on the same axis. On the other axis, x is plotted on an arithmetic scale. Then the cumulative probability, $F(x)$, obeying the normal distribution can be plotted as a straight line using normal probability paper. To plot the line, the data are arranged in ascending order of value, and the plotting position [3] for cumulative probability is calculated by Eq. (27.9):

$$F(x) = \frac{\left(i - \frac{3}{8}\right)}{\left(N + \frac{1}{4}\right)} \qquad (27.9)$$

where i is the position of the data point in the rank and N is the total number of data points. Instead of Eq. (27.9), another simple equation of $i/(1 + N)$ can be used for calculating the plotting position, but Eq. (27.9) is recommended for use with normal probability plots because it gives almost unbiased estimates of the standard deviation from the slope of the linear plot.

Table 27.2 is a working table for plotting measured values of pitting potential of Type 304 stainless steel on normal probability paper. The first column is the position of the data point. The measured values are arranged in ascending order and are tabulated in the second column. In the third column, the cumulative probabilities given by Eq. (27.9) are listed.

[b]Saturated calomel electrode.

Each set of [x, $F(x)$], for the pitting potential and the corresponding cumulative probability can be plotted on normal probability paper. The straight line fitting the points, shown in Figure 27.5, indicates that the measured data obey the normal probability distribution. The mean value of μ can be obtained at the 50% point. The standard deviation is the difference between the values at the 50% point and at the 84.13% point, or the slope of line because the slope is proportional to $1/\sigma$. In this case, the values shown in Figure 27.5, $\mu = 0.277$ and $\sigma = 0.015$ are the same values as those obtained by numerical calculation and shown in Table 27.2.

C2. Lognormal Distribution

The probability density function and the cumulative function of the lognormal distribution are given by

$$f(x) = \left(\frac{1}{\zeta x\sqrt{2\pi}}\right) \exp\left[-\frac{(\ln x - \ln\delta)^2}{2\zeta^2}\right] \qquad (27.10)$$

$$F(s) = \left(\frac{1}{\sqrt{2\pi}}\right) \int \exp\left(-\frac{s^2}{2}\right) ds \qquad (27.11)$$

where

$$s = \frac{\ln x - \ln\delta}{\zeta} \qquad (27.12)$$

By introducing the reduced variate s, the cumulative probability function of the lognormal distribution can be converted to the same form as the normal distribution expressed by Eq. (27.8). Then, normal probability paper can be used for plotting the data set, obeying the lognormal distribution by changing the x axis from an arithmetic scale to a logarithmic scale.

Data for failure times by SCC of stainless steel in boiling $MgCl_2$ solution at 154°C are listed in Table 27.3. Plotting the data set of [log x_i, $F(x_i)$] on normal probability paper results in a straight line, as shown in Figure 27.6. Again, mean and standard deviation can be determined from data at the 50% point and at the 84.13% point, respectively.

C3. Poisson Distribution

The Poisson distribution is used to describe random phenomena observed in rare events. Pit generation is a good example of a random process that can be described using a Poisson distribution. An example of random occurrence of pitting is shown in Figure 27.7 [15], in which pits in the passive film on Type 304 stainless steel were identified by platinum decoration using a displacement reaction in boiling $MgCl_2$ solution. The spatial distribution of pits on the surface was evaluated by counting the number of pits per unit area of $0.5\,\mu m \times 0.5\,\mu m = 0.25\,\mu m^2$. The results are summarized

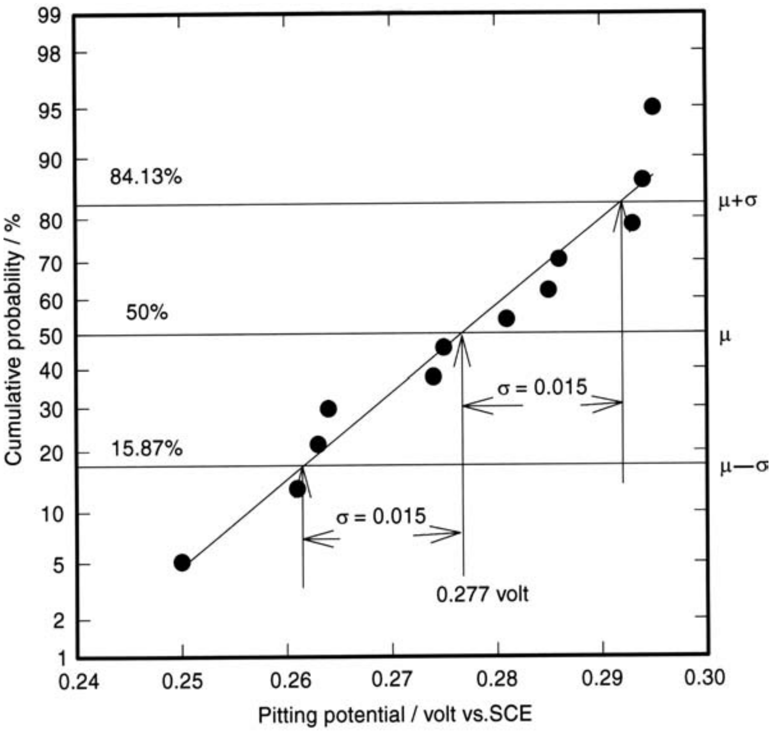

FIGURE 27.5. Probability plot for distribution of pitting potential on normal probability paper, from which mean μ and standard deviation σ can be determined.

in Table 27.4, and the distribution curve is shown in Figure 27.8 [24]. The open circles are observed values, and the closed circles are theoretical values calculated by assuming the Poisson distribution, expressed as,

$$P(x) = \left[\frac{(m)^x}{x!}\right]\exp(-m) \qquad (27.13)$$

[a]Sum: 1601, mean: 1601/14 = 114.4, standard deviation: 24.8.

where $P(x)$ is the probability of occurrence of x pits in unit area and m is the mean. Good agreement between the data points and the curve suggests that pit generation in the passive film occurs according to a Poisson process with mutual independent events. Deviation of the observed points from the theoretical curve was found in an A1 alloy and was attributed to a mutual interaction of the pit generation process, as pointed out by Mears and Evans [8].

C4. Spatial Distribution Affecting Surface Appearance

Spatial distribution of rust spots affects the surface appearance, which is sometimes more important than weight loss. Degradation in the surface appearance is usually evaluated by visual inspection. Quantitative evaluation can be achieved by rating the surface appearance as RN, which is simply related to the total corroded area. It should be noticed, however, that a simple RN may not satisfy the observer's intuition because the surface appearance could be affected not only by the total corroded surface area, but also by the distribution pattern of the corroded areas over the total surface.

Figure 27.9 shows patterns of the distribution prepared by Masuko [16, 17] in which nine different patterns with the same RN are demonstrated. Figure 27.9(a), which looks like a lattice of crystal, is called a regular pattern, and

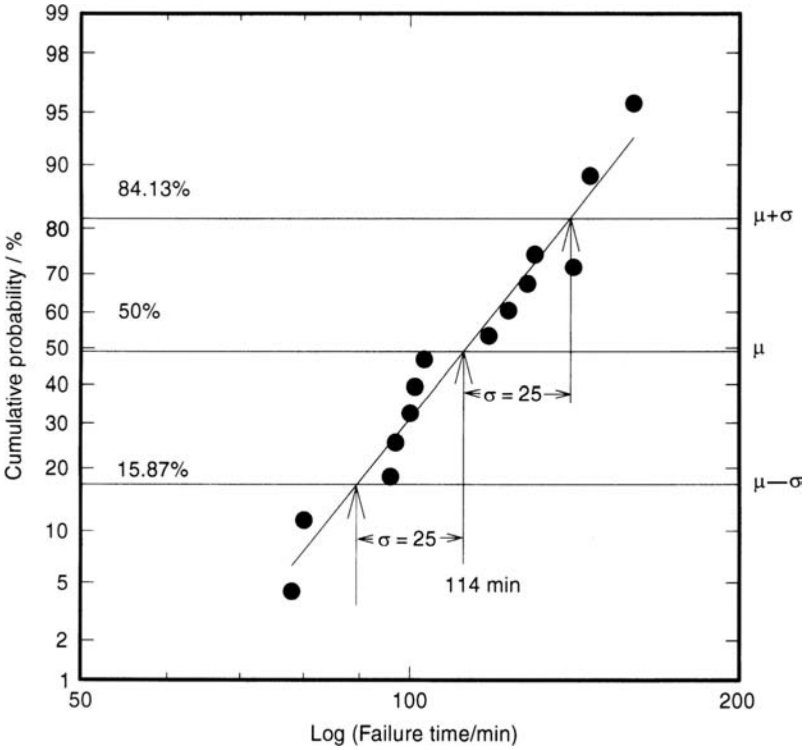

FIGURE 27.6. Probability plot for distribution of SCC failure time on lognormal probability paper, from which mean μ and standard deviation σ can be determined.

Figure 27.9(i) is called a singular or clustered pattern because spots aggregate or localize at separate local sites. Patterns in Figures 27.9(c) and (d), however, show a random appearance. It has to be emphasized, again, that all nine figures have the same RN but provide quite a different visual impression. Another index is required for quantitatively characterizing the patterns. For corroded surfaces, the mode of localization is important for characterizing the distribution pattern. The mode of localization is an important topic in ecology [18] and is analyzed based on spatial analysis theory. In order to describe the mode of localization in corrosion, Masuko [16, 17] introduced a homogeneity function expressed as

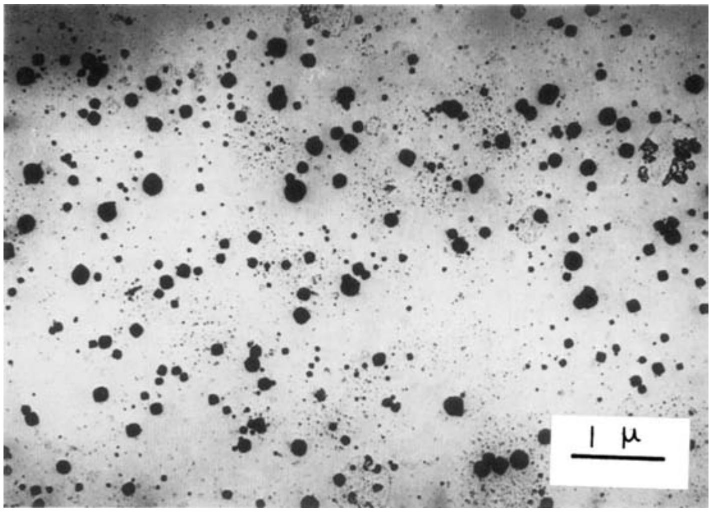

FIGURE 27.7. Transmission electron microscopy (TEM) photograph showing random distribution of pits on surface of Type 304 stainless steel.

TABLE 27.4. Frequency Distribution and Theoretical Probability of Pit Distribution[a]

x	f	xf	f/163	$P(x)$

Sum	163	418	1.000	0.994

[a]Mean = 418/163 = 2.56.

$$H = \sum \left(\frac{q_j}{q_T}\right) \ln \left(\frac{q_j}{q_T}\right) \tag{27.14}$$

where $q_j (j = 1,2,3, \ldots, N)$ is the number of pits in the jth divided area and q_T is the total number of pits observed on the entire surface, which is divided into N equal areas. The proposed function, H, of Eq. (27.14) has a maximum value when q_j is the same in every area, corresponding to a uniform distribution, and $H = 0$ when all pits concentrate in one area, that is, $q_j = q_T$ for one area whereas q_j is zero for all the other areas. A quantitative expression for deviation from a

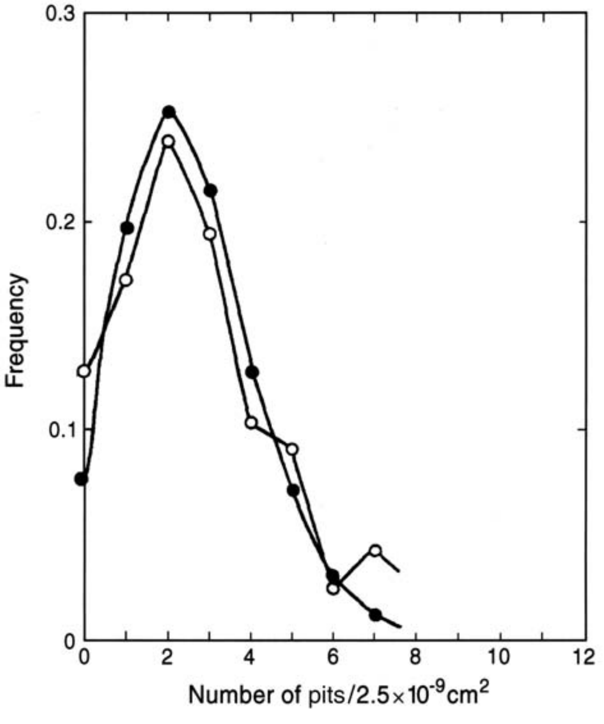

FIGURE 27.8. Distribution curves of pits obeying Poisson distribution.

TABLE 27.5. Indexes for Identifying the Distribution Pattern

	Regular	Random	Cluster
D	$D > 0$	$D = 0$	$D < 0$
V/m	$V/m < 1$	$D/m = 1$	$D/m > 1$

completely random distribution can be calculated using the following function of D:

$$D = H - H_0 \tag{27.15}$$

where H_0 is calculated from the distribution of q_j for the Poisson distribution because a completely random distribution can be produced by the Poisson distribution.

It should be noted that the Poisson distribution has the same value of mean, m, and variance, V. The ratio, V/m, equals unity if the observed distribution obeys the Poisson, or random, distribution. If there is deviation from a random distribution, the ratio $V/m < 1$ or $V/m > 1$. The ratio of the variance to mean, V/m, for an observed distribution is a simple measure for evaluating the deviation from complete randomness. The same argument could be made for H and D functions of Eqs. (27.14) and (27.15). Thus D and V/m can be used to differentiate three basic patterns of localization of pits; the regular, random, and clustered patterns by using the rule shown in Table 27.5. Martin and Mcknight [19] used the variance to mean ratio, V/m, for evaluating clustering of rust spots for painted steel. By using computer-aided image analysis and a program with the V/m ratio [20], it was found that the distribution of rust spots on stainless steel exposed at the seacoast was completely random in the initial stage of the exposure because $V/m = 1$, changing to the regular ($V/m < 1$) and clustered pattern ($V/m > 1$) after corrosion progressed. The change of the distribution pattern occurred at around RN = 4.

D. EXTREME-VALUE STATISTICS

D1. Size and Time Effect in the Corrosion Test

When the required corrosion data are not available, corrosion engineers design a laboratory test that simulates field operating conditions. In some cases, corrosion engineers may be asked to provide reliable data for scaling up the system from the laboratory to the field. They may also be asked to predict the remaining life of apparatus in operation. The size of the test coupon and the duration of testing may change over a wide range depending on the purpose of the test and the requirements of the client. As shown in Table 27.6 [21], tests can be divided into three categories: The first test is carried out in the laboratory by those concerned with materials

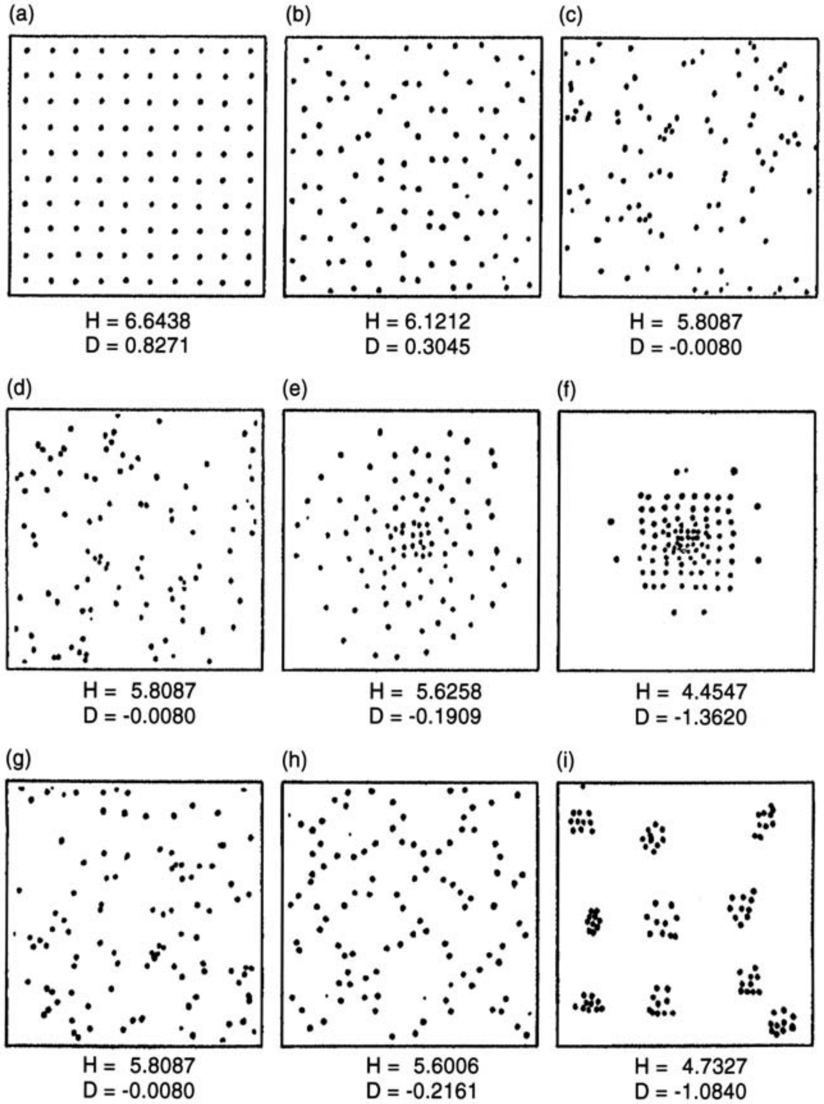

FIGURE 27.9. Model patterns of pit distribution (regular, random, and clustered), which have same rating number.

production; the second is a pilot plant test carried out by those concerned with design and fabrication of the apparatus; and the last is inspection and in-plant examination by those concerned with plant maintenance.

In the laboratory test, coupons of a relatively small area (e.g., 1 cm^2) are used and tested in a relatively short time within ~2 weeks under accelerated conditions, whereas larger coupons, several times 10 cm^2, are required in pilot plant tests that typically last for at least a few months. During plant operation, a much larger surface of the plant is exposed to the corrosive environment during longer operation times. For instance, the surface area of heat exchangers installed in a plant is in the range of 10^5–10^6 cm^2 depending on the type and design. For such a huge surface area, regular inspection is needed to assess operational reliability and to estimate residual life.

When the coupon size and testing duration in the laboratory test are each equated to unity, the relative size of the coupon and the relative duration of the pilot plant test might be in the range of 10–10^2 and 10–10^3, respectively, as indicated in Table 27.6. Differences in size as well as in duration between the laboratory test and the field examination are extremely large and in the range of 10^4–10^6 and 10^4–10^5, respectively, because plant operation is normally expected to last for >20 years. For this reason, one should be cautious in extrapolating laboratory data directly to design or to prediction of life or residual life of plants [22].

D2. Three Types of Extreme-Value Distribution

Fortunately, a method for bridging the large difference in space and time mentioned in Section D1 is provided by the

TABLE 27.6. Relative Ratio in Surface Area and Failure Time Expected in Laboratory Tests, Pilot Plant Tests, and During Plant Operation

	Laboratory Test	Pilot Plant Test	Inspection at Plant		Failure Life Estimation
Steel maker	[a]	[b]

Failure time ratio	1	$10–10^3$		$10^4–10^6$	

[a]Mainly concerned.
[b]Secondary concerned.

statistical theory of extreme values, the theoretical basis of which was well established in the 1950s. A comprehensive treatment of the statistical theory of extreme values has been given by Gumbel [23, 24], who showed examples of applications of extreme value statistics to various fields, including the analysis of the maximum pit depth of a corroded steel pipe. According to Gumbel [23, 24], the extreme value distribution can be reduced to three types of asymptotic distributions for an infinite number of samples, and which of the three types applies in a given situation depends on the initial distribution:

$$\text{Type I} \quad F(x) \sim \exp[-\exp(-x)] \quad \text{Gumbel distribution} \tag{27.16}$$

$$\text{Type II} \quad F(x) \sim \exp[-x^{-k}) \quad \text{Caucy distribution} \tag{27.17}$$

$$\text{Type III} \quad F(x) \sim \exp[-(\omega - x)^k] \quad \text{Weibull distribution} \tag{27.18}$$

Each type has two distributions, one for the largest and one for the smallest, so that six asymptotic extreme-value distributions exist. Of these six distributions, however, type I for the largest value and type III for the smallest value are most often observed in corrosion and are called the Gumbel and Weibull distributions, respectively.

D3. Generalized Extreme-Value Distribution

When corrosion data for the maximum or minimum value are collected, one must decide which type of extreme-value distribution should be fitted to the observed data. For this purpose, several methods for testing the closeness of fit are proposed, including the chi-square test, the Komologorov–Simirnov test, the correlation coefficient test, and others.

Recently, a generalized extreme-value (GEV) distribution was introduced for the closeness-of-fit test. The GEV distribution was introduced first [25] in meteorology for analyzing rainfall and other data. The probability function of GEV is given by

$$F(x) = \exp\left\{-\left[1 - \frac{k(x-u)}{\alpha}\right]^{1/k}\right\}, \quad kx \le \alpha + uk \tag{27.19}$$

where u and α are the location and scale parameters, respectively, and k is the shape parameter, which has a unique property to indicate the type of distribution by the sign and the absolute value as follows:

$$k = 0 \quad \text{Type I} \quad k < 0 \quad \text{Type II} \quad k > 0 \quad \text{Type II} \tag{27.20}$$

In most cases, k is in the range $-\frac{1}{2} < k < \frac{1}{2}$, and x has an upper or lower bound of $u + \alpha/k$ for $k > 0$ or $k < 0$. Laycock et al. [13] found that the distribution of pit depth on Type 316L stainless steel obeys type III for the largest value, because $k = 0.401 > 0$. The presence of the upper bound in the type III distribution for the area dependence is useful in rationalizing the physical model of pit initiation and growth because the existence of a limiting depth with increase of surface area is more realistic.

D4. Extreme-Value Statistics for Estimating Maximum Pit Depth

Extreme-value statistics using the Gumbel distribution is quite useful for estimating the maximum pit depth and its dependence on surface area [26–30]. A standardized procedure [30] has been proposed for analyzing the maximum pit depth distribution using the Gumbel distribution and the concept of the return period, in order to estimate the maximum depth of pits over the larger surface area from which specimens of small area are extracted.

The Gumbel distribution is expressed as

$$F(x) = \exp\left[-\exp\left(-\frac{x-\lambda}{\alpha}\right)\right] \tag{27.21}$$

where $F(x)$ is the cumulative probability of pit depth, x, and λ and α are the location and scale parameters, respectively. The probability density function, $f(x)$, is given by

$$f(x) = (1/\alpha)\exp\{-(x-\lambda)/\alpha - \exp[-(x-\lambda)/\alpha]\} \tag{27.22}$$

The reduced variate, y,

$$y = \frac{x-\lambda}{\alpha} \tag{27.23}$$

is introduced, and then

$$y = -\ln\{-\ln[F(y)]\} \tag{27.24}$$

is used for constructing Gumbel probability paper. The Gumbel probability paper shown in Figure 27.10 is constructed with values of y scaled on the vertical axis and the associated cumulative probabilities, $F(y)$, calculated from Eq. (27.24) on the same axis. Values of the extreme variate, x, are plotted on the horizontal axis using an arithmetic scale. Then the cumulative probability, $F(x)$, of variate, x, obeying the extreme value distribution can be plotted as a straight line on Gumbel probability paper. Plotting position for the cumulative probability can be calculated simply by

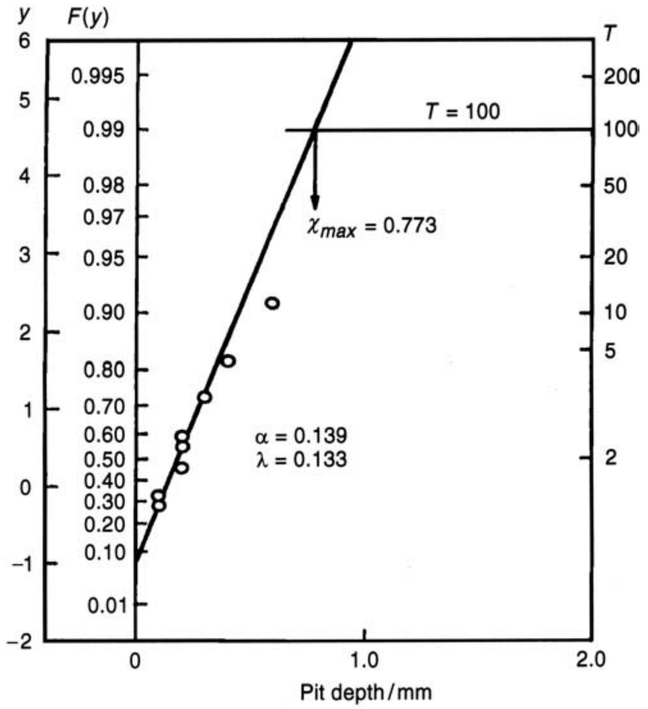

FIGURE 27.10. Probability plot of distribution of pit depth in samples of small area on Gumbel probability paper, from which maximum pit depth for larger surface area can be estimated.

$$F(y) = 1 - \frac{i}{1+N} \tag{27.25}$$

where i is the ith position of the ordered values of x, in descending order, and N is the total number of samples. Plotting y as a function of x yields a straight line, and its slope is $1/\alpha$, and the intercept at $y = 0$ gives λ.

For the pit depth distribution, the return period, T, is defined as

$$T = \frac{S}{s} \tag{27.26}$$

where S is the surface area of the object, such as the tank plate to be examined, and s is the area of the small specimens that are sampled randomly from this object. Then the return period, T, is a size factor. The return period is defined as

$$T = \frac{1}{1-F(y)} \tag{27.27}$$

and y can be correlated with T as follows:

$$\begin{aligned} y &= -\ln\{-\ln[F(y)]\} = -\ln\left[-\ln\left(1-\frac{1}{T}\right)\right] \\ &= \ln(T) \quad \text{when } T > 18 \end{aligned} \tag{27.28}$$

Then the opposite side to the y axis can be scaled as the T axis, as shown in Figure 27.10. The value of x at a given T is the maximum pit depth, x_{max}, for the T times larger surface area, S, compared with the small sample area, s.

An example of plotting the pit depth data is shown in Figure 27.10. In an atmospheric exposure test, 10 sheets of painted steel having $50 \times 50\text{-mm}^2$ area were exposed for 13 years. After the test, pits with various sizes and depths were found on the sheets. The maximum pit depth was obtained from each sheet and was tabulated in the second column of Table 27.7 in descending order. The third column lists the plotting position calculated by Eq. (27.25). Plotting the data points, $[x_i, F(x)]$, results in the line shown in Figure 27.10. The parameters of the distribution can be assessed from the slope and intercept, $\alpha = 0.139$ and $\lambda = 0.133$, respectively. The maximum depth on the surface area that is 100 times larger than the area of the sheet specimens is estimated to be $x_{max} = 0.773$ mm, which is obtained from the intersection of the linear plot of the distribution and the $T = 100$ line.

Instead of this graphical estimation of the parameters, more reliable estimates of α and λ can be obtained by using the MVLUE (minimum variance linear unbiased estimator) method, the maximum likelihood, and the method of moments. Of these three methods, the MVLUE method, discussed by Lieblein [31], is found to be more efficient and

[a]Pit depth data were obtained from the painted steel sheet after a 13-year exposure test.
[b]Location parameter $\lambda = \sum a_i;\ x_i = 0.1326$. Scale parameter: $\alpha = \sum b_i;\ x_i = 0.1390$.

unbiased for small size samples. The MVLUE estimator can be calculated by

$$\lambda = \sum a_i(N, n)x_i, \qquad \alpha = \sum b_i(N, n)x_i \tag{27.29}$$

where $a_i(N,n)$ and $b_i(N,n)$ are weights for each sample depending on the sample size, N, and truncated number, n, which are tabulated in the table up to $N = 23$ [29] or the table given by Tsuge [32] up to $N = 45$. Again the example for estimation of the parameters using the MVLUE method is shown in Table 27.7. The fourth and fifth columns list the values of the weight, $a_i(N,n)$ and $b_i(N,n)$, respectively. The sixth and seventh columns list the calculated values of $a_i(N, n)x_i$ and $b_i(N,n)x_i$, respectively, summation of which gives the parameters estimated by the MVLUE method, shown below Table 27.7. There is good agreement between the values obtained by graphical estimation and by the MVLUE estimation.

The mode, λ, of the pit depth distribution for the small specimen is obtained by the MVLUE estimation mentioned above, and then the mode, $x_{\max}$, for the T times larger surface, S, is estimated by

$$x_{\max} = \lambda + \alpha \ln(T) \quad \text{if } T > 18 \tag{27.30}$$

The perforation probability, P_p, of the maximum pit through the wall thickness, d, is given by

$$P_p = 1 - \exp\left[-\exp\left(-\left\{d - \left[\lambda + \frac{\alpha \ln(T)}{\alpha}\right]\right\}\right)\right] \tag{27.31}$$

The above procedure does not include assessing the closeness of fit of the distribution obtained to the Gumbel distribution, but the closeness of fit can be assessed using the Kolmogorov–Smirnov or chi-square test if needed. Another convenient method [35], using the GEV of Eq. (27.19), can be utilized for comparing the fit of the distribution to the Gumbel distribution because the shape parameter, k [33], defines the type of distribution, as indicated in Eq. (27.20).

The maximum pit depth, $x_{\max}$, and the perforation probability, P_p, can be estimated using the procedure in the manual method or the MVLUE program of EVAN [34], which operates with MS-DOS, and EVAN-II [35], which operates with Microsoft Excel. If further applications are intended under a variety of conditions, some problems and questions will arise (e.g., how to collect sample data for the object, how to decide on the small sample area, s, for the large area, S, of the object, and how many samples to use). A procedure to determine the suitable number of samples was developed [30] using the T versus N curve derived from a concept of variance control.

The weights, A, B, C, of variance, V,

$$V = \alpha^2[A(N, n)y^2 + B(N, n)y + C(N, n)] \tag{27.32}$$

are also found in the table [29, 31, 32], so that variance can be calculated as a function of N and y or T. At a constant variance, a relation between N and T can be determined. On this basis and with accumulated experience, a recommended procedure for the analysis has been proposed [30, 36]. The first requirement is that the values either should be measured under the same corrosion conditions or should be separated into groups based on knowledge of corrosion if data are collected under different conditions. Second, the area of the small sample, s, should be chosen so as to include multiple pits. Then T is calculated by $T = S/s$ from S, which is given, and N is decided from the T versus N curves at the given ratio of λ/α. The ratio of λ/α must be known before the analysis but fortunately can be estimated from previously accumulated data.

D5. Weibull Distribution for Analyzing SCC Failure Time

The third type of extreme-value distribution for the smallest value, the Weibull distribution,

$$F(t) = 1 - \exp\left[-\left(\frac{t-\gamma}{\eta}\right)^{m}\right] \tag{27.33}$$

can be fitted to the failure life distribution by SCC, where γ, η, and m are the location, scale, and shape parameters, respectively. This third type of asymptotic distribution for the smallest value can be transformed to the first type for the largest value; that is, Eq. (27.21), by changing $1 - F(t)$ to $F(z)$ and by introducing the following reduced variate:

$$X = \ln(t-\gamma) \quad z = \frac{X-\lambda}{\alpha} \tag{27.34}$$

The same MVLUE method used for Eq. (27.21) can be utilized to estimate the parameters of Eq. (27.33) because the following relations exist between the parameters of both distributions:

$$\lambda = \ln(\eta) \quad \alpha = \frac{1}{m} \tag{27.35}$$

The above-unified procedure for estimating parameters of the Gumbel and Weibull distribution was coded as a computer program, EVAN [34].

The lifetime during which SCC is the failure mode varies a great deal and, in the past, was analyzed using a lognormal distribution [7, 21] in case of aluminum alloys, stainless steels, and steel wire. More recent analysis, however, has been based on the Weibull distribution [37, 38], including the exponential distribution, because the Weibull distribution can be fitted to various types of distribution by adjusting the shape parameter. The shape parameter, m, is an important parameter because it controls the shape of the probability density function, $f(t)$, and also the failure rate, $\lambda(t)$, as shown below:

$$f(t) = \frac{dF(t)}{dt} = m(t-\gamma)^{m-1}(\eta)^{-m}\exp\left[-\left(\frac{t-\gamma}{\eta}\right)^{m}\right] \tag{27.36}$$

$$\lambda(t) = \frac{f(t)}{1-F(t)} = m(\eta)^{-m}(t-\gamma)^{m-1} \tag{27.37}$$

In reliability engineering [2], a bathtub-shaped mortality curve for describing failure time is widely used to illustrate the failure mode, which is controlled by the shape parameter, as shown in Figure 27.11. The first period, or mode, shows a decreasing failure rate with time and is called an early failure mode. The middle part, with a constant and lower failure rate, is a chance failure mode. The final stage, in which the failure rate increases with time, indicates a wear-out mode.

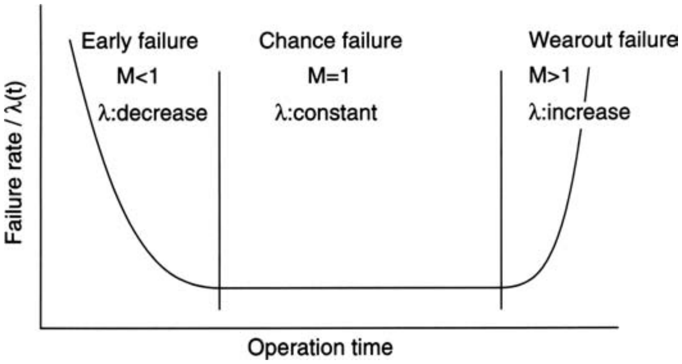

FIGURE 27.11. Bathtub curve for the change of failure rate with time, showing early failure, chance failure, and wear-out failure mode.

For austenitic stainless steel [39] in boiling $MgCl_2$ solution, applied stress causes transgranular stress corrosion cracking and changes the distribution of failure time, as shown in Figure 27.12. The effects of applied stress on the parameters of the distribution are summarized in Figures 27.13(a) and (b) [39]. With decrease in applied stress, the single distribution changes to a complex one consisting of two distributions, the first distribution of which changes its slope, approaching unity, whereas the second has a constant slope of unity. Both distributions have a trend to approach the chance failure mode with decrease in applied stress.

An opposite shift of the slope with applied stress, however, was reported by Clarke and Gordon [12], who measured the failure time distribution of intergranular stress corrosion cracking (IGSOC) of sensitized Type 304 stainless steel in high-temperature, high-pressure water, simulating the boiling water reactor (BWR) environment, as shown in Figure 27.14 [12]. The Weibull plot shifts to longer time with decreasing applied stress, but the steeper slope occurs at the lower stress. This change in the shape parameter suggests a change in the mechanism of SCC. It is interesting to note that the actual field data of SCC of steam generator rubes in nuclear power plants [40] obeys the Weibull distribution, and the shape parameter was found to be 4.2, as shown in Figure 27.15. This analysis indicates that the SCC failure of the plant was in the final stage, in wear-out mode, so that a remedy such as plugging or replacement was required for safe operation.

E. RELIABILITY ASSESSMENT AND PROBABILITY DISTRIBUTION

As discussed in Section D5, the distribution of failure life of SCC is expressed as a function of experimental conditions,

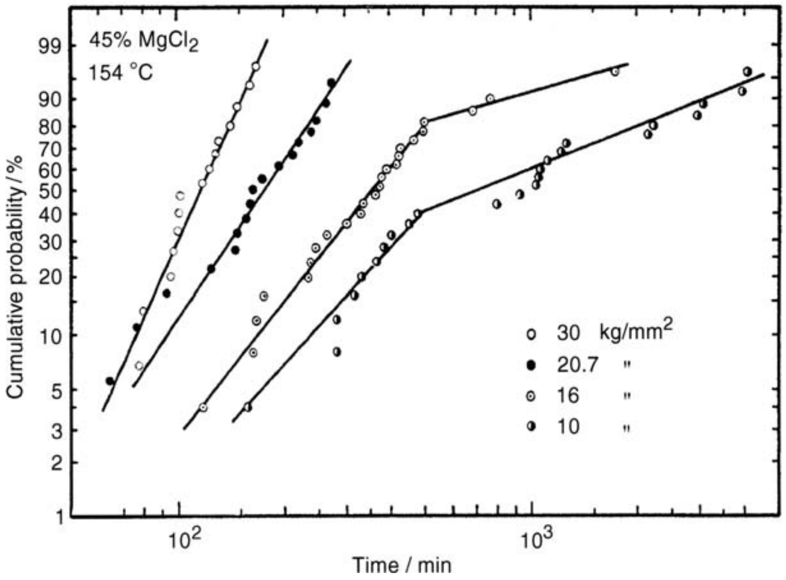

FIGURE 27.12. Probability plots of SCC failure time of stainless steel on Weibull probability paper.

such as applied stress, chloride concentration, oxygen concentration, and so on. If factors that affect failure time are expressed simply as stress, then the shift of the distributions with stress can be illustrated schematically, as shown in Figure 27.16. The laboratory test at the higher stress level produces a series of short failure time data, the distribution of which is located in the left and shorter time region. The distribution of field failure time is located in the extended time region shown on the right side. Usually, the distribution of the field failure life cannot be established because failure time data are very limited. For quantitative estimation of failure life or for assessing reliability in the field, the distribution at each level of stress is estimated. Alternatively, if the distribution is known as a function of stress, extrapolation to lower stress levels can provide the estimated distribution of the field failure time.

Three postulated changes of the distribution plotted on Weibull probability paper are illustrated in the small insert figures in Figure 27.16. Stress corrosion cracking of stainless steels in $MgCl_2$ solution, shown in Figure 27.12, is an example of case (b), and the slope of the distribution likely approaches unity with decrease in stress.

Murata [41] reported the distributions of delayed fracture of high-tension bolts tested in the laboratory as well as in

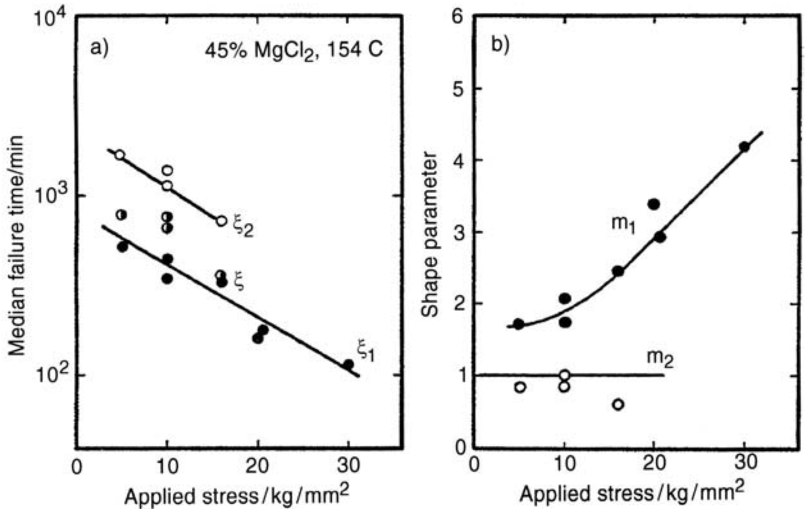

FIGURE 27.13. Median failure time and shape parameter of Weibull distribution as function of applied stress.

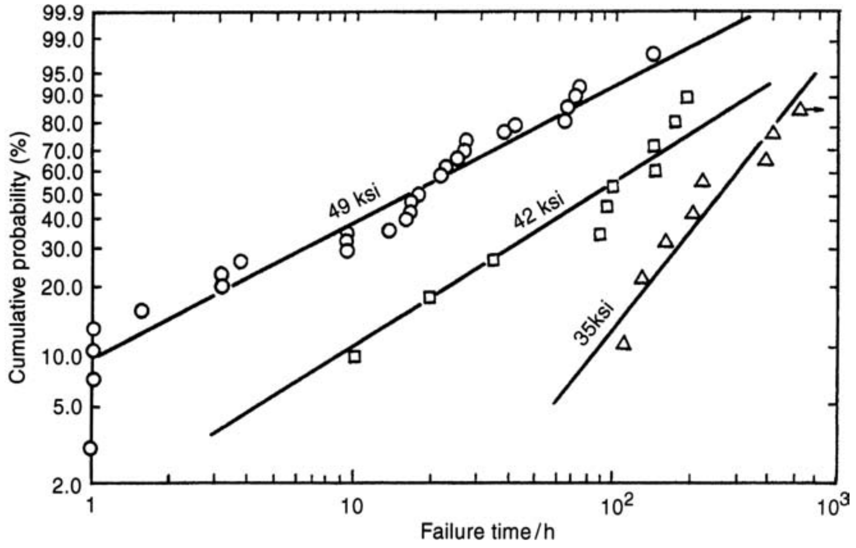

FIGURE 27.14. Probability plots of IGSCC failure time on Weibull probability paper, showing different dependence of shape parameter on applied stress compared with data in Figure 27.13.

atmospheric exposure over a period of 9 years. The results obtained for SNCM 23A (AISI-SAE4320) steel bolts in the exposure test were plotted in Figure 27.17 [41]. Distributions shifted to longer failure times in sea, coastal, industrial, and rural exposure, in that order. The small shape parameter was a specific feature of the sea exposure. In order to compare these atmospheric exposure test results, the laboratory-accelerated tests were carried out using high-temperature and high-humidity environments. The mean failure time of the accelerated test was found to be 10 times shorter than the field exposure test, and the shape parameter was almost the same as in the field exposure test [41].

Atmospheric exposure can be simulated by the high-temperature and high-humidity accelerated test because of the similar shape parameter, but failure in sea immersion cannot be simulated because of the large difference in the shape parameter.

Stress corrosion cracking of stainless steel heat exchanger tubes using industrial water as coolant is a problem in the chemical industry. Failure causes and failure life data have been analyzed [42]. It has been established that both the chloride concentration and the wall temperature are controlling factors causing SCC failures. Conditions to avoid SCC have been recommended based on the data collected. In

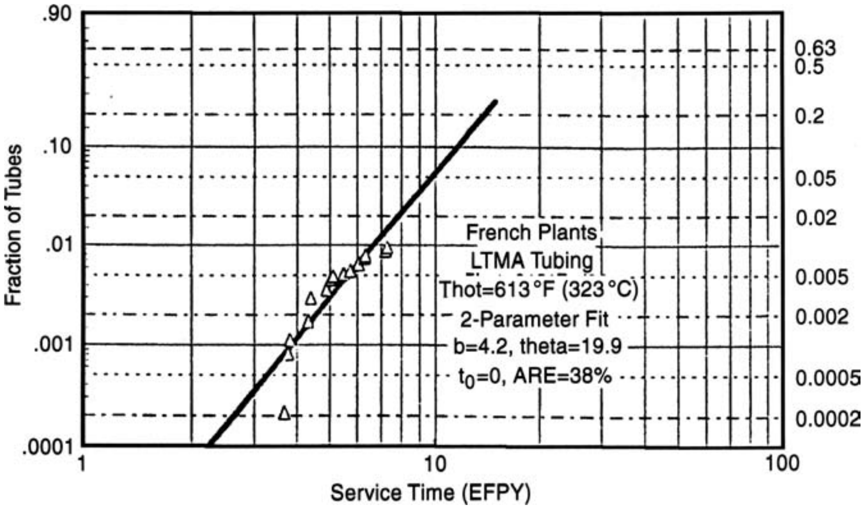

FIGURE 27.15. Weibull probability plot of service life of steam generator tubes operated in French nuclear power plant.

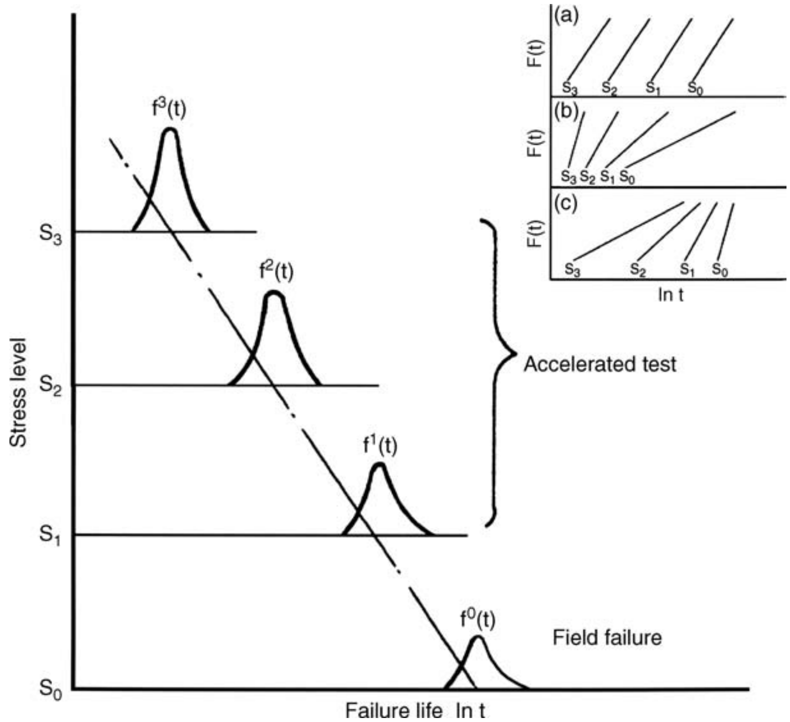

FIGURE 27.16. Distribution curves of failure time observed in various environments, at which stress level increases with severity of environment. Three different modes in the change of the distribution are shown in the insert.

addition, the distribution of failure life of 442 cases reported from 19 plants has been analyzed. The failure life data that were grouped based on wall temperature obey an exponential distribution, as illustrated in Figure 27.18 [42]. The vertical axis is the hazard function, $H(t)$, which is defined as

$$H(t) = \ln[1 - F(t)] \tag{27.38}$$

or

$$F(t) = 1 - \exp[-H(t)] \tag{27.39}$$

The hazard function was calculated by summation of the failure rate, $h(t)$, at each time

$$H(t) = \sum h(t) \tag{27.40}$$

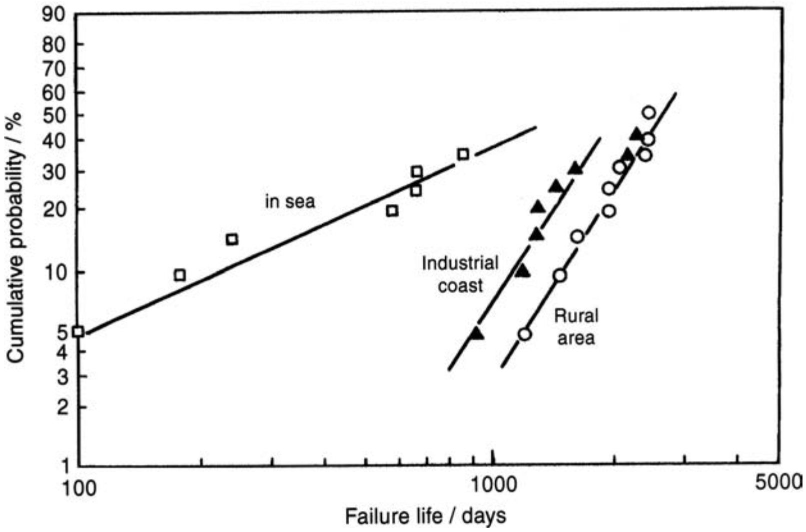

FIGURE 27.17. Weibull probability plots of SCC failure time of high-strength steel bolts exposed under various environmental conditions.

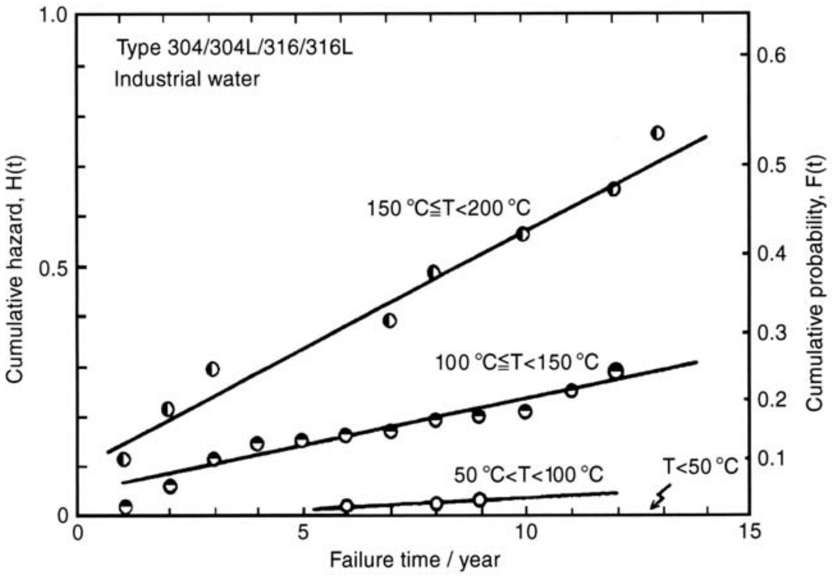

FIGURE 27.18. Hazard plots of SCC failure time of stainless steel tubes for beat exchangers using industrial water in chemical industry.

The exponential distribution has the form of

$$F(t) = 1 - \exp\left(\frac{t-\lambda}{\alpha}\right) \tag{27.41}$$

which is reduced from the Weibull distribution at $m = 1$. The slope of the line provides the failure rate, which is constant during the lifetime, but depends on the wall temperature, as shown in Figure 27.18.

The field data for the SCC failure time distribution are valuable because they provide a basis for comparison with the laboratory distribution. An example for estimating the accelerating factor of the laboratory test is shown in Figure 27.19 [43], in which the failure time distributions of Type 304 stainless steel under various conditions, including the field failure time distribution [42], are plotted on Weibull probability paper. Every distribution obeys the Weibull distribution, and the slope decreases from $m = 3.41$ to $m = 1.0$ while the mean failure time increases, indicating the change of failure mode from the wear-out to the chance failure mode. By comparing the medians of the distributions, it can be concluded that the most severe testing condition, using a boiling concentrated $MgCl_2$ solution, accelerates the SCC of stainless steel by a factor of 10^4 compared to the field failure life [42].

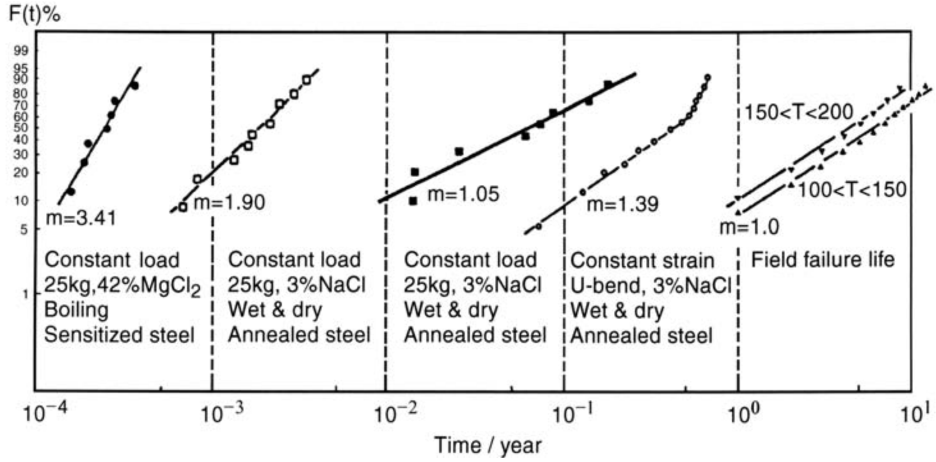

FIGURE 27.19. Comparison of cumulative probability distributions of SCC failure time of Type 304 stainless steel obtained under various conditions.

E1. Quantitative Assessment of SCC Failure by Reliability Test

In Section E, a value of the acceleration factor was estimated by comparing the medians of the distributions. It may be required, however, to estimate more reliably quantitative values for the failure life of systems or materials that need a high level of reliability. For this purpose, Post et al. [44] developed a statistical procedure by assuming that the failure life of sensitized Type 304 stainless steel due to IGSCC in the BWR-simulated environment obeys a lognormal distribution.

Figure 27.20 [38] illustrates schematically a procedure using the accelerated test to verify the reliability of a newly developed alloy or an alternative welding method, by comparing with the current materials that are susceptible to SCC. When both distributions for a reference alloy and an alternative alloy obey the lognormal distribution with the same variance ($\sigma_X^2 = \sigma_A^2$), as shown in Figure 27.20(a), the improvement factor, F, is defined as

$$\ln(F) = \mu_A - \mu_X \tag{27.42}$$

where μ_A and μ_X are the log-mean failure time of the alternative alloy A and the reference alloy X, respectively. The factor, F, depends on testing time, t, the number, n, of specimens tested, and the level of reliability, β, being expressed as

$$\ln(F) = \ln(t) - \mu_X - \sigma_X \left[K_{\ln A} + \beta \left(\frac{1}{n_X + K_{2nA}^2} \right)^{1/2} \right] \tag{27.43}$$

where K_{1nA} and K_{2nA} are the coefficients for the mean and standard deviation of the smallest value distribution of sample size n, and their numerical value can be found in the Rankit table [29].

As shown in Figure 27.20(b), the same equation could be applicable to determine the accelerating factor, L, of the laboratory test over the field failure:

$$\ln(L) = \mu_X - \mu'_X \tag{27.44}$$

where μ_X and μ'_X are the log-mean failure times of alloy X in the laboratory test and in the actual field, respectively.

For Weibull distributions, a similar procedure could be used for comparing two distributions with the same shape parameter ($m_A = m_X = m$):

$$\ln(F) = \ln(t) - \mu_X + \left(\frac{1}{m}\right) \ln[n_A - \ln\ln(1-\beta)] \tag{27.45}$$

Akashi [10] found that the distribution of SCC failure times in the laboratory obeys the exponential distribution expressed by Eq. (27.41) and the α/λ ratio is almost constant.

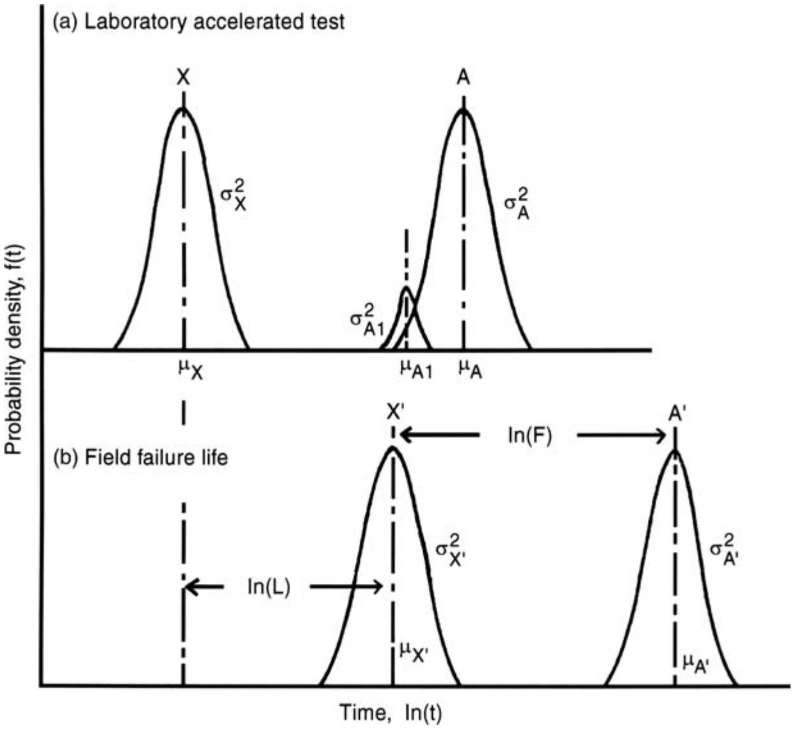

FIGURE 27.20. Schematic illustration of reliability test for assessing acceleration factor based on statistical procedures.

In this case, the condition of $(\alpha_A/\lambda_A = \alpha_X/\lambda_X = \alpha/\lambda)$ is fulfilled and

$$\ln(F) = \ln(t) - \ln(\lambda_X) - \ln\left[1 - \left(\frac{\alpha/\lambda}{n_A}\right)\ln(1-\beta)\right] \tag{27.46}$$

can be used for evaluating the improvement factor, F.

F. CONCLUDING REMARKS

The corrosion probability concept is important and useful for analyzing the highly variable data that are often observed in laboratory corrosion tests and in field failures. Statistical procedures are not very familiar to many corrosion engineers and scientists who have been educated in electrochemical disciplines. Use of statistics is essential when data on localized corrosion must be evaluated. The easiest and fastest way to learn statistical procedures is to plot, on probability paper, your own data that are already stored in your filing cabinet or in your computer.

A. INTRODUCTION

The successful use of ceramics to solve material problems involving severely corrosive conditions at high temperatures covers a wide range of applications and industries.

This chapter is focused on the corrosion of (i) industrial refractories for heat and mass confinements in combustion, chemical, metallurgical, materials manufacturing, and related processes and (ii) structural ceramics that substitute for high-temperature metallic alloys in, for example, gas turbine components in the automotive and aerospace industries and in heat exchangers in various segments of the chemical and power generation industries.

Refractories and structural ceramics are generally thought to be inert and corrosion resistant, as compared to metallic alloys, and they are, relatively so, at room temperature, under dry atmosphere, over long time intervals. With increasing temperatures and specific chemical, mechanical, and physical gradients, the propensity to degradation increases rapidly.

Degradation, deterioration, decomposition, and wear are all words used to describe corrosion of these materials. Corrosion of refractories and ceramics is indeed a complex phenomenon to describe and no single word properly fits. Corrosion involves a combination of different mechanisms, such as dissolution and invasive penetration, where diffusion, grain boundary, and stress corrosion may all be present, and oxidation–reduction reactions, where absorption, desorption, and mass transport phenomena all come into play.

Exhaustive definition of the material, including its microstructure and surface characteristics, are always needed as in any corrosion study. Here one has to realize that refractory and structural ceramic textures are widely different. Texture means the spatial arrangement of the different phases (minerals and chemicals) from the micrometer level (1 μm) up to 10 mm. In fact, refractories are multiconstituent solids, with varying degrees of crystallinity (in many cases with some glassy phase), with varying degrees of purity (natural and/or synthetic raw materials) with a wide grain size distribution (from 1 to 10,000 μm) with different grain morphology (spherical, flat, or elongated), some with highly anisotropic behavior (many noncubic crystal structures), with inherently high open porosity, as opposed to structural ceramics that are finer grained, purer, and denser.

The exponential increase with temperature in the reactivity of solids and the use of refractories and structural ceramics under pronounced thermal gradients make the study of corrosion of these materials very complex.

A simple, all-encompassing, general theory of corrosion of refractories and structural ceramics does not exist. The interplay between dissolution, penetration, and texture is not sufficient to take into account all the interactions possible with so many parameters involved. This complexity may provide the reason for the shortage of reliable comparative information on the resistance of ceramics to chemical corrosion. Carniglia and Barna [1], on refractories, and McCauley [2] and Lay [3], on technical ceramics, have provided useful compilations. In addition, two more recent reviews on corrosion of refractories have become available [3a, 3b].

The last aspect worth mentioning in this introduction is that corrosion of refractories and ceramics at high temperatures is essentially a chemical rather than an electrochemical phenomenon. Electrochemical dissolution has been considered for the corrosion of refractories in glasses and for the corrosion of oxides (as pure compounds or as minerals) and ceramics in aqueous media at lower temperatures.

B. CORROSION OF INDUSTRIAL REFRACTORIES

Having postulated that corrosion of refractories is essentially the result of a chemical reaction, where the rate-determining step does not involve electronic charge transfer at the reaction interface, this section is divided into two parts: the basic principles and a review of corrosion resistance by broad classes of materials. Corrosion testing of refractories and ceramics is considered in Chapter 83.

B1. Basic Principles

To predict the corrosion of refractories in a given environment, it is worthwhile, first, to consider the concept of acidity–basicity and, second, to estimate the driving force for corrosion using themodynamic laws. This should also be done in two steps: (1) verify the available thermodynamic data for the thermal stability of each constituent and (2) then make the appropriate thermodynamic calculations to estimate the free-enthalpy variations, $(\Delta G)_r$, for all possible reduction or oxidation (redox) reactions that may occur between constituents themselves and between constituents and the environment (gases and/or liquids). To understand the corrosion processes and to select the best refractory for a specific application, kinetic data are required. The principles of penetration, dissolution, and spalling will be presented in the following sections in order to appreciate the particularities of liquids, hot gases, and dusts on corrosion of industrial refractories.

B1.1. Acid–Base Effects. One must consider the chemical nature of the reactants (S and L or S and G), since materials of dissimilar chemical nature, when in contact, will react, especially at high temperatures. The chemical nature of the reactants is best described using the concept of acidity and basicity, a familiar idea but of limited value since a single precise understanding of high-temperature acidity and basicity of all compounds (pure and in solution) has not been developed.

Silica (SiO_2) is the best example of a solid acidic oxide that should be used in applications where the destructive materials (liquid or gaseous) are chemically acidic, for example, coal gasifier ash or iron-making slags or in N_2O_5 or SO_3–SO_2 atmospheres, the most acidic gases. Magnesia and doloma are basic in nature and should be used in applications where slags or gases are generally basic, for example, steelmaking slags and liquid clinker melt in the rotary cement kiln. These generalizations are first approximations that are insufficient in many cases because, in many industrial processes, the corrosive environment changes from acidic to basic during the operation. Nevertheless, the first rule is to make the acid–basic character of the refractory constituents similar to that of the corrosive fluid (liquids and/or gases) to increase the corrosion resistance.

The following table lists the acid–base nature of various compounds:

From most acidic				
Gases	N_2O_5(g)	Solids	SiO_2	FeO
	SO_3(g)		TiO_2	NiO
	SO_2(g)		ZrO_2	MnO
	CO_2(g)		Fe_2O_3	MgO
	B_2O_3(g)		Cr_2O_3	CaO
	V_2O_5(g)		Al_2O_3	Na_2O (s or g)
				K_2O (s or g) *to most basic*

Silica, zirconia, alumina, magnesia, and lime are the most important binary oxides in refractories.

B1.2. Thermodynamic Calculations. The second approach to predict the corrosion resistance of industrial refractories is to make the appropriate thermodynamic calculations, to evaluate the thermal stability of each constituent, to consider the melting and dissolution behavior, and finally to assess redox potentials.

B1.2.1. Thermal Stability Prior to Melting. Several polymorphic transitions may occur that change the microstructural integrity of the solids, as they are being heated, some reversible and some irreversible, with some well-known disruptive transformations, as for silica or zirconia. Other transitions are the decomposition of mixed oxides (e.g., $ZrSiO_4 \rightarrow ZrO_2 + SiO_2$), the devitrification of glassy phases, and the crystallization of high-temperature phases for amorphous or poorly crystallized ones (e.g., the graphitization of carbon). For such modifications, large volume variations may occur, creating sufficiently large compressive, tensile, or shear forces to cause microcracks, and hence porosity, an important aspect of the corrosion of refractories.

Other volume changes or debonding may occur due to thermal mismatch when solids are heated. All noncubic-lattice refractory compounds, for example, Cr_2O_3 (hexagonal), Fe_2O_3 (trigonal), and ZrO_2 (monoclinic), are susceptible to disruptive intercrystalline debonding since they exhibit thermal expansion anisotropy. Another cause of debonding is the juxtaposition of two constituents of different properties, such as different thermal expansion coefficients (e.g., alumina–mullite, mullite–silica, and magnesia–chromite). In fact, in most refractories, phase boundary microcracking can be expected.

B1.2.2. Melting Behavior and the Use of Phase Diagrams. It is still often the case that constituents of refractories are subjected to higher temperatures in service than those attained during their previous history. Frequently, refractories cannot be regarded as being at equilibrium, and it is useful to calculate the amount of liquid that they may contain at a given temperature. For this purpose, one uses thermodynamic principles (e.g., minimization of energy techniques for multicomponent systems) like the SOL/GAS mix protocol and the phase rule, and all data available on the thermodynamics of solutions as well as on the thermodynamic properties of the pure compounds under stable and metastable conditions.

For many years, compositions of refractories were limited to individual minerals as mined. With time, it was recognized that nature did not proportion the oxide contents of the minerals in the most suitable ratio for optimum refractory performance. As pure oxide became available and affordable in terms of cost (first alumina, then magnesia), improvements in performance and, in particular, corrosion resistance became possible. The use of phase diagrams was then recognized as a very good research tool to accelerate such improvements.

Phase diagrams are used to design refractories and to understand the role of slags (of the same nature as the liquid phase formed in the refractories). The early book by Muan and Osborn [4] is a requirement for new researchers in this field and the reviews by Kraner [5], on phase diagrams for fired refractories, and by Alper et al. [6], on fusion-cast refractories, are also important. Phase equilibria in systems containing a gaseous component, in particular the effects of oxygen partial pressure on phase relations in oxide systems, have also been examined. The relative importance of these issues has greatly increased with the advent of the so-called carbon-bonded refractories, magnesia–dolomite and alumina-based systems with carbon and graphite. Also, the roles of oxycarbides, oxynitrides, and sialons as well as metals and alloys in refractories have been documented. These aspects will be treated in the following paragraphs and sections.

In general, the corrosion resistance of a refractory is high if formation of low-melting eutectics and of a large amount of liquid can be avoided. Phase diagrams can be used to predict the formation of these phases. Of course, the better the system is defined, the easier it is to make an accurate prediction. There are, nevertheless, many limitations; for example, phase diagrams are readily available for no more than three constituents, while in practical cases for magnesia or dolomite basic refractories one needs to characterize the $CaO–MgO–FeO–Fe_2O_3–Al_2O_3–Cr_2O_3–SiO_2$ system. Rait [7] and White [8] offered a comprehensive treatment of the phase assemblages in such a system. A particularly important feature is the CaO/SiO_2 ratio and its effect on the quantities of low-temperature phases to be expected. This ratio is related to the acid–base effect described earlier.

According to Carniglia and Barna [1], the importance in understanding the progressive thermal softening, weakening, and ultimate destruction of refractories cannot be overstressed. It should be clear that the maximum feasible service temperature of a refractory has to be confirmed by (i) its lowest germane eutectic and the melting temperature thereof; (ii) how much liquid is produced at that temperature; (iii) and how rapidly the amount of liquid increases with increasing temperature above this. All these characteristics are linked to the appropriate phase diagrams and the application of the lever rule.

B1.2.3. Oxidation and Reduction Behavior. As for melting, or solid–liquid reactions, the thermodynamic calculations of gas–solid reactions are a powerful tool for describing the stability of refractory materials, in particular, the carbon-containing refractories that are very widely used. Gas–Solid reactions are important not only for dealing with the direct oxidation of carbon in air but also for evaluating the reduction of aggregates (MgO, Al_2O_3, SiO_2, etc.) by carbon (indirect oxidation of carbon) and the role of the antioxidants, being more reducing than carbon in most systems. A powerful use

of thermodynamics is to assess the oxidation–reduction behavior of refractories and ceramics by carrying out equilibrium calculations. It is possible to study multicomponent systems using elaborate computer codes, such as Chem Sage or Solgasmix [9, 10]. Graphical displays, such as Ellingham diagrams and volatility and predominance diagrams, are often used to describe the simplest systems of the type $S_1 + G_1 \rightarrow S_2 + G_2$ [11, 12]. For the Ellingham diagrams, all the condensed phases of the reactions are assumed to be pure phases and therefore at unit activity, but deviations from unit activity are very common, and corrections must be applied. Predominance diagrams and volatility diagrams are graphical representations in which the gaseous products are considered at various nonstandard conditions, and these diagrams are used for complex systems involving several gases (e.g., metal–oxygen–carbon–nitrogen under a wide range of partial pressures). These diagrams, the equivalent to Pourbaix diagrams for studying corrosion of a solid in aqueous media, are used to predict the direction of reactions and the phases present.

From thermodynamic calculations, it is possible to explain why and how redox cycling is harmful to any refractory containing iron oxides as impurities, how the reduction of magnesia to magnesium gas and the reoxidation to MgO can be used with great advantage for MgO–carbon bricks (a destruction–reconstruction mechanism that leads to the dense zone magnesia formation theory), how nonoxide refractories (and nonoxide structural ceramics) without exception are subject to high temperature oxidation, and finally how, in the presence of alkalies, refractory chromites (Cr^{3+}) can be oxidized in part to toxic chromates (Cr^{6+}). The alkali chromites ($Na_2Cr_2O_7$ or Na_2CrO_4) are water leachable and present, therefore, an environmental contamination risk in disposal sites.

B1.3. Kinetic Considerations. Penetration, dissolution, and spalling are the most important phenomena that control the kinetics of the corrosion of industrial refractories. They apply as well to the solid(S) + liquid(L) reactions as to the solid(S) + gas(G) reactions.

Liquids can be either slags or fluxes, molten salts or molten metals, each presenting their own peculiarities. Slags are characterized by their basicity–acidity ratio ($CaO–SiO_2$ ratio either greater or less than 2 : 1) and fluidity or viscosity (very much a function of temperature and overheat, measured by $\Delta T = T_{\text{service}} – T_{\text{melting}}$ of the lowest melting eutectic compound in the system). Molten salts are known for their low-melting temperatures, high fluidity, and high fugacity (high volatility of alkalies). Molten metals are less reactive toward refractories but are not inert.

The solid refractory material, S, has already been defined as a multiphase material having a texture with intricate surface properties, most often used under a thermal gradient and usually containing some inherent amount of liquid (ℓ) at the hot face, where ℓ may be equivalent to L in terms of affinity.

Various hot gases, reactive or nonreactive, with or without dusts, are represented by G. The reactivity of G can be determined starting with the acid–base series, noting that the strongest acids and bases are volatile, and by using thermodynamic data in predominance and volatility diagrams.

B1.3.1. Penetration. It is useful to distinguish between physical penetration and chemical invasion. Physical penetration, without dissolution at all, occurs when a strictly nonwetting liquid is forced into the pores of a solid by gravity or external forces. Chemical invasion occurs when dissolution and penetration are tied together. Both physical and chemical penetration are favored by effective liquid–solid wetting and by low-viscosity liquid. Silicates, particularly silicate glasses, are usually viscous, simple oxidic compounds, and basic slags are less viscous, and halides and elemental molten metals are, in general, the most fluid liquids.

Penetration is the result of an interplay between capillary forces (surface tension), hydrostatic pressure, viscosity, and gravity. Mercury penetration in a capillary glass tube is the best example of physical penetration. The rate of penetration in a horizontal pore, $d\ell/dt$, with a pore radius r is given by the following expression:

$$\frac{d\ell}{dt} = \frac{r\gamma_{\ell g}\cos\theta}{4\eta\ell}$$

where $\gamma_{\ell g}$ is the surface tension of mercury in air, θ the wetting angle of mercury on the glass wall, and η the viscosity of the penetrating liquid (Hg) over a length ℓ at time t. This expression is valid only at constant temperature, whereas $\gamma_{\ell g}$ and η are liquid properties greatly influenced by temperature. Such an equation has often been used to describe the penetration of liquids in refractories without distinction between physical and chemical invasion. However, in the case of chemical invasion, the penetration–dissolution causes changes in composition (which, in turn, affect the values of $\gamma_{\ell g}$ and η) and changes in porosity geometry.

When the pore size distribution is narrow (i.e., pores of the same size), penetration and filling of the porosity by capillarity produce a relatively uniform front moving gradually from the hot face and remaining parallel to it. When pore size distribution is wide (i.e., very large and very small pores) or when open joints, cracks, or gaps between bricks in a refractory wall are accessible at the hot face, rapid and irregular liquid intrusion does occur. There are many penetration paths in a refractory, and the texture of the material is of primary importance; it is important to distinguish between interconnected versus isolated porosity, between open and

total porosity, pore sizes, and unbounded boundaries between grains (aggregates and/or matrix) due to thermal mismatches during heating.

For a given temperature gradient, the pertinent eutectic temperature of the penetrating liquid determines its maximum liquid penetration depth.

B1.3.2. Dissolution. The simplest case of pure dissolution is to consider the following reaction: $S_1 + L_1 \rightarrow L_2$, where L_2 is a solution $L_1 + S_1$, S_1 having a continuous surface with no infractuosity.

A general equation useful to describe such a dissolution process is

$$j = \left\{ K \left(1 + K \frac{\delta}{D} \right)^{-1} \right\} (C_{\text{sat}} - C_\infty) \qquad (28.1)$$

where j is the rate of dissolution per unit area at a given temperature T ; K is the surface reaction rate constant; δ is the thickness of the boundary layer in the liquid phase; C_{sat} is the concentration of the dissolving solid, in the liquid, at the interface; C_∞ is the concentration of the dissolving phase in the bulk of the liquid; and D is the effective diffusion coefficient in the solution for the exchange of solute and solvent.

The parameter δ is further defined by the expression

$$\delta = \frac{C_{\text{sat}} - C_\infty}{dc/dy} \qquad (28.2)$$

where dc/dy is the concentration at the interface.

The dissolution rate j may be visualized as the ratio of a potential difference ($C_{\text{sat}} - C_\infty$) divided by a resistance term:

$$K^{-1} \left(1 + \frac{K\delta}{D} \right)$$

Three different cases will be briefly treated.

1. When $K \ggg D/\delta$—that is, when the chemical reaction takes place so rapidly at the solid–solvent interface that the solution is quickly saturated and remains so during the dissolution process. In this case, the dissolution rate, j is controlled by mass transport. Equation (28.1) reduces to Eq. (28.3):

$$j = \frac{D}{\delta} (C_{\text{sat}} - C_\infty) \qquad (28.3)$$

   The transport process is enhanced by convection due to density differences between bulk and saturated solution (natural convection) and/or by the hydrodynamics of the system under forced convection. Expressions for the boundary layer δ have been derived from first principles for both natural (or free) and forced convection for a variety of simple geometries, and Eq. (28.3) has been validated many times. This process is often called direct dissolution.

2. When $K \lll D/\delta$— that is, when the dissolution rate is phase boundary controlled as opposed to mass transport controlled. Equation (28.1) reduces to Eq. (28.4):

$$j = k(C_{\text{sat}} - C_\infty) \qquad (28.4)$$

   The phase boundary reaction rate is then fixed by the movement of ions across the interface and hence is governed by molecular diffusion. The effective diffusion length over which mass is transported is proportional to $(Dt)^{1/2}$, and therefore, the change in thickness of the specimen, proportional to the mass dissolved, varies with $t^{1/2}$. This process is often called indirect dissolution.

3. When $K \simeq D/\delta$, both phase boundary and mass transport are controlling. In this case of mixed control, the potential difference ($C_{\text{sat}} - C_\infty$) can be seen as divided into two parts: $C_{\text{sat}} - C^*$ is the part that drives the phase boundary condition, and $C^* - C_0$, the part that drives the transport process, so as to keep the dissolution rates for each process equal.

The dissolution rate is extremely temperature sensitive, largely determined by the exponential temperature dependence of diffusion, and can be expressed by the equation

$$j_T = A \exp\left[-B \left(\frac{1}{T} - \frac{1}{T_1} \right) \right]$$

where A is the dissolution rate at temperature T_1 and B is a model constant.

In most practical dissolution problems, the reaction of a solid in a solvent leads to a multicomponent system; no longer is the chemical composition defined by a single concentration nor is there a single saturation composition at a given temperature; instead of pure dissolution the reaction is of the type $S_1 + L_1 \rightarrow L_2 + S_2$, the formation of S_2 causing the interface composition to change.

For porous solids such as refractories, with open porosity and with matrix materials being fine and highly reactive, both dissolution and penetration occur; hence, most slagging situations involve chemical attack of the matrix or low-melting constituent phases, which disrupts the structure and allows the coarse-grained aggregates to be carried away by the slag movement. When penetration is more important than dissolution, another mechanism of degradation needs to be considered: structural spalling.

B1.3.3. Structural or Chemical Spalling. While spalling is a general term for the cracking or fracture caused by stresses produced inside a refractory, chemical or structural spalling is a direct consequence of corrosion penetration. It should not be confused with pure thermal or pure mechanical spalling. Structural spalling is a net result of a change in the texture of the refractory, leading to cracking at a plane of mismatch, at the interface of an altered structure and the unaffected material.

When slag penetration does not cause direct loss of material, the slag does partially or completely encase a volume of refractory, reducing its apparent porosity (by sometimes more than one-half), causing differential expansion with the associated development of stresses. As a result, there is a degradation in material strength and stiffness, the appearance of microcracks, and eventually totally disruptive cracks parallel to the hot face of the lining; this is structural spalling.

Quantification of the mass of spalled materials from the hot face has been attempted by Chen and Buyakozturk [13], who combined slag dissolution and spalling effects into one expression in terms of the residual thickness X and the rate of thickness decrease. They proposed expressions as a function of the hot-face temperature T_H and the maximum depth of slag penetration D_P, referred to the location of the hot face at time t_i during the $(i-1)$th and ith spalling.

The same authors have developed a very interesting notion to approximate the value of D_p using a critical temperature criterion; they postulated that, for a given system, slag penetration occurs only when temperature reaches a critical value T_c, which could be related to the temperature above which a certain percentage of liquid phase may still exist in the refractory (always under a thermal gradient).

B1.3.4. Corrosion by Gases and Dusts versus Liquids. For corrosion by gases and dusts, the same qualitative relationships are applicable as for gas and liquid penetration into a refractory, except that wetting is not a factor. In gas corrosion, the driving force is the pressure gradient. Gas penetration is less rapid, in terms of mass, than that of wetting liquids; reactions do not necessarily commence at the hot face; and the depth of penetration of gases can be much greater than that of liquids.

Moving down a thermal gradient, gases may condense locally to form a liquid, which then may initiate a dissolution–corrosion process and migrate still further into the solid; alternatively, gases may react chemically to form new compounds (liquid or solid). Once condensation has occurred, the basic criteria for liquid corrosion apply. The condensed liquid fills the pores and debonds the refractory material, creating thermal expansion mismatches, weakening, softening, swelling, and slabbing.

Sulfur dioxide, usually from combustion or smelting operations, provides good examples of the condensation–corrosion patterns experienced in practice. Condensation leads to the formation of sulfate in magnesia at 1100°C, in lime at 1400°C, and in alumina at 600°C. When alkali vapors (Na_2O) are present with SO_2, condensation of Na_2SO_4 overlaps with SO_2 attack. Volatile chlorides also play a role.

When dusts are carried out in hot gases, they may lead to deposition or abrasion. Deposition leads to scaling or caking with either beneficial or life-shortening consequences. Dusts entrained in gases that condense within refractories may facilitate the gradual adhesion of solid particles to the working surface. The resulting buildup can be either a hard scale or lightly sintered cake acting as a protective barrier. In less obvious cases, dust and condensing gases fuse together to create an invasive liquid. In other instances, scaling and caking of refractory walls may not be acceptable to a particular process, and periodic descaling operations can lead to degradation of refractories.

Although no deposition may occur, abrasion can take place when refractory linings are bombarded by dusts. The extent of abrasive wear depends on the impinging particle size, shape, hardness, mass and velocity, angle of impact, fluid dynamics of the system, and viscosity of the eluant gas, among other parameters. Abrasion exacerbates corrosion.

Exposure of a refractory either to a liquid or to its saturated vapor is thermodynamically the same. The differences lie in the transport mechanism. In approximate order of decreasing thermodynamic power, the oxidizing gases are NO_X, Cl_2, O_2, HCl, CO_2, H_2O, and SO_2, and the reducing gases are active metal vapors, NH_3, H_2, C_xH_y, CO, common metal vapors, and H_2S.

B2. Corrosion of Specific Classes of Refractories

Detailed compilations of data on corrosion resistance of industrial refractories are not available because there are too many different products and too many variables to consider. Corrosion is also very seldom the only criterion to consider when selecting a material for a given application; other properties, such as thermal shock resistance and mechanical strength, must also be optimized, and there may be a need to compromise on corrosion resistance.

To assess the corrosion resistance of different types of refractories, a rule of thumb is to consider the temperature limits, above which corrosion is considered to be excessive, established considering the expected durability. From one application to another, this durability does vary greatly as does the mode of degradation: corrosion–dissolution or penetration and structural spalling or both. In Table 28.1, two cases are distinguished, slagging resistance and hot gas corrosion resistance. The first case is represented by a reaction of the type S + L, where L can be either a slag (from ironmaking, steelmaking, or copper smelting) or a flux (from other nonferrous metallurgy), either basic ($CaO/SiO_2 > 2$) or acidic ($Ca/SiO_2 < 2$, on a molar ratio), where S is a

TABLE 28.1. Guideline for Corrosion Resistance Based on the Criterion: Maximum Temperature

Limit Not Reached for "Normal" Durability				
	Temperature Limits (°C) of Slags and Fluxes[a]		Temperature Limits (°C) of Hot Gases[a]	
Type of Refractories	Basic	Acid	Oxidized	Reduced
1 Magnesia (M)	1700	NR	>2000	1700
Doloma (D)	1700	NR	>1800	1700
(M), (D) or (M + D) + Graphite	1800	1700	800	1700
Magnesia–chrome (MK)	1700	1600	1800	NR
2 High alumina (A)	1600	1600	1900	1900
(A) + Graphite	1700	1700	600	1700
3 Clays + (A) (65% Al_2O_3)	1300	1300	1450	NR
Clays + (A) + C	1550	1550	600	1700
4 Superduty fireclays (F)	1200	1250	1400	NR
Medium–low duty (F)	NR	1100	1200	NR
5 High silica	NR	1400	1750	1600
6 Zircon–zirconia	1450–1600	1500–1700	>2000	1800
Silicon carbide	<1400	1500	1200	1600

[a]NR = not recommended.

given refractory with a given texture. The second case is represented by a reaction of the type S + G, where G can be various hot gases, with or without dusts, either oxidizing (oxygen, air, or CO_2) or reducing (CO, H_2) (see B1.3.4). In Table 28.1, six types of refractories, from basic magnesia to acid silica and neutral zircon–zirconia, are considered.

B2.1. Basic Refractories. Basic bricks are commonly used in the metallurgical industry: steelmaking, copper–nickel, and the cement industry. Magnesia is the most commonly used basic refractory, followed by dolomite. Magnesia bricks are made of various magnesia raw materials (sinters from natural magnesite, sinters from seawater magnesia, or grains of fused magnesia). Many other types of magnesia bricks are used, in combination with chrome (MK), alumina (NA), and doloma (MD). The most corrosion-resistant magnesia bricks are made of fused magnesia grains. Magnesia–chrome bricks were best bricks available before magnesia–carbon-bonded bricks, containing flake graphite additions, were developed for their slagging resistance. Dolomitic refractories are made of burnt natural dolomite, usually low in iron oxide (0.3%) and alumina (0.2%). As for magnesia, very efficient dolomite–carbon bricks have been developed. As shown in Table 28.1, dolomite performance may match that of magnesia for specific applications.

B2.2. High-Alumina Refractories. High-alumina refractories are those that contain more than 65% Al_2O_3, composed of α-alumina (pure Al_2O_3 99.3 + %) and mullite $(Al_2O_3)_3(SiO_2)_2$. For high corrosion resistance, electrofused alumina and mullite products should be considered. As for any type of refractory, there are many different classes of products—fired and unfired—with many different bond systems, a commonly used one being a phosphate chemical bond system. Corrosion dissolution resistance is improved with increasing alumina content, but slag penetration resistance of such bricks then decreases, and hence, the structural spalling resistance also decreases. Improvements have been achieved with addition of chrome or silicon carbide, and, more importantly, of carbon.

B2.3. High-Alumina Refractories with Clay. High-alumina bricks with clay refractories have alumina content between 45 and 65%; they may contain andalusite or mullite mixed with fire clays and binders. Corrosion resistance varies greatly with mineral composition and relatively low refractoriness (measured by the lowest temperature at which a liquid phase is present in the material). The maximum temperature limit, as indicated in Table 28.1, may not apply for specific applications.

B2.4. Fireclay Refractories. Super duty, medium-duty, and low-duty fireclays are products containing alumina and silica, with alumina content varying between 40 and 45%, 30 and 40%, and 25 and 30%, respectively. They are used in a wide variety of kilns and furnaces because of their low price but are limited to low-temperature applications (1200–1250°C).

B2.5. Silica Refractories. Silica bricks contain typically >93% SiO_2 with minor amounts of lime (CaO < 3.5%), alumina (Al_2O_3 < 2%), and iron oxide (Fe_2O_3 < 1.5%). They have high corrosion resistance to acid slags but are sensitive to high temperatures and to thermal shock even at medium temperature levels. Bricks with reduced porosity and lower alumina content may be used to prevent rapid

degradation in the presence of alkalies, when hot gas corrosion prevails.

B2.6. Zircon–Zirconia and Silicon Carbide Refractories. Among the many available zircon–zirconia refractories, zircon bricks, containing mainly zircon sand ($ZrSiO_4$), have good wear resistance and poor wettability by molten metals at processing temperatures of up to 1450°C.

Zircon is decomposed to zirconia and silica at 1540°C. The most common zircon–zirconia bricks are the very special electrofused A–Z–S bricks containing alumina–zirconia–silica made especially for glass-melting furnaces. Refractory materials with high zirconia content require the use of stabilized zirconia (CaO or MgO in solid solution) to avoid cracking on heating due to monoclinic to tetragonal transformation in the temperature range of 1000–1200°C, with a large volumetric change. Properly prepared zirconia shapes have very high corrosion resistance and are not wetted by metals, even by steels, with different oxygen content.

Silicon carbide refractories are the nonoxide refractories most often used with carbon blocks, usually under reducing conditions. Many different types of silicon carbide refractories are available. They have the following advantages over oxide refractories: high thermal conductivity, superior spalling resistance, superior abrasion resistance, and hence high corrosion resistance against nonoxidizing slag (as in nonferrous metallurgical applications). Properties and costs of SiC refractories vary greatly, depending on the sintering aid used, but they do tolerate much more "impurities" than do structural SiC ceramics, which are discussed in the following sections.

C. CORROSION OF STRUCTURAL CERAMICS

The main differences between industrial refractories and structural ceramics are their purity and texture. Structural ceramics are manufactured from purified synthetic aggregates rather than from as-mined natural minerals. Since the 1960s, the refractory industry has used the available synthetic raw materials, so that the differences between the two groups, although still very significant, are much less than they used to be.

Porosity is a very important factor that influences texture; porosity is $< 2\%$ for most structural ceramics, whereas it is 12% or more for most refractories (up to 20% for conventional refractories and 50–70% for insulating refractories). Porosity is a consequence of the manufacturing process route followed, in particular the grain size distribution selected and the sintering conditions. For structural ceramics, mainly very fine grain sizes (in the 0.1–10-μm range) are used to obtain very dense materials. For structural ceramics, the objective is to maximize mechanical properties, whereas for refractories it is to maximize thermal shock resistance and volumetric change, with, of course, good corrosion resistance for both classes of materials.

The fundamental principles of corrosion of industrial refractories also apply to corrosion of structural ceramics, in both the S + L and S + G cases. Nevertheless, as porosity of structural ceramics is much lower, dissolution is more important than penetration. For the S + L case, the corrosion resistance of structural ceramics to molten salts determines their usefulness as components in the chemical industry, such as pumps and heat exchangers. The S + G type of reaction is important for structural ceramics used as kiln furniture in industrial furnaces and as components in gas turbine and diesel engines.

C1. Corrosion by Molten Salts

Comparative information is presented in Table 28.2 on the corrosion resistance to fused salts, alkalis, and low-temperature oxides for two different classes of structural ceramics: oxides and nonoxides.

Values have been compiled from the combination of two main sources [14, 15] and refer to the chemical inertness of pure crystalline materials, with purity >99.5%. For this reason, the data in Table 28.2 are of limited generality. For example, it is to be expected that ceramics with less purity will be attacked more rapidly. The code A, B, C should be used only for comparing the materials considered. It is to be

TABLE 28.2. Corrosion Resistance of Structural Ceramics to Fused Salts, Alkalis, and Low-Melting Oxides

	Fused Salts–Alkalis–Low-Temperature Oxides[a]							
Ceramics at Purity (>99.5%)	NaCl	NaCl + KCl	KNO_3	Na_2CO_3	Na_2SO_4	KOH	Na_2O	V_2O_5
Alumina	A1000	A800	A400	A900	A1000	B500	B500	C800
Zirconia (stabilized)		C800		C900	A1000	B500	C500	C800
SiC (react. bond.)	B900	C800	A400	C900	C1000 (air)	C500 (air)	C600	C800
Si_3N_4 (RBSN)			A400	C750 (air)	C1000 (air)	C500	C500	C800
Si_3N_4 (HPSN)	A800	B900		C900 (air)	B1000 (air)	C500	B500	C800
BN (HP)			A400	C900 (air)	C1000 (air)	C500	C500	

[a]A—Resistant to attack up to temperature indicated (°C). B—Some reaction at temperature indicated. C—Appreciable attack at temperature indicated.

assumed that the information is based on short-term observations at ambient pressure. McCauley [2] and Lay [3] provide a more complete coverage of the subject, including attack by glasses, aqueous solutions, and molten metals, but no further generalizations can be made from the specific studies that they reviewed because of limitations in the scope of the studies.

The data in Table 28.2 show that both dense oxides and nonoxides are susceptible to attack at low and intermediate temperatures. The normally protective SiO_2 layer that forms on SiC and Si_3N_4 may explain why such ceramics have a poor corrosion resistance in basic salts.

C2. Corrosion by Hot Gases

The S + G reactions discussed below refer to oxidation at high temperatures in air and oxygen, gaseous corrosion in the presence of condensed deposits, and reduction or oxidation by hot gases, CO(g), H_2(g), H_2S(g), and H_2O(g). High-temperature oxidation in air or oxygen is the most important type of corrosion for carbide- and nitride-based ceramics. Although the corrosion of structural ceramics in hot gases is similar in some aspects to the oxidation of metals and the same theories are used to describe the processes, there are some important differrences:

1. Ceramics have a much higher oxidation resistance than do metals.
2. Because oxidation occurs at much higher temperatures, the corrosion products formed are liquids and gases, as well as solids, which can lead to either weight gains or losses, causing practical experimental difficulties of interpretation.
3. The textures of ceramics are not as homogeneous as those of metals, and so it is very difficult to determine the controlling mechanism of the oxidation process without considering both the processing characteristics and the intrinsic nature of the raw materials used.

Gaseous corrosion in the presence of condensed phase deposits in combustion applications is the second most important type of corrosion, with sodium sulfate and vanadate being the most corrosive deposits. Nonoxide ceramics are particularly sensitive to this type of environment.

In Table 28.3, the corrosion resistance of dense structural ceramics to hot gases are presented using the same code as in Table 28.2. The oxidation resistance of nonoxide ceramics is clearly less than that of alumina and zirconia.

C3. Corrosion of Specific Classes of Structural Ceramics

C3.1. Alumina. Alumina is considered to be one of the most versatile materials that resist corrosive attack by acids, alkalis, molten metals, molten salts, as well as oxidizing and reducing gases, even at high temperatures. It is widely used in many high-temperature laboratory and pilot plant scale applications, such as crucibles, tubes, and special shapes.

C3.2. Zirconia and Thoria. Thoria is the most thermodynamically stable oxide and the one with the highest refractoriness, with a melting point of about 3300°C. Unfortunately, it is not a readily available material, being used essentially in the atomic energy industrial sector. Zirconia is also a very stable pure oxide, but it has to be used only when stabilized, fully or partially, with CaO, MgO, or Y_2O_3 additions. Such additions make the solid solutions $\langle ZrO_2–X\rangle$ more vulnerable to acid attacks and to alkalis.

C3.3. Silicon Carbide. Silicon carbide has very good resistance to acidic solutions (even HF) and molten metals but is prone to attack under severe alkaline (basic) conditions, in particular in air. The SiC ceramics produced by reaction sintering and containing free silicon are more susceptible to oxidation and chemical corrosion than is single-phase SiC obtained by hot pressing. The SiC is very susceptible to attack by liquid sodium and potassium sulfate. On oxidation, SiC forms a layer of SiO_2, but the possibility of forming SiO(g) increases with temperature and when the partial pressure of oxygen is decreased. The transition between "passive" oxidation (SiO_2 protective layer) and "active" oxidation [SiO(g) without protection] occurs at low pressures

TABLE 28.3. Corrosion Resistance of Structural Ceramics to Hot Gases[a]

Ceramics at Purity (> 99.5%)	Air	Steam	CO	H_2	H_2S	F(g)
Alumina	A1700	A1700	A1700	A1700		
Zirconia (stabilized)	A2400	C1800				
SiC (RB)	A1200	B300	A > 1000	A > 1000	A1000	A > 800
Si_3N_4(RBSN)	B1200	A220	A > 800	—	A1000	
Si_3N_4 (HPSN)	B1250	A250	A > 900	A > 800	A1000	A > 1000
BN (HP)	C1200	C250	A2000	A > 800		

[a]A, B, C, as in Table 28.2.

and high temperatures. SiC ceramics are more sensitive to hot corrosion than is Si_3N_4.

C3.4. Silicon Nitride. Thermodynamic calculations of equilibria in the system Si_3N_4–O_2 revealed that several reactions resulting in the formation of solids SiO_2, Si_2N_2O, SiO, and gaseous N_2, N_2O, NO, SiO, and SiN are possible. Reactions leading to the formation of SiO_2(s) are characterized by the most negative change in free enthalpy, but at high temperatures and low oxygen partial pressure, the possibility of reactions leading to the formation of SiC increases (significant at 1300°C and higher). The notion of passive and active Si_3N_4 oxidation has been well documented, but the controlling factor can be either diffusion of oxygen to the Si_3N_4–SiO_2 interface, diffusion of nitrogen to the SiO_2–air interface, or diffusion of impurity ions and sintering aids from the inner layers to the surface of the ceramic. A detailed survey of the subject is presented in [15].

For hot corrosion to complement the data listed in Table 28.2, only one significant result obtained on reaction-bonding silicon nitride (RBSN) will be recalled. Although Si_3N_4 exhibits high corrosion resistance in the stream of combustion products of pure fuel (10^{-5}% Na and V, 0.5% S) below 1400°C, it corrodes rapidly at 900°C when fuel contains 0.005% Na, 0.005% V, and 3% S. In liquid media, Si_3N_4 resists attack by acids up to ~ 100–200°C. The Si_3N_4 exhibits higher resistance in alkaline solutions than in alkali melts and is rapidly attacked by (Na_2SO_4, Na_2SO_4–NaCl, $Na_2SO_4 + V_2O_5$) melts but have good resistance to chloride melts NaCl + KCl up to 600°C and up to 1100°C in NaF.

C3.5. Boron Nitride. Boron nitride ceramics are usually prepared by hot pressing and normally contain a small proportion of boric oxide, a useful impurity that helps pressing but not its oxidation behavior at high temperatures. The BN ceramics are reported to be attacked by strong acids but are relatively inert toward alkalies. The nonwetting behavior of BN, similar in some ways to pure graphite, may account for this behavior.

Boron nitride starts to oxidize at about 700°C. Oxidation mechanisms differ from Si_3N_4 and SiC because in this case the oxide layer first formed, B_2O_3, is liquid and tends to evaporate to BO(g), BO_2(g), and B_2O_3(g) as temperature increases. Under reducing conditions, pure BN may be usable up to 1800°C. The most valuable characteristic of BN is its resistance to wetting by metals and alloys.

D. PREVENTING CORROSION

Minimizing corrosion of refractories and ceramics under severe conditions at high temperature is a very important task that requires the following three sets of problems to be addressed simultaneously:

1. Material selection, considering both intrinsic and extrinsic characteristics, such as the design and configuration of the component
2. Installation methods and maintenance procedures, considering that each material is a part of a bigger identity
3. Process control to minimize variability and extreme values

In this section, only the first set of problems will be considered, although, for practical solutions, the other two sets of problems should not be overlooked. To select the most appropriate material, the first rule is to make the acid–basic character of the refractory or ceramic constituents similar to that of the corrosive fluids (liquids and/or hot gases) and then to control the penetration–dissolution mechanisms to improve the corrosion resistance. The single, most important factor, in terms of material properties, is the porosity and in a broader sense the texture of the material.

D1. Porosity and Texture

Improvements in the corrosion resistance of refractories have been obtained through texture control resulting from the evolution in manufacturing processes toward much larger size distribution, better mixing, better pressing, and purer raw materials. Total open porosity has decreased to ~12%, a level of porosity that is required to maintain good thermal shock characteristics and acceptable insulating properties. While maintaining the porosity at this value, further improvements are possible through reducing the pore size distribution, so that the larger pores are of a smaller size, and through reducing the permeability of the refractory by using fused grains instead of sintered grains to reduce the openness of the porosity. Other possible ways to minimize penetration in refractories will be discussed in subsequent sections.

For structural ceramics where high strength is more important than thermal shock resistance, porosity can be controlled to very low values (<0.5% in many cases). For these materials, various sintering and densification techniques have been developed, such as reaction-bonded sintering and hot pressing, using very pure, fully densified powder of very small grain size. Porosity control in structural ceramics is nevertheless important. For example, to achieve full density, Si_3N_4 and SiC can be impregnated either with an organosilicon compound that is subsequently decomposed to produce a pore-filling oxide or with a material that is subsequently exposed to a nitriding or a carbiding treatment.

D2. Factors Governing Penetration

Once porosity has been adjusted to its optimal value (fixed for a refractory, nil for a structural ceramic), penetration can be

minimized by (1) adjusting the composition of the penetrant fluid; (2) adjusting the wetting–nonwetting characteristics of the same fluid; (3) adjusting the thermal gradient in the material, if at all feasible; and (4) glazing or coating the working face or in some specific cases the back or cold face when oxidation of nonoxide constituents is important.

D2.1. Composition Adjustment of the Penetrant Fluid. The composition of the penetrant fluid changes during penetration because dissolution and penetration occur simultaneously; if either the melting temperature or the viscosity of the liquid penetrant increases, the depth of penetration can be minimized. This desirable result can be achieved by carefully selecting the matrix additives; for example, a small amount of microsilica can be added to a cement-free alumina-spinel used in some steelmaking applications.

D2.2. Changing the Wetting Characteristics. In steelmaking applications, wetting characteristics can be changed by adding nonoxides to traditional oxide compositions and using nonfired instead of fired products, for example, by using carbon-bonded refractories and graphite. Insertion of graphite in magnesia-based materials limits penetration and improves corrosion resistance by a factor of 10. Graphite is not wetted by CaO–SiO_2 slags and is therefore a barrier to penetration. Of course, graphite can be oxidized and should not be used in every situation. Impregnation of pitches and tars modifies the bonding phases in refractories and influences penetration phenomena very significantly. Numerous other examples are available in the technical literature, for example, the use of specific additives, such as $BaSO_4$ and CaF_2 in alumina–silica-based castings containing liquid aluminum metal and alloys.

D2.3. Adjusting the Thermal Gradient. To minimize corrosion, it is important that the penetrating liquid solidify as closely as possible to the hot face, so that the rate of penetration is minimized. For a given hot face temperature, the thermal gradient should be as steep as possible, which can be achieved by vigorously cooling the cold face, by using highly conductive material, and by increasing the thermal conductivity of the lining by conductive backup material.

D2.4. Use of Glazing or Coating. Sacrificial coatings can be used in some specific situations in which penetration is an important factor. For black (carbon-containing) refractories and for structural ceramics sensitive to oxidation (nonoxide ceramics), the protection of the back face to avoid oxidation has been identified as an important factor. Glazing the hot face using compounds of low-melting temperature has to be analyzed very carefully because glazing can lead to less penetration but more dissolution. Preoxidation treatment to form a protective oxide layer on Si_3N_4 or SiC materials can be beneficial. Uses of multiple layers of new materials, such as "Sialons" (silicon–aluminum oxynitride) and "Simons" (silicon-magnesium oxynitride), have also been studied.

D3. Factors Governing Dissolution

Penetration and dissolution act together and interact, so that the factors controlling them are, to a certain extent, inseparable. Dissolution is controlled by both the chemical reactivity and the specific area of the constituents—the smaller the grains, the faster they dissolve—but in refractories, the smallest grains, by design, bond with the coarser grains (the aggregate), and since this bonding occurs by liquid–solid sintering, the matrix materials (the bonding phases) have the lowest melting temperatures and the highest reactivity. In general, the dissolution of the bonding phases (or the matrix) leads to debonding between the coarser grains, the dissolution of which is inherently slower and usually apparent only at the refractory hot face.

To minimize dissolution of the matrix, the composition can be altered to raise its melting temperature by increasing the chemical purity of the matrix, so as to decrease the importance of segregated impurities. Practical examples include the use of tabular alumina, instead of bauxite grains, and very high purity magnesia grains. Alternatively, to raise the melting temperature of the matrix, finely powdered matrix additives can be included in the refractory mix. Because the matrix is a flux in sintering, these additions require higher sintering temperatures to optimize the bonding and the mechanical properties of the resulting products. The logic of reducing or eliminating additives of low-melting temperature for improved corrosion resistance is compelling, but the consequence is that the sintering temperature must be raised.

A thorough knowledge of the different binder systems (for nonfired refractory products) and the different bonding systems (after firing) goes a long way to explain the different dissolution characteristics of the many refractory materials and ceramics of a given type. The texture and, in particular, the porosity are key parameters to be considered. Dissolution of the coarse grains becomes a life-limiting factor only when penetration and matrix invasion are sufficiently minimized.

D4. Factors Governing Oxidation

Oxidation of carbon-bonded refractories will be considered first. Carbon and graphite oxidation is very detrimental because these material losses lead to porosity; the low specific gravity of carbon causes a 5% material loss to lead to 7–10% porosity. To minimize the rate of carbon and graphite oxidation, new additives, called antioxidants or oxygen inhibitors, have been successfully used. Some general reviews on the role of antioxidants, in such cases, are available, but this topic is outside the scope of this chapter. Among the many additives [16, 17] now available, the

metallic aluminum-based alloys are the most commonly used, sometimes in conjunction with various nonmetals, such as silicon carbide and boron compounds. These additives are used to delay carbon debonding and graphite oxidation. In addition, they often act as pore blockers, and many of them have a net positive effect on the mechanical strength of the refractories.

Oxidation of nonoxide structural ceramics can be improved by using protective coatings. The use of a chemically vapor deposited (CVD) layer of the same composition as the substrate is a very promising application of coatings to retard the hot corrosion of structural ceramics [18]. Other methods investigated are cathode sputtering and thin multilayer coating.

As an example, a potential high-temperature oxidation protection scheme could involve a coating system consisting of a refractory oxide outer layer for erosion protection, a silica glass inner layer for an oxygen diffusion barrier and crack sealant, another refractory oxide layer for isolation from the carbon surface, and a refractory carbide inner layer for a carbon diffusion barrier [19]. This system, as with other current or potential protection technologies, involves interfaces between metal oxides and carbides or oxynitrides. The oxidation resistance of nonoxide ceramics is a dominant problem that restricts the wider usage of these materials.

A. INTRODUCTION

Corrosion properties of glass have been investigated since the advent of modern chemistry. Surface reactions of glasses with fluid media, such as adsorption and desorption, chemical reactions, ion exchange, and so on, play an important role both in manufacturing (polishing, cleaning, coating, and production of silica-rich glass) as well as in product properties, such as mechanical strength, reflectance, and catalytic activity. Studies have been performed to qualify glass as a material for reaction vessels and optical instruments, for use in building construction, for cement and plastic reinforcement, for bone replacement, for radioactive waste fixation, and for many other applications.

The corrosion behavior is typically studied in the laboratory using a large variety of test methods. Included are various standard test methods [1–6] allowing comparison of specific dissolution properties of different glass compositions, test methods for quantification of rate law parameters [7, 8], tests for simulating service conditions, and so on. In these tests, powdered or bulk glass samples with or without special surface treatments are exposed to stagnant or flowing aqueous media, distilled water [9], or other corrosive fluids at low or high temperatures in autoclaves [10]. Vapor hydration tests are used by archeologists to understand natural alteration of obsidians [11] or stability of nuclear waste glass in vadose zones. Corrosion properties are characterized by the analyses of detached glass components dissolved or dispersed in these fluids, of solution pH, solid corrosion products or by analyses of corrosion depth (ion implantation or profilometry), concentration gradients of reactants, or glass components at the glass surface. In addition to laboratory testing, features of natural or archeological glasses are analyzed, mainly by surface-sensitive techniques.

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

Probably the most widely studied glasses today are soda lime glasses, vitreous silica, and nuclear waste glasses. By using a multitude of test methods, extensive experimental databases have been created and models have been developed to predict the behavior of these glasses in geological environments for thousands of years. Reviews of the current state of knowledge are available [12–16].

In most cases, it is not possible to use corrosion test results directly to assess behavior under service conditions. A ranking of the relative corrosion resistance of glass compositions often depends on the test method used. To a large extent, this is due to multiply coupled processes, resulting in highly nonlinear corrosion behavior with respect to parameters such as glass composition, pH, solution volume, and so on. Consequently, the prediction of glass performance under service conditions can hardly be based on a single test but requires an extensive test plan. This is particularly obvious when using results from laboratory tests that may be carried out over a period of a few years to assess the performance of nuclear waste glasses intended to immobilize radiotoxic elements for thousands of years. In the laboratory, short-term phenomena and test artifacts become important, while dominant long-term processes are difficult to quantify.

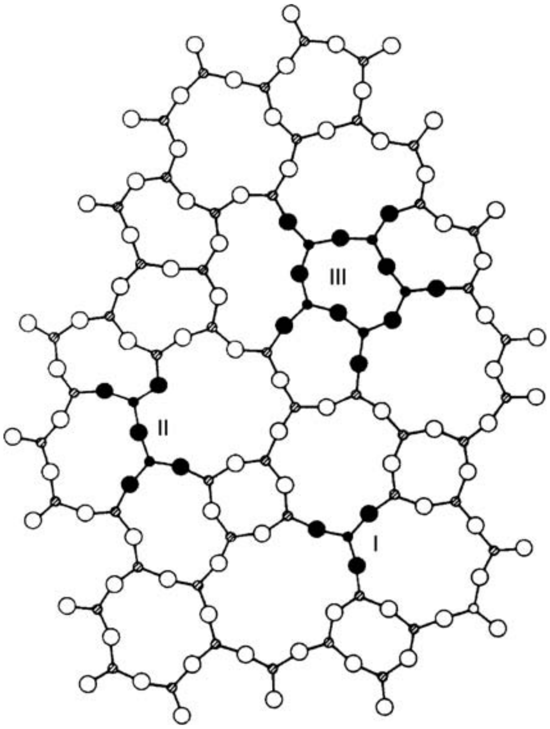

FIGURE 29.1. Glass network according to Zachariasen without far range order but with order in the ranges I, II and III [15].

B. STRUCTURE OF GLASS

For understanding basic glass corrosion mechanisms, some fundamental knowledge of glass structure is necessary. Glass structure can be described as a randomly oriented continuous glass network [24, 27]. The amorphous structure is very complex. Neutron-scattering analyses and extended X-ray absorption fine structure (EXAFS) allow three ranges of order for silicate glasses to be distinguished (Fig. 29.1; [17]):

Range I: ordered cation, coordination spheres, as in crystals [18] (with a tendency to smaller coordination number [19, 20]

Range II: cation polyhedra connected by oxygen (in oxide glasses)

Range III: larger units such as rings and chains (e.g., in phosphate glasses)

Depending on formal charge, size, and coordination number, a given cation, such as Si, P, B, or Al, may increase the connectivity of the glass network (network former); others, like the alkali elements, may decrease it (network modifier) or may take an intermediate role [21–24], Glass network connectivity is maintained by mixed ionic–covalent bonds [25]. In silicate glasses the fundamental structural units are silica tetrahedra, which easily interconnect by forming siloxan bridges ($\equiv$Si$-$O$-$Si$\equiv$) [24, 26, 27]. Pure vitreous silica has a high chemical resistance but has various technical disadvantages (high melting point, small working range), so that it is only used for specific applications. Addition of alkali ions reduce both melting point and corrosion resistance due to disruption of oxo bridges and formation of strongly ionic nonbridging oxygen bonds (NBOs) bonds ($\equiv$Si$-$O$-$Si $\equiv$ + $Na_2O \leftrightarrow 2\equiv$Si$-O^-Na^+$), In case alkali concentrations become very high, one can observe the formation of channels with high mobility for alkali ions. Using ^{29}Si nuclear magnetic resonance (NMR) one can distinguished between Si-tetrahedra with four, three, two, and one oxo bridges (Q^4, Q^3, Q^2, Q^1 sites). The distribution is governed by the alkali–SiO_2 ratio. By Coulombic forces, the glass network takes a structure of maximum distance between negative charge centers [28]. Alkali earth cations can increase the crosslink density of the glass network (e.g., Ca^{2+}: bonds $\equiv$Si$-$O$-$Ca$-$O$-$Si$\equiv$). The number of oxo bridges in the glass can also be increased by adding Al to the glass, leading to the formation of anionic aluminate tetrahedra bound to Si-Q^3 sites [29]. The resulting negative charge is compensated by locating alkali ions in the vicinity. At a ratio $R =$ Al–alkali of 1, the charge is compensated entirely and Na ions are very immobile [30].

According to Hinz [32] the coordination number of cations in the glass structure depends on the ratio cation radius/anion radius. Up to a ratio of 0.225, threefold coordination is dominant, to 0.414 tetrahedral, to 0.732 octahedral, and to 1.00 there is cubic coordination. A comparison of

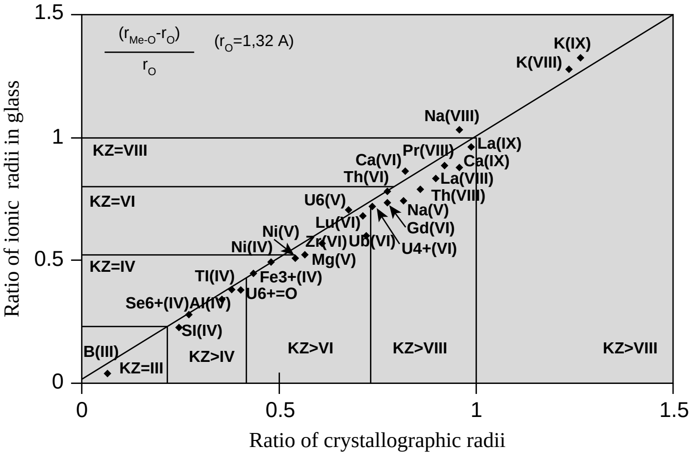

FIGURE 29.2. Comparison of crystallographic ratios of cation to anions with respective ratios for glasses.

cation–anion radii ratios and coordination numbers of various cations in crystalline structures and oxide glasses is given in Figure 29.2. Average crystallographic radii are obtained from bond length data of Shannon [31] (with $r_{\text{oxygen}} = 1.32\,\text{Å}$ [32] instead of 1.26 used by Shannon). Figure 29.2 shows a 1inear relation clearly indicating that bond length in glasses and crystals are similar, but coordination numbers appear to be slightly higher in crystalline structures. According to this diagram, network-forming cations occur up to a ratio of radii of 0.55.

B1. Heterogeneity

When glasses contain multiple phases, typically one phase is more soluble than the other and may control the corrosion resistance or leaching rate. Examples are B-rich borosilicate glasses with an easily leachable B-rich glass phase or soluble alkali molybdate phases formed in ill-defined nuclear waste glass compositions. In contrast, in silica-rich borosilicate glasses, phase separation can lead to an increase in glass durability if a durable Si-rich continuous phase is formed, which includes the B-rich phase in dispersed form [33]. Even in the absence of phase separations, microheterogeneities may occur. In 1921, a glass structure theory was developed [34] based on randomly oriented microcrystals similar to the recent "strained mixed cluster" model [35, 36]. Typical clusters are boroxol rings in B_2O_3–glass, P_8, or P_9 cages in some phosphate glasses or layered Ca octahedra in Ca silicate glass. Cluster boundaries are reactive centers.

C. GLASS CORROSION MECHANISMS

The corrosion rate of glass is not an inherent material property but depends on glass composition, structure, and surface states as well as on environmental conditions, such as the composition of the corrosive fluid (including pH), hydrodynamic conditions, temperature, stress, strain, vapor pressure, and so on. An overall mechanism of sequential and parallel partial reactions can be formulated for the glass–water reaction, probably applicable to most glass compositions. Different reaction rates and empirical rate laws as well as specific selective leaching properties and pH changes are interpreted as resulting from the different relative importance and consequences of the various partial reactions in the overall reaction scheme. The nature of the rate-limiting reaction in this overall scheme depends on both environmental constraints and glass composition and structure.

The principal partial reactions in the glass–water interaction are glass network hydration, ion exchange, and dissolution of the glass network, resulting in changes of composition of corroding fluids and formation of altered surface layers. Additionally, transport processes, such as access of reactants (e.g., water molecules) and removal of products (e. g., dissolved glass network formers), may become rate limiting under certain conditions.

Glass hydration and alkali–H^+ ion exchange are reactions that occur in parallel with glass network dissolution [37–40], and these reactions are interrelated; for example, in silicate glasses, alkali exchange leads in most cases to pH increase in solution (but not in Mg-rich solution), which increases glass matrix dissolution rates.

The alkali–H^+ ion exchange process is often (not always [41]) diffusion controlled, implying that the rate of selective alkali release from glasses is initially highest and decreases with the square root of time until it becomes equal to the rate of matrix dissolution. The process may be governed either by the electroneutrality coupled, diffusion coefficients of alkali ions, and H^+-bearing species in opposite directions, with the lower mobility of H^+-bearing species such as H_3O^+ ions [42, 43] normally being rate controlling.

Alternatively, the rate-limiting reaction may be the diffusion of water molecules into the glass network [44–46], that is, the hydration of the glass network. Based on findings that the pH response of glass electrodes is essentially determined by exchange equilibria of the outermost surface species with species in solution, it was suggested that ion exchange at the surface is driven by electrochemical potential differences between charged and uncharged surfaces species and the bulk glass [47]. However, the electrical coupling of H^+ and Na^+ migration in the surface layer leads to electrical fields much stronger than those between the surface and the glass [48].

Various models for the coupling of ion exchange and matrix dissolution can be found in the literature [49–51]. The relative importance of the ion exchange reaction depends on the diffusion coefficient D (m^2/s) and the corrosion rate r (m/s). The D depends on glass and solution composition. For borosilicate glasses it can be shown that D is not related to the diffusion coefficient of Na in the dry glass [52]. The ion exchange process is strongly reduced with increasing alkali content of the solutions. The effect increases in the order $Li^+ < Na^+ < K^+ < Cs^+$ [53]. In the time between $t = 0$ and $t \ll r^2/D$, the overall reaction is diffusion controlled [54]. Matrix dissolution becomes dominant for times $t \gg r^2/D$. The ratio D/r gives the average steady-state depth of either alkali diffusion or water diffusion in the glass and the product $r \cdot t$ denotes the thickness of corroded glass.

For silicate glasses, it has been shown [55] that the corrosion rate r is proportional to the thermodynamic stability of a hypothetical mechanical mixture of component oxides. This linear free-energy relationship has been confirmed for window glasses, medieval church glasses, natural basalt glasses, and nuclear waste glasses [56], In general, the corrosion rate r is not constant but depends on solution composition. The pH and the concentration of matrix formers (e.g., dissolved silica) in solution are particularly important. Minimal corrosion rates are often observed at neutral pH [57, 58]. The pH dependence is related to the concentration of activated surface complexes [59]. Often, a decrease of corrosion rate r with time is observed. Initially, this decrease with time was interpreted as an effect of protective layers, but later it was shown, for silicate glasses, to be an effect caused by solution saturation, described in a simplified way as [60–62]

$$r = k_+ \left(1 - \frac{C_{\text{Si, actual solution concd.}}}{C_{\text{Si, saturaton concd.}}}\right) \tag{29.1}$$

with the saturation concentration of silicic acid and the forward rate constant k_+ depending on pH, solution composition, temperature, and ionic strength. Saturation effects were also reported for some phosphate glasses [212]. With the approach of saturation, the affinity [63] of glass dissolution and thus the reaction rate decrease [64–66]. At saturation, the corrosion rate decreases by up to a factor of 1000, but corrosion continues, due to either formation of secondary phase or continued alkali release by the ion exchange reaction. The saturation effect may result in an increase of corrosion rate with increasing solution volume. The effect of surface area to volume ratio (S/V) on glass corrosion rates has been known for more than 20 years [67, 68] and is illustrated with experimental data for a nuclear waste glass in Figure 29.3 [71].

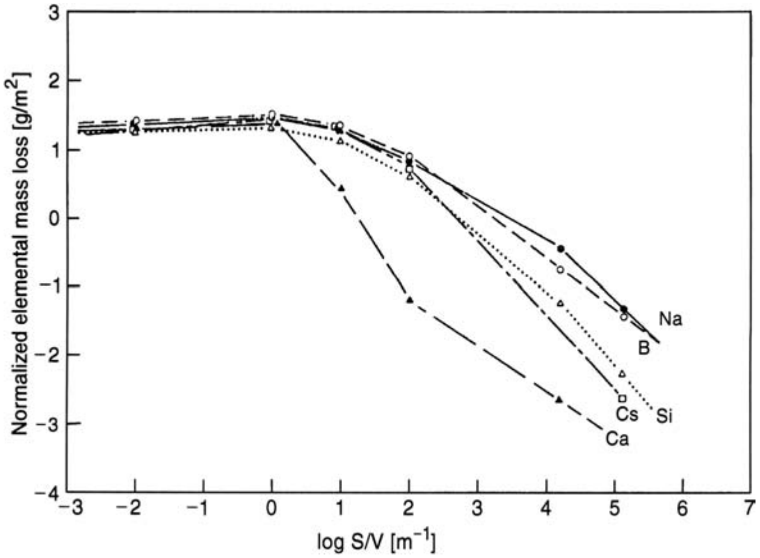

FIGURE 29.3. Dependence of the extent of glass corrosion [normalized elemental mass loss (NL)] on the ratio *S/V:* PNL–76/86 glass, 90°C, pure water [67]. Divided by the density of the glass ($2.7\ g/cm^3$) NL values can be translated into equivalent reaction layer thickness (in μm).

At the lowest *S/V*, mass loss per unit surface area, corrosion rates, and corrosion layer thickness are maximum values and independent of *S/V*. Two further reaction steps can be observed with higher *S/V* [69]: an intermediate step where the reaction rate decreases to a minimum (as shown in Fig. 29.3) and at very high *S/V*, where the reaction rate is augmented by secondary phase formation. Whether or not this last step occurs depends on glass composition, particularity on the Al content [70].

Two *S/V* effects should be distinguished: pH-related effects and saturation effects. Larger *S/V* values lead to faster saturation and often to pH increase (not always, e.g., not with phosphate glasses, or with silicate glasses in Mg-rich waters). Thus, in a nonbuffered system, the pH-dependent corrosion mechanism [68] varies with the *S/V* ratio. The saturation-related *S/V* effect leads to a dependence of the extent of glass corrosion on the product *t. S/V*, as confirmed experimentally [71]; however, simultaneous occurrence of saturation effects and pH variations may complicate this simplistic view [72].

D. EFFECTS OF GLASS COMPOSITION ON CORROSION KINETICS

The stability of the glass matrix against corrosion, ion exchange, and water diffusion as well as saturation concentrations and long-term corrosion mechanism, depend to a large extent on glass composition. The chemical nature and concentration of the glass components are both important. Depending on the interactions with other glass components, a given component may act as either a stabilizing or a destabilizing agent; it may enhance or decrease the relative importance of ion exchange when compared to matrix dissolution.

A comparison of the corrosion rates of important commercial silicate glasses at 90°C and buffered pH 7 is given in Table 29.1 [73].

The table shows that glass components do influence glass stability. However, since effects are not additive, it is difficult to predict the corrosion rates of multicomponent glasses from the corrosion rates of simple glasses. The effect of composition on stability is not an inherent glass property but depends on solution composition, the *S/V* ratio, and so on. The corrosion stability of a given glass must be experimentally determined if performance is to be predicted for specific service conditions. Nevertheless, some quantitative estimations of glass corrosion effects are possible and are described in the following paragraphs.

There are both theoretical and empirical models describing the effect of glass composition on corrosion rates. Theoretical models are based on semiempirical linear-free-energy relationships (LFER). The most important model is based on studies of Paul [75] showing a relation between corrosion resistance and the hydration enthalpy of a mechanical mixture of component oxides and silicates. This model applies particularly to k_+ in Eq. 29.1 [76]. A list of standard hydration enthalpies $\Delta G^{\mathrm{o}}_{\mathrm{hyd,i}}$ is available [77, 78] and can be used to formulate the standard hydration enthalpy of the glass phase in order to calculate corrosion rates caused by solution hydrolysis using the equation

$$\ln r = k_1 \sum X_i \Delta G^{\mathrm{o}}_{\mathrm{hyd},i} + k_2 \qquad (29.2)$$

where k_1 and k_2 are empirical constants that are specific for a given corrosion test. For borosilicate and lead-rich glasses, deviations from linearity were interpreted as resulting from different structural roles of boron in the glass and were corrected [79]. If solution hydrolysis and complexation of

TABLE 29.1. Corrosion Rates of Silicate Glasses at 90°C, pH7[a]

	Composition (wt %)	Linear Rate (μm/d)	E_a (kJ/mol)	Hydration Free Energy (kJ/mol)	References
Sodium-trisilicate	SiO_2 (75), Na_2O (25)	344		– 18.5	73
Corning 015 soda lime	SiO_2(72), Na_2O(22), CaO(6)	5.7	84	– 19.6	73
PPG soda lime	SiO_2(74), Na_2O(13.3), CaO(8.3), Al_2O_3 (0.06), MgO(3.7)	0.8	68	– 13.8	73

[a]See [73].

dissolved glass constituents as well as surface complexation constants are taken into account, the corrosion rates of silicate glass fibers can be accurately described in the pH range 1–12 [80]. An alternative model is the structural bond strength model [193]. This model assumes that the corrosion resistance is controlled by the average bond strength *V* in the glass, which can be calculated from the enthalpy of formation of the component oxides, considering the role of a glass component as network former, modifier, or intermediate oxide. For more accurate prediction, empirical models are used that allow interpolation (not extrapolation) in an empirical compositional multidimensional space. These models are based on a multivariate fit of thousands of experimental data to a general equation [81].

E. SURFACE MODIFICATION

After the first contact of a corrosive fluid with the glass, the surface becomes electrically charged, bonds resulting from the population of charge carriers (surface species: $\equiv SiO^-$, $\equiv SiOM$, $\equiv SiOH$, $\equiv POH \cdots$) that belong both to the glass and to the solution. Surface species distribution is responsible for the response function of glass electrodes, and not ion exchange, as is assumed normally [82].

Often, a sequence of reaction layers can be identified, consisting of an inner diffusion layer, followed by a porous gel layer, and one or more laminar layers of precipitated reaction products. The dissolution front of the glass phase is located between the gel layer and the inner diffusion layer. In many cases, there is a smooth transition between the diffusion layer and the gel layer and both together are termed the "gel layer" without distinction [91]. The chemical and mineralogical composition of the assemblage of layers determines the retention capacity for radiotoxic or chemical toxical substances, the reflection properties, and so on. The principal scheme of these layers is given in Figure 29.4

In water-containing fluids, the initial surface modification is glass hydration without loss of the glassy state. If sufficient network bonds are hydrolyzed, a transformed layer [83] (gel) is formed with a clear phase boundary to the glassy phase. The transformed surface layers are porous [84], containing molecular water [85, 86] and allowing for high ionic mobility [87] as well as high water mobility. Molecular water may result from inward diffusion of water carrying H^+ ions or may alternatively, result from the condensation reaction [88, 89], $2\equiv Si{-}OH \rightarrow H_2O + \equiv Si{-}O{-}Si\equiv$ bonds. The quantity of water entering the glass depends, among other parameters, on space and strain in the glass network [90].

Ion exchange results in a depletion of alkali ions in the hydrated glass. Potassium-rich silicate glasses show concentration profiles with smoothly decreasing K concentration from the bulk glass to the surface, whereas sodium-rich silicate glass show S-shaped profiles with almost constant Na concentrations between an inflection point and the surface [91]. This difference in shapes was explained by the different structures of Na and K silicate glasses [92], but this is unlikely, as in mixed Na–K lime glasses the same difference in respective concentration profiles was observed [93]. Conradt and Scholze [91] provided a convincing explanation for the different shapes: When ion exchange in the "gel layer" is more rapid than the formation of this layer, the S shape is found, whereas for comparable velocities of the two processes the potassium profile results. In natural tektite glasses [94] and obsidians [95] one has observed water diffusion without alkali release, clearly indicating that ion exchange is a secondary process to water diffusion. Alkali release is also suppressed if the alkali content of the solution is high [96].

The corroded glass may also dissolve entirely (as occurs with some potassium silicate glasses), but in many cases the glass surface becomes enriched at the surface with sparingly soluble glass constituents. This is particularly true if the glass contains large quantities of heavy metals. Depending on glass

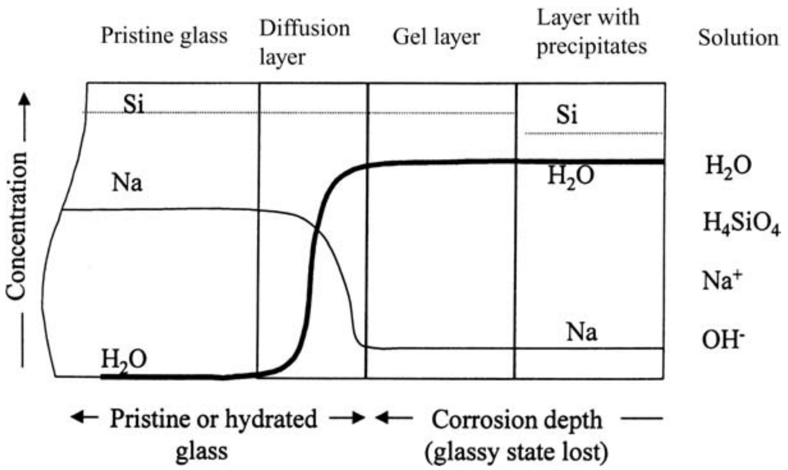

FIGURE 29.4. Schematic representation of different surface regions of corroded silicate glasses.

composition and environmental constraints (temperature, pressure, solution composition, pH, flow rate, vapor pressure, contact time, etc.), amorphous (gel) for crystalline reaction products are formed.

When compared to the original glass, the gel layer is depleted in network-modifying elements (Na, Ca, Li, Cs, etc.) but enriched in Si, Al, transition, and heavy metal contents (Fe, Ti, Nd, U, Zr, etc.) [97, 98]. Under acid conditions, even rare earth elements become depleted [99]. Metal ions from solution may become incorporated into the gel layer (e.g., Mg). The content of molecular water is significantly higher than the content of silanol groups [100] and water may occur phase separated in the structure of the layer [101]. The interface between the diffusion layer and the gel layer often has the character of a phase boundary. The gel layer is attached to the diffusion layer by siloxane bridges ($\equiv$Si–O–Si$\equiv$) bonds [136] but is often possible to mechanically remove the adhering gel from the glass surface.

The gel layer is a rather stable alteration product whose dissolution rate may become smaller [102] or larger [103] than that of the glass. It is likely [102] that the solubility of the gel determines the saturation effect with respect to the glass [Eq. 29.1].

Released glass components accumulate in solution until solubility limits with respect to pure and mixed secondary phases are achieved. If the solubility is exceeded, precipitates form at the outer surface or even within the gel layer. The composition of the precipitates is a strong function of chemical alteration conditions (e.g., pH, pCO_2, redox potential). In principle, the composition can be predicted both for closed and open systems using models based on equilibrium thermodynamics [104] (geochemical modeling [105]). Successful modeling efforts are reported in the literature, particularly on basalt glass alteration [106–108] and nuclear waste glass alteration [109, 110]. The sequence of secondary phases during silicate glass corrosion is metal (hydrate) oxides → clays → zeolites → SiO_2.

Typical oxides and oxyhydroxides are amorphous or crystalline iron oxyhydrates such as goethite or akaganeite, Tihydroxides, or aluminum hydroxides such as gibbsite. These phases are formed in the first hours of glass/water contact within a layer of few hundred nanometers [111–114]. Clays are among the most abundant crystalline alteration products of both natural glasses and man-made glasses [97, 115–117, 148]. Zeolites are formed mainly at alkaline pH (8–14). Typical zeolites formed are phillipsite [118] and chabazite. Analcime is formed particularly at temperatures between 150 and 250°C [12, 97, 98, 115, 119, 148]. Other crystalline alteration products include calcium–silicate hydrate (CSH) phases $BaSO_4$, anhydrite, molybdates, phosphates (e.g., Apatite [120], $LiPO_4$ [148]), silicates (e.g., uranyl silicates, Weeksite [121], Uranophane, and Haiweeite [122]), and layered double oxides like hydrotalcite [123]. The kinetics of zeolite formation can be described by growth and dissolution reaction processes, closely resembling the Oswald step sequence [124].

With certain glass compositions, secondary-phase formation may also be detrimental to glass corrosion. This is particularly the case if formation of silica-rich zeolites prevents silica concentrations in solution to reach saturation values. Frequently, an increase of corrosion rates is observed once zeolites are formed [125].

F. PROPERTIES OF SURFACE LAYERS

F1. Surface Layers as Protective Surface Films

In order to explain the time-dependent decrease of corrosion rates, it has been assumed [126, 127] that the corrosion layers are protective, but, in many instances, corrosion rates decrease because of saturation effects in solution [131]. Mass balance calculations have shown that borosilicate glass dissolution continues even if tightly adhering surface layers are formed [128]. However, particularly in Mg-rich solutions, a protective effect was observed for borosilicate glass compositions [129], soda lime glasses [130], and natural tektites [131]. For soda lime glass, the addition of Al had a similar effect as Mg in decreasing corrosion rates. Protective effects of surface layers were also observed on bioactive glasses exposed to artificial plasma [132] and phosphate-containing solutions [133]. This effect was attributed to formation of Ca–phosphate crystals (apatite) at the glass surface.

The protective effect of the surface layer may be interpreted by local saturation phenomena, that is, by the formation of a diffusion barrier for dissolved H_4SiO_4(aq) [134, 135]. This implies a protective effect being particularly important if the forward reaction rate of the glass is high. This protective effect becomes unimportant if the bulk solution becomes saturated with respect to dissolved H_4SiO_4(aq) or if, because of tensile stress, fractures are formed in the surface layer [136].

G. EFFECT OF FLUID MEDIUM

G1. Effect of Composition of Aqueous Solution

G1.1. pH The most important parameter governing glass corrosion is probably the solution pH. Solution pH influences the reaction mechanism, the solubility of silica and metal cations, the degree of selectivity of the corrosion process. For example, with borosilicate glasses in acid media, selective extraction of glass modifiers and of B is observed, whereas under alkaline conditions congruent dissolution occurs. Dissolution rates under alkaline conditions increase significantly with pH [137]. If the boron concentration in the glass is sufficiently high to hinder the formation of a continuous

three-dimensional Si–O–Si network, smaller $(Si–O–Si)_n$ units may be formed and may be released by a percolation process, leading to congruent release even under acid conditions (pH2) [138].

For evaluating the effect of pH on glass dissolution, it is important to recognize the inverse effect of glass dissolution on pH. A self-accelerating failure mechanism of glass occurs if glass dissolution leads to increase or decrease of pH, and corrosion rates increase because of these pH changes. The interrelationship may be illustrated with some examples:

1. In a nonbuffered static test with limited solution volume, the alkali released from commercial Al-containing soda–lime silicate glass leads to a rapid increase in pH, with increasing dissolution rates. Rates become significantly higher than those of Pyrex glass, the latter showing less increase in pH during corrosion. The situation is entirely different if the pH is buffered at 7. Then the soda–lime glass becomes more stable than Pyrex glass [73]. The slower increase of pH when dissolving Pyrex glass was explained with the smaller Na content of this glass. However, a factor probably even more important is the boron content of the glass. Dissolved boron can act as a very efficient buffer, fixing the pH at a value of ~9. The high stability of borosilicate glasses may, at least in part, be attributed to this buffer effect. A key factor controlling pH changes during glass corrosion is the alkali–B ratio in the glass. If this ratio is smaller than or equal to unity, there will always be sufficient B in solution to buffer the pH.
2. Silicate glass dissolution in Mg-rich solutions leads to decreased pH and increased corrosion rate of Al- or Fe-rich glasses. This effect also occurs during the alteration of natural rhyolitic glasses in arid environments [139]. A particularly detrimental effect of the pH decrease is the mobilization of heavy metals. This effect was observed when actinides were released from borosilicate nuclear waste glasses [140].
3. The phosphoric acid release from phosphate glasses, as well as the fluoride release from heavy metal fluoride glasses, in static tests leads to a rapid decrease in solution pH and to an increase in glass corrosion rates, as discussed in the following paragraphs.

Often, these pH changes occur in standard tests, making data interpretation difficult. Studies on the effect of pH on glass corrosion must therefore be performed in buffer solutions at constant pH, in very high solution volumes, or at high water flow rates. The design of more stable glass compositions may focus more clearly on this self-accelerating mechanism; for example, constituents that provide a pH buffer effect can be added to the glass formulation.

G1.2. Effect of Special Ions in Solution Highly concentrated alkali salt solutions are known to decrease glass corrosion rates [141]. This effect has been explained by the suppression of the initial ion exchange processes. The corrosion resistance of alkali borosilicate glasses can be enhanced significantly by adsorption of certain ions from solution, such as Al^{3+}, Ca^{2+}, Mg^{2+}, or Zn^{2+} [142]. The effect may in some cases be explained by the formation of protective layers. Also, the solubility of the surface gel layer may be decreased by adsorption of these ions. If the saturation effect of glass dissolution is associated with the solubility of the gel, then the decrease of solubility should have a strong effect on glass corrosion rates. Adsorption of ions from solution was found to decrease in the order $Ca > Ba > Ag > Mg$ [143].

G2. Corrosion by Vapor-Phase Hydration and the Atmosphere

There are many similarities but also significant differences when comparing glass corrosion in liquid water with vapor-phase hydration. In vapor test hydration, only a surface film of adsorbed water molecules exists on the glass surface and dissolved glass constituents cannot be transported away. The thickness of the water film depends on relative humidity (RH) as well as on the hygroscopy of the glass phase and hence, on glass composition. For some glasses, even 30% RH leads to attack of the glass surface. The quantity of water adsorbed increases with time and with the quantity of leached alkali. The humidity resistance increases in the order soda–lime bulb tumblers < soda–lime tubing < commercial plate glass, television panels < commercial window glass, soda–lime bottle glass, soda–lime tubing < commercial light bulb (outside) < alumino silicate, alkali borosilicate tubing < opal tableware, borosilicate tubing [144].

Due to the small thickness of the surface film, one may think of the vapor-phase hydration process as being similar to glass dissolution at high surface area–solution volume ratio (S/V). In such a thin water film on silicate glasses, the pH can rise rapidly. Once the pH is > 9, the corrosion of the glass network may occur, reaction products become deposited, and the glass surface loses its transparency and reflectance. Vertically stacked flat glass sheets may become unusable if stored under humid conditions. On the other hand, in the case of glass windows, the rain always washes these reaction products off, surface pH decreases, and glasses remain stable for longer periods of time.

For corrosion of window glass in buildings under attack of atmospheric agents, four stages can be distinguished [145]:

1. Adsorption of water and CO_2 associated with the formation of alkaline surface pH, leaching and formation of secondary minerals. This surface precipitate can easily be removed by cleaning with water.

2. If humidity contact continues, surface precipitates become thicker ($\sim$1 μm) and calcite forms and the surface becomes colored but can still be cleaned with water.
3. Further contact with humidity leads to strong leaching and enrichment of alkali and alkali earth elements as salt minerals at the surface and the silicate network becomes corroded by forming residual silica-rich structures. After cleaning with water, the surface remains modified, and effective cleaning requires acid treatment or even the use of hydrofluoric acid.
4. In the last stage the surface becomes rough and even a hydrofluoric acid cannot clean the surface.

High *S*/*V* ratios are also attained by vapor-phase hydration of stacked window glasses in humid environments, for example, during transport in mountain or maritime regions [145]. On the other hand, at a lower relative humidity of 75% and 22°C it takes $\sim$70 days before significant dealkalization occurs [146]. Alteration phases (e.g., $CaSiO_3$) [147] are rapidly formed due to high surface pH conditions. Also, hydrated carbonate minerals may form upon contact with carbon dioxide from the air. It is recommended to prevent stacked glass sheets to remain for a long time in humid environments, that interleaving materials be used, which may buffer potential pH rises, and that storage areas be well ventilated.

In a corrosion test of borosilicate glass with steam at 200°C (steam generated 0.25 mL liquid water at the bottom of the reaction vessel), water condenses on the glass without dripping and an effective *S*/*V* of 4000 m^{-1} was estimated [148]. Higher water volumes led to condensation of water at the glass surface and dripping and thus recycled rinsing of the sample. After an induction period of a few days, corrosion rates insteam were found to be higher (linear rates of 2.5 and 21 μm/day for two similar glasses) than rates (after 30 days 0.01 and 1 μm/days) under hydrothermal conditions at $S/V = 40\ m^{-1}$ at the same temperature. Corrosion layers in steam were found to be richer in alkali contents and contained more silica–rich crystalline phases (zeolites and feldspars) than the corrosion layers formed under hydrothermal conditions. It was suggested that these phases drive the long-term glass corrosion rate at high *S*/*V* ratios caused by uptake of silica and prevention of saturation effects.

Vapor-phase hydration was also studied with phosphate glasses. Here no diffusion control was observed but a linear rate law was observed associated with hydrolysis of the glass network [149].

G3. Hydrofluoric Acid

Etching of glasses by HF is used in many technological and scientific fields, such as glass surface cleaning, glass strengthening, and fission track edging. Wet chemical etching of silicate glasses in HF solutions has been reviewed [150]. Up to HF concentrations of $\sim$5 wt. %, the etching rate increases linearly with HF concentration, whereas higher HF concentrations lead to an over proportional increase in etching rates. The mechanism of dissolution is governed by adsorption of HF and HF_2^- species and catalytic action of H^+ ions [150]. The initial reaction step is HF adsorption, followed by leaching of alkali and alkali earth. The rate-limiting step appears to be the breakage of siloxane bonds both at the outer surface and in the interior of the leached layer [153]. The reaction between HF solutions and silicate glasses was found in certain cases to be transport controlled with respect to the mass transfer of dissolved glass constituents in solution with a typical activation energy of 20–45 kJ/mol [150–152]. Initial corrosion rates in 10 wt % HF solutions were $\sim$100 μm/day at 25°C for fused silica [150]. Corrosion resistance in HF decreased with the addition of Na, Mg [152], Al, and Ca [150] as well as of P or As to the glass, whereas the etching rate decreased after B addition [150]. The relations between glass composition and etching rate are highly nonlinear [153]. The etching of multicomponent glasses by HF does not always lead to complete dissolution. In particular, if the glass contains alkali earth or rare earth elements, the precipitation of sparingly soluble fluoride phases can be observed [150].

G4. Strong Acids

Corrosion of borosilicate glass has been tested in strong nitric acid up to a normality of 16. A maximum corrosion rate of 2500 μm/day (2-h test at 25°C) was observed in 6 *N* solution, and higher acid strength led to a decrease in reaction rates, attributed to a decrease in water activity [154].

H. BIODEGRADATION OF GLASSES

In contact with bacteria, many glasses show increased corrosion. There is evidence for the existence of “silicate bacteria,” defined as chemolithoautrophic bacteria, which gain their energy by deterioration of Si–O bonds in silicates [155]. The effect also depends on the availability of nutrition [156]. Microorganisms, such as molds, are known to affect the stability of optical glasses [157] as well as medieval window glasses [158]. Experimental corrosion measurements of model glasses of medieval glass composition in the *presence* of fungi have shown 5–30 more glass corrosion (gel layer formation) than in the *absence* of fungi [159]. The effect was explained by a combination of an acid attack on the glass surface and a corriplexation reaction.

I. SPECIAL GLASS COMPOSITIONS AND APPLICATIONS

I1. Alkali/Alkali Earth Silicate Glasses—Window Glasses

Among the most important industrial glasses are soda-lime glasses, that is, a special type of alkali/alkali earth silicate glasses. Alkali ions in general decrease the stability of silicate glasses by decreasing the cross-link density of the three-dimensional glass network and by provision of ion exchange sites. In the pH range 1.4–10.9 the reaction of pure alkali silicate glasses with water is characterized by selective alkali release, following initially a square root of time rate law [160]. Divalent or trivalent cations stabilize alkali silicate glasses by formation of O–R–O bridges in the glass structure [161, 162] which hinder the water diffusion/ion exchange process. For a soda–lime glass with the composition SiO_2 75 wt %, Na_2O 15 wt %, CaO 10 wt % exposed to a buffered pH5.3 solution at 88°C, the diffusion coefficients for H and Na where 6×10^{-16} and 6×10^{-13} cm^2/s, respectively [163], probably governed by diffusion through a transformed surface layer. Diffusion coefficients decreased by about a factor of 5 if an aliquot of 3 wt % of the Na_2O content of the glass is replaced by K_2O, emphasizing a mixed alkali effect [164]. An isotopic effect D/H, as well as ^{18}O update data, is consistent with rate control by breaking an H−O bond (or D−O bond) of indiffusing water molecules and subsequent hydrolysis of Si−O−Si bonds to 2 Si−OH as necessary precursor reactions to Na/H ion exchange [165] Isotopic exchange reactions indicated condensation reactions according to the Scheme $2\equiv Si-OH \rightarrow \equiv Si-O-Si\equiv + H_2O$ as well as high mobility of water in the leached layer, ~1000 times faster than the rate of leached layer growth. Hence, water diffusion was not rate limiting. Condensation of silanol groups in the leached surface layer was also evidenced by an increase in Q^4 silica groups for a potash–lime glass, analyzed by (magic-angle-spinning nuclear magnetic resonance) ^{29}Si MAS–NMR [166].

While ion exchange and diffusion processes dominate the initial stages of the glass water reaction, glass network corrosion subsequently dominates. For a soda–lime composition for flat glass SiO_2 72.0 wt %, Na_2O 13.9 wt % MgO 4.0 wt %, CaO 8.3 wt % activation energies for forward glass network corrosion rates were found to be 66kJ/mol [167] at a neutral pH, while increase in activation energy is observed at lower and decrease at higher pH [191]. A primary factor controlling soda-lime glass network corrosion in nonbuffered water is a pH effect associated with the S/V ratio. Under static dissolution conditions the pH rises with the progress of glass corrosion. The higher the temperature or the S/V ratio, the faster this pH rise occurs. If pH > 9, a rapid increase of corrosion rates occurs. This does not happen if the pH is buffered at neutral values [168]. Then slow corrosion rates of about 1 μm/day are observed at 90°C [191].

The rather poor resistance in alkaline solutions results in staining of window glasses at the rainexposed side of buildings if constructions allow for contact with alkaline runoff water from concrete or cement walls [169]. Introduction of nitrogen by adding Si_3N_4 to the glass melt increased durability of window glass considerably (factor of 3 in 2 N NaOH) [170].

For a soda–lime float glass, the composition of top and bottom surfaces are not identical, which is attributed to tin from the bath and Fe enrichment at the bottom. The tin layer can easily be dissolved in 1 M NaOH [171]. The tin-rich layer was found to protect the glass, resulting in about one order of magnitude lower glass surface leach rates [172] and less hydrogen penetration [173] when compared to the tin-free top surface. An addition of 2.5 wt % of tin to soda–lime glass increases glass stability [174].

I2. Alumosilicate Glasses

Addition of Al to soda–lime glasses leads to another class of rather stable glasses, the alumosilicate glasses. The replacement of half of the CaO content of a soda–lime glass by Al_2O_3 (composition SiO_2 75 wt %, Na_2O 15 wt %, CaO 5 wt %, Al_2O_3 5wt %, leads to a decrease of diffusion coefficients for hydration by H-bearing species by a factor of 5 to a value of 10^{-16} cm^2/s and of Na by a factor of 50 to a value of 10^{-14} cm^2/s [163]. An increase of the Al–Si–ratio of silicate glasses increases the network corrosion resistance [175] by formation of Si–O–Al bridges and immobilization of a fraction of Na ions for reason of charge compensation in the vicinity of these bridges. The ratio of mobile to immobile Na ions in the glass (exchangeable and nonexchangeable Na) depends on the molar Na–Al ratio in the glass. With a molar ratio or $Na/Al \leq 1$, an increase in the alkali content of the glass does not lead to an increased glass corrosion rate, because there are no nonbridging oxygen in the glass structure [176]. There are also some cases with no effects of Al on corrosion stability of the glasses [177].

The formation of Si–O–Al bridges stabilizes the glass only if the hydrolytic stability of this bond structure is high. This is the case at neutral to slightly alkaline pH but not at acid pH. Also in strongly alkaline solutions corrosion was observed to increase with increasing Al contents, attributed to the ease of hydrolysis of Al–O bonds under alkaline conditions and the gradual change from tetrahedral to octahedral coordination of Al ions by contact to alkaline solutions [178]. Hence, the stabilizing effect of Al depends also on solution chemistry. In addition, the effect of alkali earth elements on the corrosion resistance of alumosilicate glass depends on the chemistry of the aquatic medium. For example, the partial replacement of Si by alkali earth ions decreases the corrosion resistance of alkali aluminum silicate

glasses (18.5 Na_2O–7.4–Al_2O_3–74.1 SiO_2) at neutral pH and increases it at pH 10 [179]. This effect results from the reduced mobility of alkali earth ions at high pH values.

In addition, aluminum plays an important role in controlling the solution concentration of silica. This is important under closed system alteration conditions, where saturation effects may decrease glass corrosion rates. Two cases may be distinguished: (1) control of Si solution concentration by the transformed surface of the dissolving glass, leading to faster slowdown of glass corrosion rates due, to saturation [180, 181], or (2) control of Si concentration by the formation of secondary phases resulting in a hindrance of the slowdown of reaction due to a hindrance of saturation at the glass–solution interface. For example, an Al-rich glass showed a much higher long-term corrosion rate than a glass with much less Al [182], This was due to the reduction of silica concentrations in solution due to the formation of analcime, a zeolite mineral, as secondary solid reaction product.

I3. Borosilicate Glass

Borosilicate glasses with ~4–8% alkali oxide, 2–7% Al_2O_3, 0–5% alkali earth oxides, 70–80% SiO_2, and 7–13% B_2O_3 are particularly water and temperature resistant. Typical samples are Duran or Pyrex glass. Zinc added to borosilicate glasses at concentrations up to 16 mol % leads to increased glass stability [183]. In aluminum silicate glasses without NBO (Na/Al $\leq$ 1), a replacement of up to 80% of Al_2O_3 by B_2O_3 leads to an increase in corrosion resistance.

The corrosion resistance of borosilicate glass can be understood only on the basis of glass structure. The relation between glass structure, glass composition, and glass stability is described by a model of Dell et al. [184]. Including new results for the ternary system [186] as well as for the binary alkali borate [185] and alkali silicate system, the results of the model are illustrated in Figure 29.5

Besides SiO_4 tetrahedra (Q^n), additional structural units of borosilicate glasses are anionic BO_4 tetrahedra (N_4 sites) and symmetric or asymmetric trigonal groups (N_{3s} or N_{3a} sites), with a distribution among these sites determined by the mol ratio $R = Na_2O/B_2O_3$ and $K = SiO_2/B_2O_3$. The occurrence of tetrahedral groups depends, on the presence of alkali. The maximum tendency for phase separation into Si-rich and B-rich glass phases [186] occurs at $R = 0.19$. The increase of alkali content of the glass increases the solubility of borate groups in the silicate glass network [184] by forming borosilicate groups related to Danburite groups and Reedmergnerite ($NaBSi_4O_{10}$) units [184, 186]. At higher R values, not all Na ions are associated with tetrahedral borate groups but to Si–Q^3 tetrahedras or with further alkali content to Si–Q^2 sites. This leads to an increase of alkali mobility in the glass, resulting in a stronger tendency for ion exchange with contacting aqueous solutions.

High-silica glasses can be fabricated based on phase-separated glasses in the Na_2O–B_2O_3–SiO_2 system (Vycor process [187]). Here, glass corrosion is not detrimental to glass use but is a key design parameter because the borate-rich phase must be dissolved rapidly. The microstructure of the glass determines the rate of dissolution. Rapid dissolution can, for example, be achieved by adding a small amount of high-valency cations such as V, P, or Mo, increasing the size of phase separations in the glass and the rate of borate phase dissolution [188, 189].

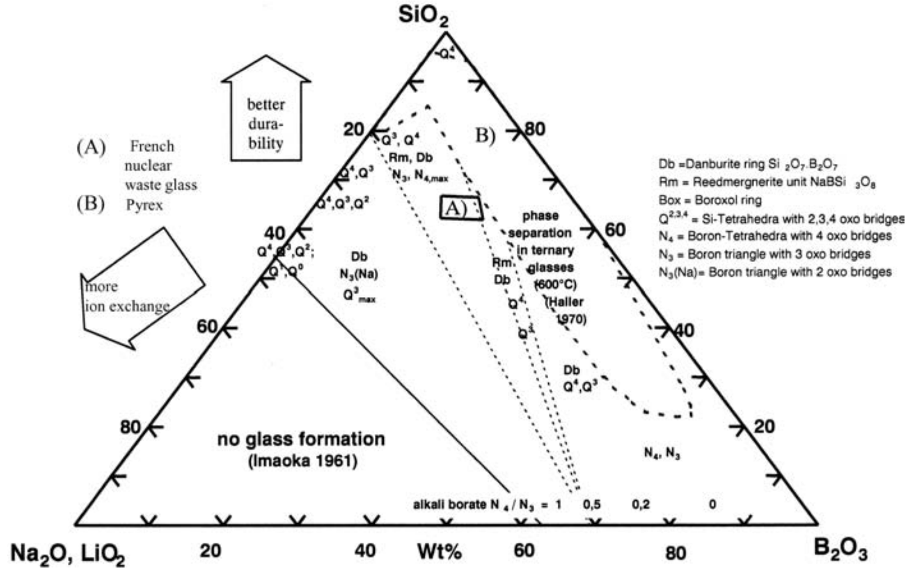

FIGURE 29.5. Ternary Na_2O–B_2O_3–SiO_2 Structure unit stability diagram and relation to glass durability and phase separation.

An industrially important, durable borosilicate glass is Pyrex glass, (SiO_2 80 wt %, Na_2O 4 wt %, Al_2O_3 2 wt % B_2O_3 14 wt %). As expected from Figure 29.5, Pyrex glass is phase separated into a nearly pure silica matrix with a dispersed borosilicate phase with spherical regions of 5–10 nm diameter [190]. Corrosion rates are probably dominated by the dissolution of the boron-rich phase. Corrosion rates were found to be invariant with pH between 0 and 4 and increased by about a factor of 10 until pH 9. At 95°C and pH 9 a linear forward corrosion rate of 0.6 μm/day was measured with pH-independent activation energies of about 60 kJ/mol [191]. At 250–260°C in a closed system, boron release continued with a linear rate of ~4 μm/day, but Na and Si loss reach a temperature-dependent saturation state, with Na/Si ratios in solution equal to those in the glass [192]. Activation energies for hydration were only 17 kJ/mol, much lower than the activation energies for B release. This indicates that hydration and B release are independent processes, and hydration does not occur by filling the holes of phase-separated boron-rich phases.

With simple borosilicate glasses, as well as nuclear waste borosilicate glass compositions, the corrosion resistance is not a linear function of glass composition but shows strong nonlinear behavior. For example, the addition of 0–2 wt % SiO_2 to a waste glass for West Valley (USA) led to only a small increase in corrosion resistance, but 3% addition decreased the corrosion rate by a factor of 10 (Fig. 29.6). A further increase in silica content had a negligible effect [193].

For glass compositions containing redox-sensitive elements, the corrosion resistance becomes a function of the redox conditions during glass production as well as of the redox-state of the aqueous solution. For example, Fe^{III} acts much more as a stabilizing agent than does Fe^{II} (Fig. 29.7) because Fe^{III} may take a similar role in the glass structure as a network-forming element, such as Al. Consequently, if such glasses are melted under oxidizing conditions, they become more stable when compared to glass melting under reducing conditions [193].

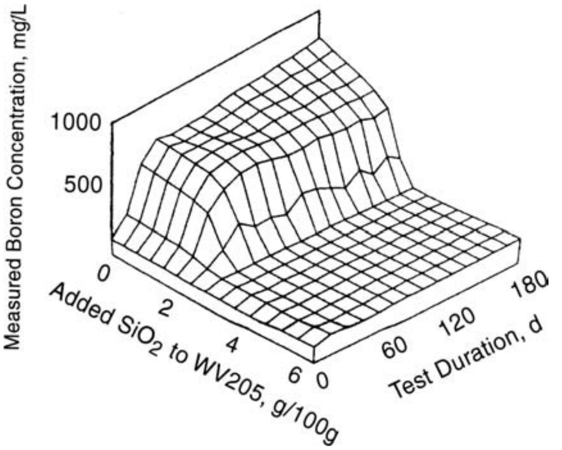

FIGURE 29.6. Dependence of the extent of glass corrosion (release of boron) on the content of silica in the glass [212].

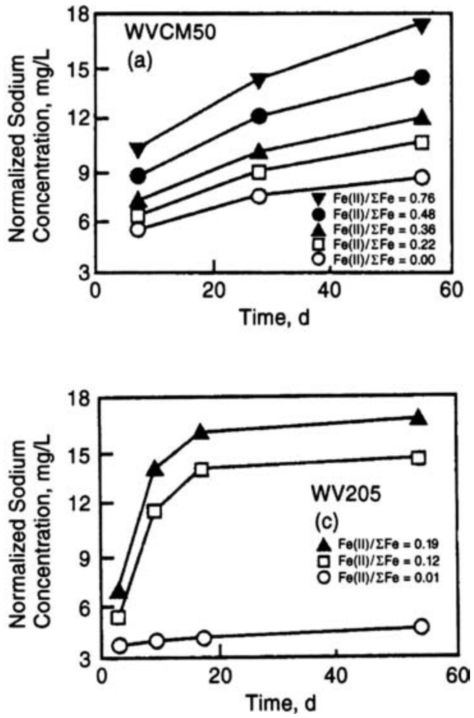

FIGURE 29.7. Corrosion results at 90°C in MCC-3-Test (Na release) of two American radioactive waste glasses as function of redox state ($Fe^{II}/Fe^{(tot)}$) of the glass matrix [212].

I4. Nuclear Waste Borosilicate Glasses

Borosilicate glass is the principal solid matrix for immobilizing high-level radioactive waste for deep geological disposal. Numerous borosilicate glass compositions have been suggested [194]. Compositions of all industrially produced European radioactive waste borosilicate glasses are located in Figure 29.5 in an optimum balance between (1) low tendency for ion exchange, (2) relatively high corrosion stability, and (3) absence of phase separation. Higher corrosion resistance could be achieved by higher Si content (more Q^4 groups), but this would increase the tendency for production of phase-separated glasses. The resulting structure is a stable three-dimensional glass network with N3, N_4, Q^3, and Q^4 with coordination cages of oxygen of various sizes and coordination, capable of hosting a large suite of different multivalent radioactive cations simultaneously.

The glass corrodes slowly in groundwater and humid air and inevitably certain quantities of radionuclides are mobilized. Various reviews on nuclear waste glass performance have been published [13, 14]. Predicting long-term glass performance is difficult. Disposal sites are located in deep

rock with very slow groundwater flow rates. Hence, saturation effects become much more important than for other types of glass applications. Accumulation of dissolved silica and other glass constituents in solution leads in many (not all) cases to a significant decrease in the overall reaction rate [195–197]. Provided the accumulation of Si is not hampered (i.e., by formation of Si-rich crystals such as zeolites, by high water flow), a saturation state will be reached with reaction rates $< 1/1000$ of the initial rates [198]. This decrease in reactivity has been attributed to decreasing affinity for the rate-limiting dissolution reaction [198–200]. Protective layers were normally not formed. The fundamental disequilibrium between the bulk glass phase and the solution remains, that is, overall affinity remains appreciable and the glass/water reaction will continue as long as an aqueous phase is present. The mechanism of this "long-term reaction" is not yet fully understood. It has been suggested that the dissolution rate may either be driven by the precipitation of secondary phases [198, 201], formation of colloids [196], or resumption of rate control by water diffusion/ion exchange [202].

Glass alteration may or may not be accompanied by transfer of glass constituents (including radionuclides) to a potentially mobile aqueous phase. Sparingly soluble glass constituents become incorporated in or sorbed on solid glass alteration products on the glass surfacer—the gel layer and a precipitated layer—but may also be sorbed on groundwater colloids. The formation of new secondary phases, such as silicates, molybdates, uranates, carbonates, and so on, establishes a new geochemical barrier for reimmobilization of radionuclides dissolved from the waste matrices. As an example, secondary clay minerals (saponite), powellite, and baryte phases formed on the surface of Cogema type HLW-glass during corrosion in brine. The phases formed are normally not pure but are solid solutions of quite complicated composition. Solid-solution formation is a beneficial effect for retention of radionuclides. The clay mineral saponite is important for sorption of trivalent and hexavalent actinides, while powellite and barite are host phases, incorporating either trivalent actinides or divalent radionuclides within their crystal structure. Tetravalent elements appear to become concentrated into thermodynamically very stable zircon or cereanite-type phases. Recently, it has been shown that the retention behavior of trivalent, tetravalent, and hexavalent elements can be described by sorption isotherms in certain pH ranges, whereas solubility/coprecipitation is dominant in other ranges [203].

Radiation damage of the glass phase and transmutation have only a minor effect on glass durability, whereas the effects of radiolysis of water and aqueous species may increase in glass dissolution rate by a factor of 5 [14]. Initial reaction rates may become higher if neutral starting solutions are acidified by radiolysis. Alternatively, for experiments at very high *S*/*V* in the presence of nitrogen, it has been shown [204] that dissolution rates of radioactive glasses may be as much as a factor of 40 lower than the corresponding rates of a simulated glass. In this case, the alkaline evolution of solution pH is partly balanced by acidification due to radiolysis. In the absence of nitrogen the initial rate is slightly affected by radiolysis, but there is only little effect on the rate of long-term dissolution at high *S*/*V* [205, 206].

I5. Alkali-Resistant Glasses

Glass-fiber-reinforced cement (GFRC or GRC) composites are based on glass fibers with high alkaline durability. Mechanical properties of these cements depend on the chemical durability of the fibers. Suitable alkali-resistant fibers contain high contents of Zr, for example, in CemFIL (16 wt %) or ARG-fiber. The Zr-containing glass fibers (CemFIL-1) were leached at 55°C for a year in Portland cement pore fluids, resulting in only 2 μm of corrosion. Glass stability was caused by the formation of a shell of Zr- and Ca-rich reaction products [207]. In the absence of Ca, no protective effects of Zr-rich surface reaction products were observed. Maximum glass stability was observed with 100 mg/L Ca in solution [208].

Disadvantages of the Zr-rich fibers are the expensive high-melting and processing temperatures. Therefore, a number of alternative alkali-resistant glass compositions have been developed. Glass compositions in the mole percent range $CaO < 9$, Na_2O 13–15, $BaO < 10$, ZrO_2 7, MgO 3, SiO_2 65–75 show similar resistance to ChemFIL and 100°C lower manufacturing temperatures [209]. Low corrosion rates, ~0.01 μm/d, of Zn–Al–silicate glass fibers, modified with Fe, Mn, or Ti oxides, were observed at 60°C in $Ca(OH)_2$ solutions at pH 12.6 [210].

I6. Phosphate Glass

Phosphate glasses show a number of advantages when compared to silicate glasses: optical properties, high thermal expansion coefficient, low melting points, and formation of sparingly soluble host phases for radiotoxic elements. However, instability to crystallization and low chemical durability of many phosphate glass composition lead to less widespread use than silicate glasses. Depending on glass composition, the corrosion rates of phosphate glasses cover a range between 1000 and 0.01 μm/day [211].

A particularly stable class of glasses is to be found in the lead–iron phosphate system. A review is given by Sales and Boatner [212].

I7. Glass-Reinforced Plastics

Low specific gravity ($<2 g/cm^3$), low cost, easy repair and shape adaptation, high strength, and so on, make glass-reinforced plastics very popular as structural and

corrosion-resistant material for pipes, tanks, and chemical process equipment. There are three main factors controlling corrosion: the fiber, the matrix, and the interface. With respect to the fiber, corrosion stability depends on the same principles as for ordinary glasses. Highly corrosion resistant vitreous silica fibers can, for example, be made from acid-leached E-glass fiber. Stress-induced corrosion processes are important [213]. The fibers may be attached to the resin by silanation [214]. The effect of chemical attack can greatly be reduced by proper choice of the resin and proper fabrication. The following basic principles [215] are useful for resin selection to provide resistance to various chemicals. Aqueous solutions and salts are generally nonaggressive, but strong oxidizing acids attack the resin; organic solvents, such as benzene, attack most polyester or vinyl esters, whereas epoxy esters are better for organic solvent resistance.

I8. Optical Glasses

Corrosion may change the optical properties of glasses during manufacturing, polishing, and so on. The variety of compositions used for optical applications does not allow a generalized treatment of chemical durability. With respect to glass durability, five families of glasses have been distinguished [216], as presented in Table 29.2.

As for alkali silicate glasses, a square root of time rate law was followed by a linear rate law for optical lead silicate glasses (SiO_2 65 mol %, PbO 25–35 mol %, K_2O 0–10 mol %, Al_2O_3 0–2 mol %) under acetic acid static corrosion conditions [217]. Activation energies were $\sim$50 kJ/mol. As for alkali ions in alkali silicate glasses, diffusion-controlled surface depletion profiles were observed for Pb release from the glass [218].

Contact of xBaO/$y$$SiO_2$ glasses to distilled water led to Ba leaching from surface regions 50–300 nm thick, resulting in decreased density and refractive index of this surface region [219]. Even the initial surface conditions of optical glasses are strongly affected by dissolution effects; for example, mechanical polishing effects were found to be governed by stress-induced chemical surface dissolution [220] or by direct chemical leaching in the polishing solution.

I9. Glass Corrosion and Human Health

Corrosion of glassware may be detrimental to health if toxic elements are released into food to a significant extent. Examples are lead crystal wine decanters, an important potential source of lead exposure (release of 66 μg Pb/L into white wine in 4h) [221]. On the other hand, glasses with 0.2 wt % Cr_2O_3 did not show any release of Cr into solution [222]. For Ni, a beneficial effect may be observed; for example, bottled wine may have significantly less Ni content than the original grapes, attributed to sorption of Ni on the glass surfaces [223].

Bioglass as bone replacement was discovered by Hench et al. [224], characterized to form tight bonds to living bones (bioactivity). Some glasses and glass ceramics are already in clinical use. Bioactivity is based on the ability of the glass or glass ceramic to form, as a reaction product, bonelike apatite during corrosion in body fluids at 37°C. Hence, most glasses contain CaO and P_2O_5 as a main component; however, bioactivity has also been reported for soda–lime glasses, showing apatite formation during corrosion in body fluids [225] and other phosphate-containing solutions [133]. Apatite formation in glass surfaces leads to formation of protective surface layers [132, 133].

Aspirable silicate glass fibers can be detrimental to health if they do not dissolve sufficiently rapidly in physiological solutions. Long-term (120-day) experiments in Gamble solution at 37°C at pH 7.6 have indicated a substantial difference in the residence time of natural mineral fibers and artificial fibers (Table 29.3) [226] expected under in vivo conditions. In another study, 30 glass compositions in the system SiO_2–Al_2O_3–B_2O_3–CaO–MgO–BaO–Na_2O were studied. Predicted corrosion rates in physiological solutions varied between 0.2 and 200 ng/day [227].

I10. Silicate Glass Fibers

Glass fibers and bulk glasses of the sample composition differ in various physical and chemical properties. Faster cooling rates during production make the glass network of fibers more open. Also density, refractive index, and Young's modulus are lower. Consequently, corrosion behavior might

[a]See [226].

also be different. Corrosion of silicate glass fibers have been extensively studied for application fields such as optical waveguides, cement, or plastic reinforcement. A review of the resistance of glass fibers in corrosive environments is given in [228]. A comparative study of the corrosion behavior of glass fibers, in the composition range $(Na.K)_2O$, 0.5–15 mol. %, SiO_2 46–70 mol %, Al_2O_3 0.7–11 mol %, (Ca,Mg)O, B_2O_3 0–7 mol %, ZrO_2 0–2 mol % show saturation effects under static corrosion conditions (interpreted as "formation of protective layers") and continued dissolution in dynamic corrosion tests [229]. Specific surface areas of silicon aluminate ($SiO_2 \cdot Al_2O_3$) glass fibers were found to increase dramatically during corrosion at pH 1 and only little at pH 3. This was interpreted as resulting from Al release, leaving micropores in the glass network [230].

Microphase-separated E-glass fibers SiO_2 52.8 wt %, B_2O_3 10.8 wt %, Al_2O_3 14.4 wt %, CaO 16.7 wt %, MgO 4.9 wt %, Na_2O 0.2 wt %, and K_2O 0.02 wt %) are known to become converted to high-silica glass by leaching in mineral acids [231]. After leaching, the surface area is very high (100–300m^2/g) caused by micropores of <2 nm diameter [232], probably only 0.4 and 0.8 μm, coexisting with larger mesopores of 6 nm [233]. During corrosion, a core-sheath structure is built up with loss of mechanical strength of the outer sheath caused by replacement of Ca and Al (and probably B) by H^+ [234]. The extraction of metal ions proceeds in two steps: (1) dissolution of an interconnected phase exterior to the silica network and (2) dissolution of metal ions form the silica network [235].

Due to formation of voluminous alkali-depleted surface layers, acid corrosion of E glass leads to an increase in the thickness of the fibers and formation of fractures. The thickness of the layer increases with the square root of time [236]. Under alkaline conditions, E glass is not stable. For example, as long as <40% of 10–15-μm-thick glass fibers were dissolved, corrosion rates in saturated $Ca(OH)_2$ solutions (pH 12.6) at 25°C were found to be in the range of 0.08 μm/day [237].

I11. Fluoride Glasses

Heavy metal fluoride (HMF) glasses have been proposed as the next-generation optical waveguides for their transparency to infrared (IR) light. It is particularly important that these glasses show some stability against liquid water and water vapor of common environments. Early studies of BeF_2 glasses have shown highly hygroscopic behavior. A systematic study of chemical durability in multivariate compositional space in the Th–Ba–Al–Zr–F system has been reported [238]. In contrast, ZrF_4-based and BaF_4-ThF_4- based glasses show remarkably high corrosion resistance for atmospheric moisture and temperatures <200°C, but they were not very durable in liquid water.

With congruent matrix dissolution rates at 25°C of 3–30 μm/day BaF_4–ThF_4-based glasses were ~50–100 times more stable in deionized water than Zrf_4 glasses [239]; however, they are still much less durable than typical silicate glasses. Leach rates follow the aqueous solubility of the modifier metal fluorides ($A1F_3$, NaF, LiF) > (BaF_2, LaF_3) [240]. The high corrosion rates were attributed to evolution of acid pH values in static dissolution tests and corresponding high solubility of glass components, particularly severe with ZrF_4 glasses ($pH_{fin} = 2.5$). A systematic study of pH effects on HMF glass stability confirmed this interpretation. Indeed, when the pH was fixed at neutral to slightly alkaline values (pH < 10), corrosion rates as low as 0.01–0.1 μm/day were observed after a few hours of testing, even with ZrF_4-based compositions [241]. Corrosion results indicate that the reaction of fluoride glasses with water is controlled by moving boundary diffusion according to a square root of time rate law as a thermally activated process [242]. Corrosion layer formation is accompanied by ion exchange of fluoride ions with OH^- [243, 244]. The existence of this ion exchange reaction leads to a technical application of HMF glasses as fluoride ion-selective electrodes [245]. The release of fluoride ions and consumption of hydroxyl ions thus explains the decrease of pH with the proceeding corrosion reaction. The adherence of surface layers to the glass is rather weak, and thus the layer appears to be nonprotective. Nevertheless, after initial ion

exchange, water diffusion into the glass appears to play a significant role in controlling glass corrosion rates [246].

In contrast to HMF glasses, much less work is done on the corrosion stability of other fluoride glasses such as fluoroaluminate glasses. During corrosion, a slight increase in pH is observed. The corrosion mechanism appears to be different from that of the HMF glasses. Congruent leach rates are controlled by metal fluoride solubilities [247].

J. METHODS FOR IMPROVING GLASS SURFACE STABILITY

J1. Polymer Coatings

Successful attempts have been made to protect poorly resistant medieval church window glasses by polymer coatings, such as viacryl resin [248]. Though organic polymers allow for water diffusion to the glass surface beneath, the surface was found unattacked after seven years. This surprising effect was explained by saturation effects of silica in the pore space of the coating, slowing down reaction rates.

J2. Resistant Oxide Glass Coatings

The weathering characteristics of soda–lime glass can be improved by coating with sol–gel derived SiO_2 or nine TiO_2–91 SiO_2 films [249]. The film with Ti is even more protective than pure SiO_2. The durability of soda–lime glasses against alkaline solutions can be enhanced by coating with Ti or Zr [250].

In order to improve the chemical durability of heavy metal fluoride glasses, many efforts have been undertaken to develop different types of coating materials, for example, lead phosphate glass coatings with a transformation temperature t_g of only 227°C and a corrosion rate of ~0.5 μm/day [251].

A. INTRODUCTION

Polymeric materials are used in a wide array of applications in engineering and construction, ranging from basic infrastructure to critical components of aviation and space travel, because of their flexibility, lightness, and high strength. The available literature on deterioration and degradation of organic polymeric materials under natural and/or artificial environments is very limited [1–8], and much less is known about the mechanisms involved in degradation of these materials by microorganisms [4, 6, 7]. Such information is important when assessing material life span and maintenance cost, but available results are widely distributed in different scientific journals due to the highly diverse applications of polymeric materials compared to metals. Because of their versatility in chemical compositions, molecular weights, and applications, issues of polymer deterioration and prevention measures begin to receive more attention as their applications continue to expand.

Polymeric materials differ in their chemical composition, physical forms, processing and molding, mechanical properties, and applications. Variations in their chemical composition and molecular weight of the polymeric monomers

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

are largely due to the versatility of the carbon–hydrogen (–C–C–) bond in the chemical structure and their possible configurations, stereochemistry, and orientation. Their applications include product packaging, insulation, structural components, protective coatings, medical implants, drug delivery carriers, slow-release capsules, electronic insulation, telecommunication, aviation and space industries, sporting and recreational equipment, and building consolidant. In many of these applications, over time of service, they are constantly exposed to a range of natural and artificial conditions that often involve microbial colonization and contamination, resulting in aging, disintegration, discolorization or colorization, and deterioration as well as degradation [9–12].

Evidence of polymeric material degradation by microorganisms was reported in a number of diverse environments, including the Russian Mir space station [6, 8, 13–16], shipping [17], aircraft [18], and sewer pipes [19–21]. In addition, medical devices are also susceptible to microbial contamination [22] and deterioration in vivo [23, 24]. Other materials, including electronic insulation polyimides [8, 25–31], fiber-reinforced polymeric composites [4, 6, 32–36], and corrosion protective coatings [27–29, 36, 37], were also reported for their biodeterioration by microorganisms commonly found in the environment. Degradation and mineralization of polymers used in product packaging were investigated under both aerobic and anaerobic conditions with reproducible methodology [6, 8, 26, 29, 38–46].

Detection of microbial deterioration at the early stage of development is a challenge because of the complex interactions between the materials and their environment, the microbial populations, and the available techniques. Since engineering materials are designed to be highly resistant to change, any physical and chemical change in the material and matrices cannot be observed using traditional techniques because of low sensitivity [6, 8, 29, 46]. Electrochemical impedance spectroscopy (EIS) coupled with microbiological methods enables quantitative and mechanistic analyses of microbial degradation of high-strength polymeric materials within a reasonable period of time [7, 8, 25–31, 33–35, 47]. This technique is particularly useful for detecting the physical failure of polymeric electronic insulating thin films and surface coatings that are water impermeable and may degrade slowly by environmental conditions and/or microorganisms [27, 28, 33, 37]. Furthermore, fiber-reinforced polymeric composite materials (FRPCs) were also successfully assessed using this approach successfully, but the time required to observe any detectable changes in the materials due to microbial growth was at least several months [6, 27–29, 33–35]. With the increasing usage of this class of materials in infrastructure and aviation and space, deterioration, detection, and preventive measures are critical issues that have drawn the attention of end users worldwide.

This chapter is intended to cover selective groups of materials with different properties and applications to illustrate current knowledge and where information and research efforts should be directed. It is also our intention to describe the general mechanisms of degradation and deterioration using selected polymers, the current status of material degradation research, and the strengths and weaknesses of research techniques currently in use. In addition, preventive measures such as incorporation of biocides and implementation of environmental controls are also discussed. Because this chapter deals with biological deterioration of polymers, the wide range of materials is arbitrarily grouped based on their biodegradability for convenience of discussion as (1) relatively degradable, (2) recalcitrant, and (3) completely resistant to breakdown. Our definition of polymeric materials is limited to synthetic industrial polymers, excluding natural polymers, for example, cellulose, chitin, chitosan, lignin, polysaccharides, proteins, and deoxyribonucleic acids.

B. APPLICATIONS OF POLYMERIC MATERIALS

The production and consumption of plastics has increased dramatically worldwide since the 1970s and does not appear to be slowing down. On a volume basis, polymeric materials had already exceeded that of copper, aluminum, and steel by the mid-1980s [48] and they play a major role in our daily life. In 1996, production of polymers reached 3.4 million tons of thermosetting resins, 27.6 million tons of thermoplastic resins, 4.5 million tons of fibers, 2.3 million tons of synthetic rubber, and 4.7 billion liters of paints and coatings [49].

Uses of polymers have constantly expanded to new frontiers, including transportation, aerospace, aviation, medical, infrastructure, electronic, computers, military, and recreation. In addition, demands are also visible in the communication, structural and construction, and protective coatings industries. Polymeric materials may be exposed to natural environments, including soils, seawater, and freshwater under aerobic and strictly anaerobic conditions. In certain cases, artificial or enclosed environments with high acidity or alkalinity (e.g., specialized containment) are encountered in industrial processing, manufacturing, and storage and even within human tissues as implant materials. In most of these incidences, contamination by microorganisms on surfaces of materials is common and, indeed, inevitable, and as a result, susceptibility assessment to microorganisms is not only justified but necessary to provide a better understanding of material performance.

Contact between microorganisms and surfaces of materials is generally unavoidable except under extremely clean conditions where sterility is strictly maintained and reinforced through vigorous filtering and ultraviolet treatment. Information on the extent of microbial biofilm formation on

surfaces of materials and subsequent damage to polymers becomes a very important issue in telecommunications, information storage, medicine, aviation, and space travel. This information is invaluable to polymer chemists, engineers, materials scientists, and applied biologists for designing materials with predetermined life spans, stability, and performance under deployed conditions.

C. MICROBIAL BIOFILMS ON POLYMERS

In submerged or humid environments, all surfaces, including metals and polymers, are susceptible to colonization by microorganisms even under nutrient-starved conditions (oligotrophic). A physical layer of microbial cells and their exopolymeric materials may develop on any exposed surfaces when nutrients become readily available for microbial growth. Both sessile microorganisms on surfaces and their microbial exopolymeric materials are collectively called microbial biofilms [7, 50–59]. Biofilms are interfacial communities of microorganisms occurring between the substratum surfaces of materials and the bulk solution, and they may have a very strong influence on the property of the substratum materials, including integrity.

Microbial biofilms are complex communities of microorganisms embedded in a matrix of their exopolymers under natural conditions. When an inert surface of material is introduced into an aqueous environment, the substratum is fouled sequentially with soluble organics and then microorganisms [55, 60–63]. The growth and multiplication of these attached cells increase the thickness of the biofilm and the heterogeneity of the biofilm in terms of O_2 distribution and nutrient profiles. Within the heterogeneous layer of bacteria and their products, both aerobic and anaerobic processes can take place simultaneously over space and time in the highly porous biofilm [8]. Aerobic processes facilitate consumption of more oxygen, which is extremely toxic to the activity of anaerobic microorganisms, and anaerobes benefit from the lowering of oxygen tension by aerobes. Even in nonaqueous conditions, biofilms can form on surfaces [28, 37, 59, 64].

Formation of bacterial biofilms on surfaces provides a strategy for microorganisms to survive environmental stress and predation and to grow, providing an opportunity for invasion and destruction of the colonized materials. It has been widely reported that growth of microorganisms on surfaces may result in corrosion of the underlying metals [65–75] or, in the case of humans, tissue may be infected by pathogens [76]. This detrimental effect occurs particularly in the presence of an active population of sulfate-reducing bacteria in anaerobic corrosion [74, 77–82], during degradation of polymeric materials in contact with soils [38, 39, 42, 44, 45], and in human tissue in contact with polymeric materials, for example, urinary tract catheters [22, 29].

D. DEGRADATION PROCESSES

Polymeric materials may be susceptible to deterioration through physical stress and chemical effects. Microorganisms are ubiquitous and are constantly associated with material surfaces under aerobic and anaerobic conditions depending on the specific application. Some environments can be extreme, such as microgravity in space missions and high levels of irradiation in nuclear power plants or waste depositories. Due to the wide array of environments, simulation studies are often carried out to assess the potential degradability of polymers under either aerobic [26, 33–35, 38, 39, 83, 84] or anaerobic [38, 39, 41, 43, 85] conditions. Other studies emphasize marine environments [86–89], natural soils [90, 91], and river water [86, 92, 93]. In addition, enzymatic assays have been used to assess degradability of a specific polymer under laboratory conditions [86, 94–96] or to detect specific enzyme activity indicative of a degradative process, for example, esterases [12, 97–112]. Experiments in situ always suffer from poor reproducibility because of the broad range of variables involved [83, 84] and the difficulty in interpretation of experimental results and extrapolation of possible mechanisms involved. In contrast, laboratory-simulated conditions with high reproducibility are often used for evaluation of the fate of polymeric materials and investigation of the degradation mechanisms involved [4, 6, 38, 39–45, 113].

Assessment of polymer biodegradability in anaerobic simulation environments can be conducted in laboratory bioreactors. In such systems, the composition of the components and the environmental conditions need to be defined specifically beforehand. The anaerobic Hungate technique [114] can be applied using serum bottles or Bulch anaerobic tubes [115–118]. Degradation of polymer can be determined with either processed thin films [41–43] or powder [119, 120]. However, it should be borne in mind that unprocessed powder does not have the same crystallinity as processed polymers; therefore information about the degradability of a polymer should be interpreted with caution. In addition, aging of the film and the conditions leading to aging also affect the crystallinity of the polymer and then the rate of degradation. A lack of awareness about the physical nature of the polymer results in misinterpretation of polymer degradability in natural environments.

D1. Aerobic Processes

Oxygen is the most favorable electron acceptor in metabolism for a large population of microorganisms. Aerobic conditions are often used to assess polymer biodegradation in many tests; examples are aerobic soil exposure [121, 122], thermophilic composting [42, 44, 123], immersion in surface seawater [88, 89, 122] and freshwater [86, 93], and laboratory batch conditions [92, 95, 96, 124–126]. In addition, the

enclosed living environment not only harbors a range of microorganisms; the microorganisms are detrimental to both human health and material integrity [6, 127–138]. Each of these experimental conditions has its weaknesses and strengths and will be discussed later.

Under aerobic conditions, microorganisms capable of utilization of molecular oxygen as an electron acceptor are the dominant species. During degradation, physical disintegration of polymers may subsequently accelerate biological degradation. Mechanisms of polymer degradation by microorganisms usually involve enzymatic attack as the main process. For example, one set of extruded film strips of poly(β-hydroxybutyrate) (PHB) with a molecular weight of 1.46×10^5 (M_w) and a racemic diad of 0.62 were aged at room temperature for two months and buried in flasks containing moist soils incubated at 35°C in the dark. In parallel, a control was prepared by adding antibiotics (streptomycin, nystin) to the moist soil to inhibit microbial growth. During incubation, weight losses of 34 and 66% were observed in the biologically active flasks after 60 and 95 days of incubation, respectively. In contrast, weight loss of the abiotic control was less than 8% during the same period. Dense microbial biofilms were observed on surfaces of the exposed polymer strips, and surface erosion was evident. It is probable that the polymers' physical structure was degraded by exoenzymes excreted by the colonizing microorganisms. *Pseudomonas lemoignei* and *Alcaligenes faecalis* are capable of degrading PHBs through activity of PHB depolymerases [139, 140]. Other polymers, for example, PHB, a copolymer of poly(hydroxybutyrate-*co*-hydroxyvalerate) and poly(d, l-lactide), were also assayed [40, 41].

Thermophilic composting [38–45, 141] and respirometric biometry [39, 43, 46] have been used extensively in quantitatively assessing the fate of polymeric materials. Historically, weight loss was the primary parameter monitored after exposure [32, 40, 41]. For example, in a study of cellulose acetate (CA) degradability in thermophilic composting tests, CA films with an acetyl substitution value of 1.7 were degraded faster than CA with a value of 2.5 [40–45]. It took approximately 14 days for CA with a degree of substitution (DS) of 1.7 to degrade completely, while it took 25 days for DS 2.5 to decompose [42–44]. Biodegradation of CA was confirmed by determining changes in polymer molecular weights before and after the test period as an important indicator of degradation [43, 46]. When necessary, further microbiology work can be conducted to investigate the properties of the microorganism in details. *Pseudomonas paucimobilis* was isolated from CA film surfaces after exposure to aerobic thermophilic microorganisms from compost for two weeks and was found to degrade CA with a DS 1.7 and 2.5 at similar rates [38, 39]. The limitation of this technique is that fragmentation of polymer films may result in nonrecoverable small debris, which may be misinterpreted as degradation, thereby exaggerating the degradation rate.

The respirometry technique is based on quantitative monitoring of O_2 consumed and/or CO_2 produced and can also be used for understanding polymer degradation and more specifically mineralization. In such a test, one set of the test system without polymer amendment serves as a control [40] while another identical set will contain various amounts of polymer powder. In this way, mineralization of polymer can be determined by quantitatively measuring the carbon balance over time without the employment of radiolabeled chemicals. As much as 64% of the substrate polymer carbon was liberated and recovered as CO_2 in NaOH traps during the course of CA degradation under aerobic conditions [38, 39, 42, 46]. It should be borne in mind that complete mineralization of the polymer is not achieved because a fraction of the substrate carbon is always immobilized in microbial biomass and humification materials.

D2. Anaerobic Processes

Simulated anaerobic conditions used to measure polymer degradability include anaerobic soils, landfills [142–146], sewage sludge [147], and laboratory methanogenic or sulfate-reducing environments. These simulations have been widely used in metal corrosion studies involving the sulfate-reducing bacteria (SRB) [74, 75, 78, 79, 81, 82]. Most of the research efforts have been focused on understanding the susceptibility of materials to microorganisms and the mechanisms involved. Polymer biodegradation can be carried out under strictly anaerobic conditions in the laboratory with high reproducibility, but the incubation time is anticipated to be long [38, 39, 40–46]. Other studies were carried out under either natural conditions [148] or semi-natural environments, such as a municipal landfill [144, 148]. The choice of the systems for testing and study is mostly dictated by the objectives and questions to be answered.

Only a very limited number of studies have been conducted on microbial degradation of polymeric materials under strictly anaerobic conditions [39, 41, 119]. Some have also been carried out using natural microbial communities. The powder form of PHB was used in a sludge-amended incubation experiment [119]. Reconstituted microbial consortia containing SRB were used in a study of polymeric composite degradation [149], but this approach may fail to reflect the natural microflora and the relationship between microbial colonization and the possibility of damage to the underlying materials. The mechanisms of SRB corrosion of metals are due largely to the presence of hydrogenase systems causing depolarization of adsorbed hydrogen on metal surfaces and changes to the open-circuit potential [59, 64, 113]. However, the inclusion of a SRB as the major microbial group may not be justified for polymeric materials. As stated earlier, polymer degradation occurs through reactions carried out by depolymerases from microorganisms [139, 150].

E. MECHANISMS OF DEGRADATION

Microbial biofilms are ubiquitous on material surfaces, including polymers. Earlier reports tended to use biofouling as an indication for degradation [151], which should be more carefully stated. Quantitative methods have been introduced coupled with scanning electron microscopic observations to substantiate the extent of deterioration by microorganisms [26–28, 33–35, 37], but elucidation of the mechanisms involved remains a major challenge due to the complexity of the polymeric materials and their chemical constituents. Formation of microbial biofilms on surfaces is the first step and also a prerequisite for subsequent degradation to occur, but it cannot be used as the sole indicator alone. Occasionally, exoenzymes from nonsessile microorganisms may contribute to degradation of polymers, but the extent of such degradation is considerably lower than the decomposition by surface colonizers. When bacteria are attached to a substratum surface, they become protected from predation and may become metabolically more active [61, 152]. They form patches of biofilms on material surfaces. Within biofilms, several groups of microorganisms, including aerobic, facultative, and anaerobic, can coexist in synergistic associations, also called consortia, effectively attacking a wide range of substratum materials [36, 153–158].

Different polymeric materials are degraded to different extents. Some materials are susceptible to mineralization, while in others, specific components are utilized. It is interesting to know that slow-growing bacteria have much high degradation potential than the fast-growing ones [11]. This information is both interesting and important because current methods are biased toward the use of short-term tests and fast-growing microorganisms.

E1. Utilization of Polymers as a Source of Carbon and Energy

Some polymers can be completely utilized as a source of carbon and energy, while others are only partially degraded by microorganisms. Examples of the former include the natural and microbially synthesized materials—poly(hydroxyalkanoates) (PHAs) [121, 150, 159, 160], γ-poly(glutamic acid) [161], cellulose acetates [7, 29, 38, 39, 40–45], polyethers [162], polylactide [40, 41], and polyurethanes [28, 37, 163–168]. A general rule is that biologically synthesized polymers are readily biodegradable in natural environments, while synthetic polymers are either less biodegradable or degrade very slowly, depending on their chemical composition, structural complexity, and molecular weights. However, the rate of degradation is in large part determined by the chemical structure, for example, molecular weights, structure, and configuration of the monomer units. Apart from the intrinsic properties, the environmental conditions, aerobic versus anaerobic, also play a significant role.

Understanding the relationship between the chemical structure of a polymer and its biodegradability is very important for designing a new generation of environmentally degradable polymers. As a general rule, high-molecular-weight polymers are less biodegradable or degrade at a slower rate than those with low molecular weights. Heterogeneity of the monomers also affects degradation rate; the hydrolytic chain scission is dependent on the copolymer composition: poly(3-hydroxybutyrate-*co*-27% 4-hydroxybutyrate) [P(3HB-*co*-27% 4HB)] > [P(3HB-*co*-17% 4HB)] > [P(3HB-*co*-10% 4HB)] > poly(3-hydroxybutyrate-*co*-45% 3-hydroxybutyrate [P(3HB-*co*-45% 3HV)] > [P(3HB-*co*-71% 3HV)] [121]. Similarly, the sequence of enzymatic hydrolysis follows [P(HB-*co*-16% HV)] > [P(HB-*co*-32% HV)] > PHB [169]. The crystallinity of the polymer also affects the rate of degradation but is rarely taken into account [119].

Structural substitution groups, and their number per repeating unit, also affect the degradation kinetics. For example, (CAs) with a lower degree of substitution (DS) values are more quickly degraded than higher substituted ones under both aerobic and anaerobic conditions [38–45, 120]. During degradation of CAs, both molecular weight and degree of substitution showed a decreasing trend, suggesting that deacetylation and decomposition of the polymer backbone proceed simultaneously [44]. Earlier data suggested that CAs with DS values greater than 0.82 are recalcitrant to biodegradation and the limiting step is deacetylation followed by breaking of the polymer carbon–carbon bonds [100].

The general theory of polymer degradation assumes that exoenzymes from microorganisms break complex polymers to yield short units, including oligomers, dimers, and monomers, small enough to be allowed to pass through permeable outer bacterial membranes and subsequently to be assimilated as carbon and energy sources. The process is called depolymerization. The closer a polymer structure is to a natural analog, the easier it is degraded. Cellulose, chitin, pullusan, and PHB are all biologically synthesized and are completely and rapidly biodegradable [170]. The complete decomposition of a polymer to CO_2 and H_2O under aerobic conditions or organic acids, CO_2, and CH_4 under anaerobic conditions is rare. Degradation and mineralization of a polymer substrate can hardly achieve 100% due to the synthesis of microbial biomass and humus matter [171].

Under different conditions, predominant groups of microorganisms differ and degradation pathways vary. In the presence of oxygen, aerobic microorganisms are responsible for destruction of complex materials, with microbial biomass, CO_2, and H_2O as the final products (Fig. 30.1). In contrast, under anoxic conditions, anaerobic consortia of microorganisms are involved in polymer deterioration, and the primary products will be microbial biomass, CO_2, CH_4, and H_2O [142–144] (Fig. 30.1). These conditions are widely

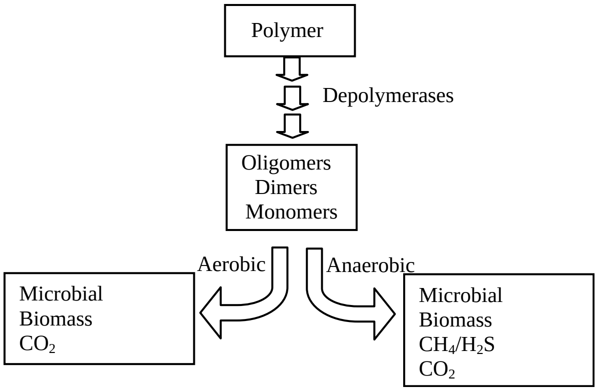

FIGURE 30.1. Schematic diagram showing degradation of polymeric materials under aerobic and anaerobic conditions.

found in natural environments and can be simulated in the laboratory with appropriate inocula.

E1.1. Poly(β-hydroxyalkanoates). Bacterial poly(β-hydroxyalkanoates) are a class of aliphatic polyesters consisting of homo or copolymers of [*R*]- β-hydroxyalkanoic acids. The polymer is a microbial intracellular inclusion in the cytoplasmic fluid in the form of granules with diameters between 0.3 and 1.0 μm. They can be as much as 30–80% of cellular mass. Unlike other biopolymers, such as polysaccharides, proteins, and DNAs, PHB is a thermoplastic with a melting temperature around 180°C, making it a good candidate for thermoprocessing. Furthermore, a copolyester consisting of 3-hydroxybutyrate and 3-hydroxyvalerate, poly(3HB-*co*-3HV) can be synthesized in cells of *Alcaligenes eutrophus* [172]. Both long side-chain and novel side-chain polymers have been synthesized by the addition of appropriate substrates in the culture medium and with different bacterial strains [173–175]. The copolymers range from thermoplastics to elastomers. The *A. eutrophus* genes encoding PHB synthesis have been transferred into cotton for PHB synthesis in fiber cells for production by agriculture [176].

Homopolymers and copolymers can be degraded in biologically active environments, for example, soils [91, 177], sludge, compost [38, 39, 43], river water [86, 92, 93], and seawater [86, 88, 89]. Extracellular PHB depolymerases have been isolated from *P. lemoignei* [178] and *A. faecalis* [140, 179]. The enzymatic degradation occurred at the surfaces of the polyester film, and the rate of surface erosion was strongly dependent on both the molecular weight (degree of polymerization) and composition of the polyester crystallinity, and the dominant species of bacteria. The stereochemistry of these chemically synthesized polymers also affects their fate after disposal in the natural environment [180, 181].

E1.2. Cellulose Acetates. Cellular acetates are chemically modified natural polymers designed to improve their mechanical properties for different uses. Generally, CAs with a degree of substitution from 1.7 to 2.5 can be degraded in thermophilic compost in 45 days [38–45] and transformed into constituent chemicals through biologically catalyzed reactions [182]. Increasing the DS value on a repeating unit makes the CA less degradable. CA degradation occurs more rapidly under aerobic conditions. The mechanisms of degradation are deacetylation, which releases the substitution groups, followed by cleavage of the carbon–carbon backbone. The decrease in molecular weight and deacetylation proceed simutaneously during degradation.

E1.3. Polyethers. Polyethers include polyethylene glycols (PEGs), polypropylene glycols (PPGs), and polytetramethylene glycols (PTMGs). They are widely used in pharmaceuticals, cosmetics, lubricants, inks, and surfactants. They frequently contaminate natural water, including coastal waters and streams where wastewater is discharged. Degradability of this class of polymers has been studied under both aerobic [162, 183–186] and anaerobic [187–189] conditions. Polyether degradability is dependent on molecular weight, with molecular weights higher than 1000 considered resistant to biodegradation [162, 190]. However, degradation of PEGs with molecular weights up to 20,000 has been reported. The ability of a microflora to degrade larger PEG molecules is dependent primarily on the ability of a syntrophic association in mixed cultures of bacteria to metabolize the chemicals. For example, *Flavobacterium* and *Pseudomonas* can degrade PEG. After each oxidation cycle, PEG molecules are reduced by a glycol unit.

The central theme of PEG degradation is cleavage of an aliphatic ether linkage. In a coculture of aerobic *Flavobacterium* and *Pseudomonas* species, PEG degradation proceeds through dehydroxylation to form an aldehyde and a further dehydrogenation to a carboxylic acid derivative [184, 185]. Neither of these bacteria can degrade PEG in pure culture. Cellular contact between them seems to be essential for effective cooperation. In the *Flavobaterium* and *Psuedomonas* system, three enzymes are involved in the complete degradation of PEG [162]. PEG dehydrogenase, PEG–aldehyde dehydrogenase, and PEG–carboxylate dehydrogenase (ether cleaving) are required. All three were found in *Flavobaterium*, while only PEG–carboxylate dehydrogenase was present in *Pseudomonas*. However, *Pseudomonas,* though not directly involved in the degradation, utilizes a toxic metabolite that inhibits the activity of the *Flavobacterium*. This appears to be the essential link for their syntrophic association in the degradation of PEG.

E2. Effects on Physical Properties

E2.1. Polyimides. The wide acceptance of polyimides in the electronics industry [191–195] has drawn great attention to the issue of stability of these materials. The National

Research Council in 1987 [3] emphasized the need to develop deterioration preventive measures for polymers used in the electronic industries because data acquisition, information processing, and communication are critically dependent on materials performance and integrity. The interlayering of polyimides and electronics in integrated circuits prompted several studies on the interactions between these two materials [196, 197].

Polyimides are also widely used in load-bearing applications, for example, struts, chasses, and brackets in automotive and aircraft structures, due to their flexibility and compressive strength. They are used in appliance construction, cookware, and food packaging because of their chemical resistance to oils, greases, and fats; microwave transparency; and thermal resistance. Their electrical properties are ideally suited for applications in the electrical and electronics markets, especially as high-temperature insulation materials and passivation layers in the fabrication of integrated circuits and flexible circuitry. In addition, the flammability resistance of this class of polymers may provide a halogen-free flame-retardant material for aircraft interiors, furnishings, and wire insulation. Other possible uses may include fibers for protective clothing, advanced composite structures, adhesives, insulation tapes, foam, and optics operating at high temperatures [195].

Electronic packaging polyimides are particularly useful because of their outstanding performance and engineering properties. However, they are susceptible to degradation by the colonization of fungi (Fig. 30.2, Table 30.1)[25–31, 33–35, 47]. Polyimide degradation occurs through biofilm formation and subsequent physical changes in the polymer. Using electrochemical impedance spectroscopy (EIS) [198, 199], fungal growth on polyimides yields distinctive EIS spectra, indicative of failing resistivity [20, 21, 26]. Two steps are involved during degradation: An initial decline in coating resistance is related to the partial ingress of water and ionic species into the polymer matrices. This is followed by further deterioration of the polymer by activity of the fungi, resulting in a large decrease in resistivity. The data support the hypothesis that polyimides are susceptible to microbial degradation resulting in the corrosion of underlying metal. They also confirm the versatility of EIS as a method in evaluation of the biosusceptibility of polymers.

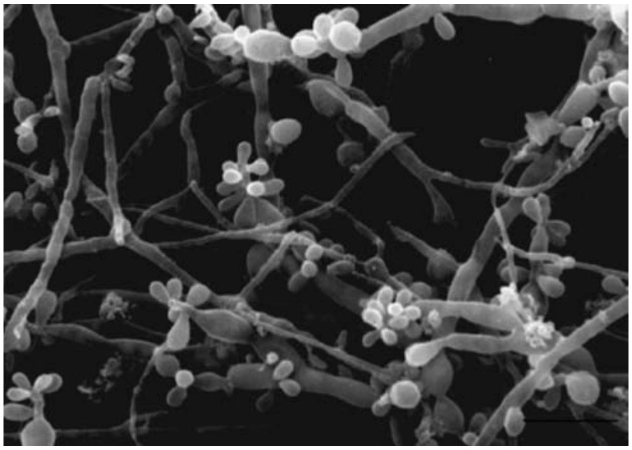

FIGURE 30.2. Scanning electron micrograph of fungi on deteriorated polyimides (scale bar, 5 μm).

	Epoxy/graphite fiber unidirectional	[28]
	Epoxy/carbon fibers, epoxy/glass fibers, bismaleimide/aluminum	[28, 36, 200]
Protective coating	Aliphatic polyurethane coating	[28]
Kapton polymimdes	Pyromellitic dianhydride and 4,4′-diaminodiphenyl ether	[26, 30–32]

The dielectric properties of polyimides could be altered drastically following growth of microbial biofilms [25, 26, 30, 31, 47], which has wide implications for protection of this class of materials under tropical and subtropical conditions because both humidity and airborne microbial loading are high. This form of deterioration may be slow under ambient conditions in dry and cold regions; however, the deterioration processes can be accelerated in humid conditions or in enclosed environments, for example, submarines, space vehicles, aircraft, and other closed industrial facilities. Very small changes in material properties by the formation of biofilms and trapping of moisture will result in serious functional consequences to the systems.

E2.2. Fiber-Reinforced Polymeric Composite Materials. The increasing usage of fiber-reinforced polymeric composite materials (FRPCMs) as structural components of public

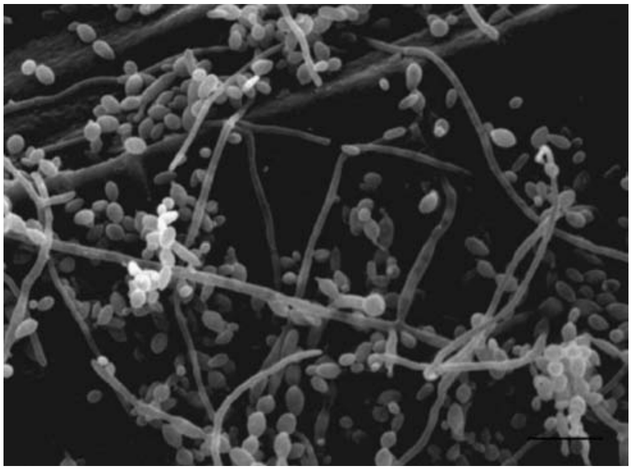

FIGURE 30.3. Scanning electron micrograph of fungi on fiber-reinforced polymeric composite coupon (scale bar, 10 μm).

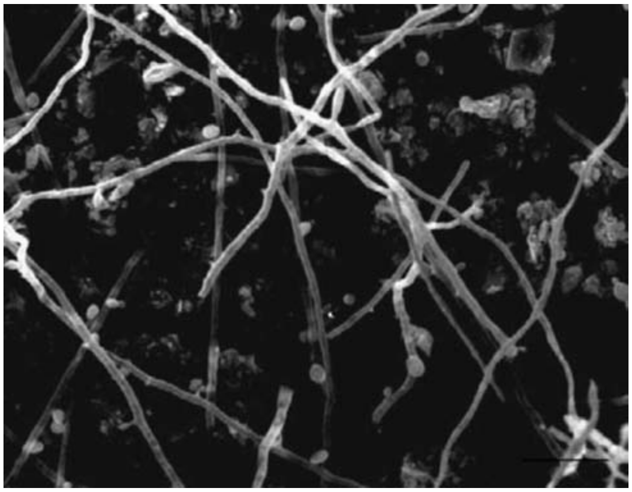

FIGURE 30.4. Scanning electron micrograph of fungi penetrating into matrices of fiber-reinforced polymeric composite coupon (scale bar, 10 μm).

structures and aerospace applications has generated an urgent need to evaluate the biodegradability of this new class of material. It has become clear that FRPCMs are not immune to the colonization by natural microorganisms, including both fungi and bacteria [4–7, 27–29, 37]. Through a series of investigations, impurities and chemical additives in FRPCMs promote microbial growth as they are sources of carbon and energy (Fig. 30.3, Table 30.1). Research has shown that slow-growing microorganisms cause much greater damage to materials than the fast-growing microorganisms [11], but no critical assessment has been made in relation to FRPCMs. At least two groups reported microbial degradation of FRPCs [6, 26, 32–35, 149]. Wagner and her collaborators used a mixed culture of microorganisms, including a sulfate-reducing bacterium, commonly used in corrosion tests. In contrast, Gu and colleagues [8, 26–29, 33–35, 71] used a fungal consortium originally enriched from degraded polymers. This consortium consisted of *Aspergillus versicolor*, *Cladosporium cladosorioides*, and a *Chaetomium* sp. Initial physical and mechanical tests were not sufficiently sensitive to detect any significant physical changes in the bulk materials after 120 days exposure [34, 36, 200]. However, physical penetration of fungal hyphae into the resin matrices has been observed with Scanning electron microscopy (SEM) (Fig. 30.4), indicating that resins were being actively degraded, in turn suggesting that the materials were at risk of failure.

Natural populations of microorganisms are capable of growing on surfaces of FRPC coupons at both relatively high humidity (65–70%) and lower humidity conditions (55–65%) [6, 28]. The accumulation of bacteria on surfaces of composites develops into a biofilm layer, providing some initial resistance to further environmental changes, for example, drying. Since use of a range of mechanical tests did not detect changes in composite coupons after exposure to a fungal culture [200], EIS was applied to examine changes in resistivity of composite materials after fungal exposure. EIS indicated a significant decline in material resistivity and an increase in conductance, providing the first demonstration that this technique can be used in monitoring FRPCMs and electrochemical properties can be used to identify microbial attack [33, 35]. The polymeric composites tested included fluorinated polyimide/glass fibers, bismaleimide/graphite fibers, poly(ether-ether-ketone) (PEEK)/graphite fibers, and epoxy/graphite fibers (Table 30.1) [35]. Graphite fibers are very susceptible to biofilm formation and the surface treatment sizing chemicals are utilized by bacteria as a source of carbon and energy (Fig. 30.5).

A critical question remains about the effect of FRPCM degradation on the mechanical properties and integrity of these composite materials. It is apparent that EIS is sufficiently sensitive to detect resistivity/conductance of com-

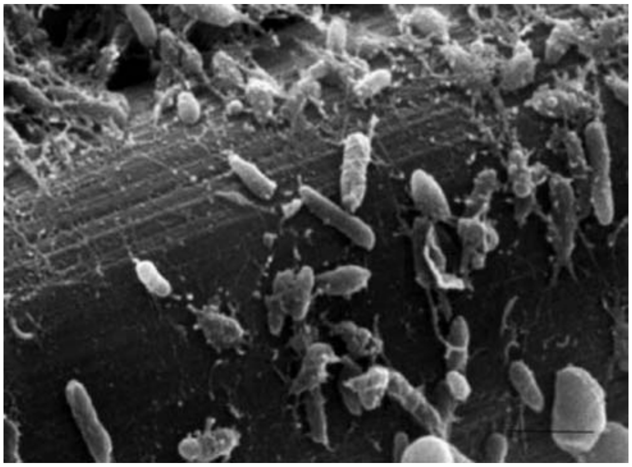

FIGURE 30.5. Scanning electron micrograph of bacteria forming biofilm on surface of graphite fiber (scale bar, 5 μm).

posite coupons, but surface-sensitive analytical techniques are needed to register the minor changes correlating to changes in structure and integrity of polymeric matrices. Acoustic techniques have been proposed as a means of detecting changes in the physical properties of the composite [149], but no comparison has been made between EIS and acoustic techniques.

E2.3. Protective Coatings. Polymeric coatings are a class of chemicals with increasing production volume and are designed to protect underlying metals from corrosive chemical species and microorganisms. Microbial colonization and formation of biofilms on coatings may accelerate and severely damage the protective coatings and then the underlying metals. Natural bacterial populations were found to readily form microbial biofilms on surfaces of coating materials, including epoxy and polyamide primers and aliphatic polyurethanes (Table 30.1) [6, 28, 36]. Using EIS, both primers and top coatings demonstrated susceptibility to exposure to a mixed culture of fungi compared to sterile controls [28]. Primers were more rapidly degraded in terms of the EIS signal than aliphatic polyurethane coating. A common approach in dealing with coating life is to incorporate biocides in coating formulations, but addition of biocides to polyurethane coatings did not inhibit bacterial attachment or significantly reduce bacterial growth [28, 37].

E2.4. Packaging Polyethylenes. High-density and low-density polyethylenes (PEs) are primarily used in product packaging as sheets and thin films. Their degradability in natural environments poses serious environmental problems due to their very slow degradation rate under natural conditions and the hazard they present to freshwater and marine animals. Biodegradation of PEs has been studied extensively [90, 92]. It is believed that polymer additives, such as starch, antioxidants, coloring agents, sensitizers, and plasticizers, may significantly alter the biodegradability of the parent polymers. Degradation rates may be increased by 2–4% following photosensitizer addition.

In one study, extracellular culture concentrates of three *Streptomyces* species were inoculated to starch containing PE films [95, 96], and PE was claimed to be degraded. Degradation of PE by microorganisms may be minimal without taking into account physical and chemical processes, and the data on degradation of PE-containing starch are

questionable. In addition, microbial metabolites may contaminate the PE surfaces and could be misinterpreted as degradation products of the parent PE when chemical characterization is carried out.

Abiotic degradation of PE is evidenced by the appearance of carbonyl functional groups in abiotic environments. In contrast, an increase of double bonds was observed when polymers showed weight loss resulting from biodegradation [201]. It was then proposed that microbial PE degradation is a two-step process: an initial abiotic photooxidation followed by a cleavage of the polymer carbon backbone. However, the mechanism of the second step needs extensive analysis before plausible conclusions can be drawn.

Lower molecular weight PEs including paraffin can be biodegraded and they undergo hydroxylation oxidatively to form an alcohol group followed by formation of carboxylic acid. At higher temperatures, ketones, alcohols, aldehydes, lactones, and carboxylic acids are formed abiotically within six weeks [201]. PE pipes used in gas distribution systems may fail due to cracking, but it is unlikely that biological processes are involved [202].

E2.5. Polypropylenes. Polypropylenes (PPs) are widely utilized in engineering pipes and containers. Degradation of PPs results in a decrease of their tensile strength and molecular weight. The degradation mechanism may involve the formation of hydroperoxides, which destabilize the polymeric carbon chain to form a carbonyl group [126, 203]. This step has been confirmed by infrared spectroscopy, but no strong evidence is available for the biochemical basis of degradation of PPs.

F. DEGRADATION METHODOLOGY

Traditionally, microbiological degradation of polymeric materials is carried out in microbiological nutrient media for short-term investigations [73, 113, 149]. The American

TABLE 30.3. Comparison of Several Methods Available for Testing Degradability of Different Polymers and Under Range of Environmental and Simulation Conditions

Methods	Polymer Forms	Inoculum and Degradation Criteria Monitored	Comments	References
Gravimetry	Film or physical intact forms	A wide range of inocula can be used, from soil, waters, sewage, or pure species of microorganisms from culture collections.	This method is robust and also good for isolation of degradative microorganisms from environments of interest. Reproducibility is high. Disintegration of polymer cannot be differentiated from biodegradation.	[40–46, 83, 84, 92, 93]
Respirometry	Film, powder, liquid, and virtually all forms and shapes	Either oxygen consumed or CO_2 produced under aerobic conditions. Under methanogenic conditions, produced methane can be monitored.	This method is most adaptable to a wide range of materials. It may require specialized instruments. When fermentation is the major mechanism of degradation, this method gives an underestimation of the results.	[40–46, 204–209]
Surface hydrolysis	Films or other	Generally aerobic conditions, pure enzymes are used. Hydrogen ions (pH) released are monitored as incubation progresses.	Prior information about the degradation of the polymer by microorganims or particular enzymes is needed to target the specific test.	[180, 181]
Electrochemical impedance spectroscopy	Films or coatings resistant to water	The test polymers should be adhered on the surface of conductive materials and electrochemical conductance is recorded.	Polymer must initially be water impermeable for signal transduction. Degradation can proceed quickly, and as soon as degradation is registered, no further degradation processes can be distinguished.	[26, 28, 30–35]

Society for Testing and Materials (ASTM) offers a range of standard methodologies for assessment of material degradation under specific conditions [6, 46, 204–208] (Table 30.2). These methods are widely accepted by chemists and engineers but few biologists. However, the guidelines (1) are designed for a specific set of conditions which can be reproduced anywhere but may not be relevant to an individual environment; (2) fail to take into account microbiological processes and subsequent biochemical characterization; and (3) are usually qualitative with no or minimal emphasis on the mechanisms involved during degradation (Table 30.3).

Materials used for aerospace applications have been assessed in the United States by application of MIL-STD-810E method 508.4 [209]. In addition to the problems described above, a weakness of this method includes the failure to determine the effects of long-term exposure of the materials, as slow-growing microorganisms appear to be more effective in degrading polymeric materials than fast growers [210]. This method also emphasizes fungi and ignores any participation of bacteria in degradation processes even though both groups of microorganisms may play synergistic roles in the complete degradation of complex polymeric materials.

G. PLASTICIZERS

Polymeric materials are known to contain a wide array of chemicals, including plasticizers to improve their processibility and product quality; these plasticizers mostly include phthalate esters, specifically dimethyl phthalate esters (namely *ortho*-dimethyl phthalate ester, dimethyl isophthalate ester, and dimethyl terephthalate ester), di-*n*-butyl phthalate ester, and dibutylbenzyl phthalate ester [12, 101–112]. Since these chemicals are not covalently bound to the polymer resins, they can be utilized by many bacteria isolated from activated sludge [211], mangrove sediments [101–105, 108] and deep-ocean sediment [12, 106, 107] (Table 30.4). Biochemical cooperation is required between two different bacteria, namely *Arthrobacter* species and *Sphingomonas paucimobilis* in utilization of *ortho*-dimethyl phthalate ester (Fig. 30.6) [105, 107], but *Variovorax paradoxus* T4 isolated from deep-ocean sediment of the South China Sea is capable of utilizing dimethyl terephthalate ester as sole carbon and energy source (Fig. 30.7). Di-*n*-butyl phthalate dibutylbenzylphthalate esters can be degraded by *Pseudomonas fluorescence* B-1 isolated from mangrove sediment [109–112]. Results collectively indicated that enzymes involved in the initial cleavage of the two ester bonds can be highly selective.

H. USE OF BIOCIDES

Microorganisms are commonly controlled by application of biocides. While most antimicrobial products are effective against the growth of microorganisms in liquids, biofilm bacteria are more resistant and can rapidly develop resistance after exposure to chemicals [28, 37, 128,

212–215]. Biofilms reduce the effectiveness of the biocides because of reduced diffusion rates and the binding affinity of exopolymeric materials in the biofilm for biocides. In addition, microorganisms have plasmids which can be effectively exchanged between organisms to rapidly build resistance to the environmental chemicals and biocides [213]. Most industrial tests are conducted in the liquid phase, which does not represent real environmental conditions of exposure. For example, a biocide that effectively inhibits bacterial growth in a test involving liquid culture failed to control growth on surfaces of a polyurethane coating [4, 6, 28, 37]. It is strongly recommended that tests for biocide efficacy should be applied to material surfaces. In addition, compatibility of a biocide with a material should be considered.

It is routine practice that corrosion protective paint formulations are amended with biocides to prolong the shelf-life of products and extend service time [216]. Industrial development of water-based paints and coatings creates the problem of increased microbial contamination and degradation (Fig. 30.8), because these environmentally friendly chemicals may be susceptible to rapid colonization and utilization by microorganisms. Microbial growth deteriorates the quality of products and also provides initial contamination to the product in service. The basic approach to such a problem should emphasize environmental control so that microorganisms are prevented from attaching to surfaces in the first place. Conditions that promote microbial growth should also be avoided so that microbial population growth is kept to a minimum.

I. BIODEGRADATION AND HEALTH

Polymeric materials are increasingly used not only in engineering and structures, building, and decoration but also in medical implants. Material types cover a wide range of composition, including absorbable sutures and artificial skin. The materials must be thoroughly examined and tested for potential biofilm formation. Some additives, such as PEGs, can promote microbial growth by providing readily available sources of carbon and energy. Other chemicals may serve as attractants for bacteria. In addition, microbial metabolites during active growth, particularly secondary ones, can be allergens or irritants to humans in building materials [217, 218]. Fungi have been studied for their tolerance to lower humidity, where bacteria are barely capable of survival or growth [28]. The growth of fungi may not only damage the materials, integrity but also produce toxic secondary metabolites [8, 219].

J. CONCLUSIONS

Polymeric materials are a diverse class of polymers with multiple applications. Assessment of their biodegradability must address the relationship between their chemical structures and proposed applications. An array of test protocols are available and should be developed to detect early changes in polymer physical and chemical properties. EIS is a sensitive method for detecting early physical changes in polymer films, but the microbial role in deterioration needs to be confirmed with more sensitive methods. In most cases, accelerated testing under specific environmental conditions will be required to determine susceptibility to microbial deterioration and to assess protective measures.

ACKNOWLEDGMENTS

We thank Zhenye Zhao for drawing Figure 30.1; Ed Seling at the Museum of Comparative Zoology, Harvard University, for the scanning electron micrographs taken and used here in Figures 30.2–30.5; and Jessie Lai for assistance in organizing the final figures and archiving.

A. INTRODUCTION

According to the American Concrete Institute (ACI) Committee 201, durability of Portland cement concrete is defined as its ability to resist weathering action, chemical attack, abrasion, or any other process of deterioration; that is, durable concrete will retain its original form, quality, and serviceability when exposed to its environment. If concrete is proportioned correctly and is cast, consolidated, and cured properly, it should be maintenance free for a very long time. But in practice this rarely happens with the result that concrete structures deteriorate prematurely and need constant repairs and maintenance at a considerable cost. This chapter discusses selected aspects of physical and chemical attacks that affect significantly the long-term durability of concrete. The physical attack that causes major distress in concrete structures is the freezing and thawing phenomenon; the chemical attacks include distress caused

by the sulfates, alkali-aggregate reactions, seawater, and carbonation of concrete.

Before discussing in some detail the deterioration of concrete by physical and chemical mechanisms, it should be stressed that porosity of hydrated cement paste, and hence concrete, plays a very major role in its durability. As porosity of concrete is directly related to its water–cement (W/C) ratio, any decrease in W/C will reduce significantly the porosity and hence its permeability. The decreased permeability will decrease the transportation of aggressive chemicals into concrete and will also control the moisture content during environmental changes. For example, a decrease in W/C concrete from 0.80 to 0.40 will reduce the coefficient of water permeability from $\sim 130 \times 10^{-12}$ to 10×10^{-12} m/s.

B. DETERIORATION CAUSED BY FREEZING AND THAWING CYCLES

In Canada, northern parts of the United States, northern Europe, Japan, Korea, Russia, and northern parts of China, concrete is subjected to repeated cycles of freezing and thawing. In addition, in several of these countries, deicing chemicals, such as sodium chloride, are routinely used to melt ice and snow on the highways, roads, and sidewalks. The freezing and thawing cycling and the combined action of freezing and thawing cycling and the application of the deicing salts result in considerable deterioration of concrete. In the deicing salt scaling of concrete, the mortar near the surface flakes or peels away. It is primarily a surface phenomenon, in contrast to the internal cracking of concrete in freezing and thawing cycling when the bulk of the concrete is affected. The concrete made with sound aggregates can be fully protected against freezing and thawing by proper air entrainment; however, air entrainment is found rarely to protect concrete totally from damage due to the combined action of freezing and thawing cycling and the deicing concrete chemicals. It is generally agreed upon that the deterioration caused by the deicing chemicals is mostly physical in nature and that the chemical reactions of the salts with the cement hydration products play only a secondary role in the deterioration mechanisms. Figure 31.1 shows a concrete structure damaged by freezing and thawing cycling.

B1. Mechanisms of Freezing and Thawing Deterioration

B1.1. Hydraulic Pressure. Water in the capillary pores of cement paste in concrete expands $\sim 9\%$ upon freezing. If the increased volume is smaller than the space available, no damage will occur; otherwise the excess water will be expelled by the hydraulic pressure. As cement paste is a permeable material, there is a possibility that excess water can escape from the capillary pores to the nearest air void during the process of freezing if the air void is unfilled. An entrained-air void will be unfilled, that is, filled with air unless a crack has penetrated it. Water forced into it by the mechanism described will exit immediately on thawing, forced out by the compression of the air, and hence no liquid will remain to evaporate and form secondary deposits. The presence of such deposits indicates that the bubble has been penetrated by a crack. Thus, the magnitude of this hydraulic

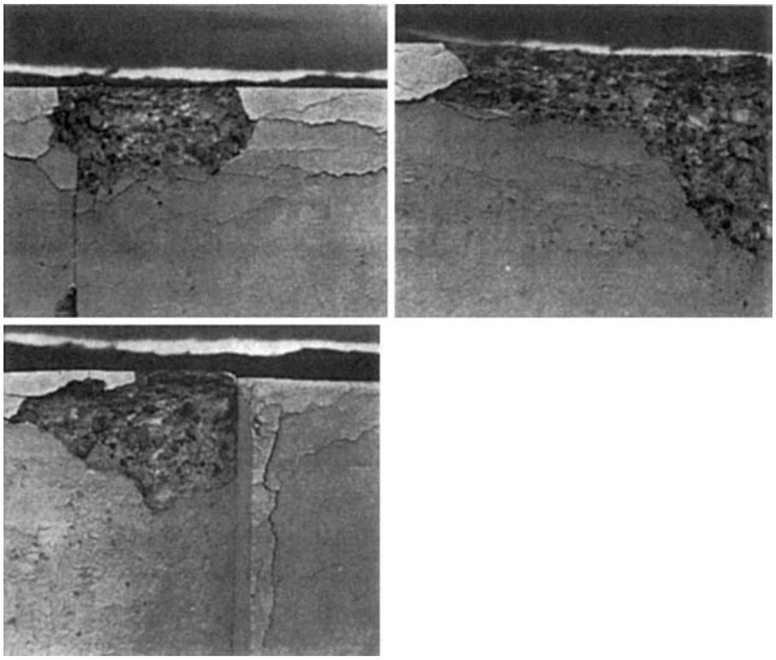

FIGURE 31.1. Damage of a concrete structure caused by freezing and thawing cycling [6].

pressure depends on the permeability of the cement paste, the distance that water must travel to reach the nearest unfilled void, the rate of freezing, the rate of ice formation, and the degree of saturation of the paste. If the pressure is high enough to stress the surrounding paste beyond its tensile strength, it will cause cracking [1, 2].

B1.2. Osmotic Pressure. In addition to hydraulic pressure caused by water freezing in capillary cavities, the osmotic pressure resulting from partial freezing of the solutions in such cavities can be another source of destructive expansions in cement paste. Water in the capillary cavities is not pure; it contains various soluble substances. Such solutions freeze at slightly lower temperatures than pure water. When solutions of different concentrations of soluble materials are separated by a permeable barrier, the solvent particles move through the barrier toward the solution of greater concentration. The existence of local salt concentration gradients between capillaries is envisaged as the source of osmotic pressure [3].

The hydraulic pressure due to an increase in the specific volume of water on freezing in large cavities and the osmotic pressure due to salt concentration differences in the pore fluid do not appear to be the only causes of expansion of cement paste exposed to frost action [4], but they are believed to be the main ones.

B1.3. Measures to Avoid Damage Due to Freezing and Thawing Cycling. Air entrainment in concrete has been used as a means of reducing internal damage due to frost action. In air-entrained Portland cement paste, every air void is assumed to be bordered by a zone in which the hydraulic pressure cannot become high enough to cause damage. By reducing the distance between the voids to the point where the protected zones overlap, the generation of disruptive hydraulic pressures during the freezing of water in the capillary cavities can be prevented. In order to avoid damage due to freezing and thawing cycling, concrete in North America is routinely air entrained using chemical admixtures. At a given air content, the protection provided by the air voids against repeated cycles of freezing and thawing is usually greater, the larger the number of voids per unit volume of paste. This implies that voids are more effective when they are close together. It is generally agreed upon that the cement paste is well protected against the effects of frost action if the spacing factor $\bar{L}$ of the air-void system is 200 μm or less, as determined in accordance with American Society for Testing and Materials (ASTM) C 457 test procedure. Field experience has shown that concrete incorporating between 5 and 9% air by volume will generally yield values of $\bar{L}$ which are of the order of 200 μm. When supplementary cementing materials such as fly ash or blast-furnace slag are incorporated into concrete together with superplasticizers, the value of $\bar{L}$ can reach ~230 μm with no detrimental effects on the performance of concrete subjected to freezing and thawing cycling.

B2. Mechanisms of Surface Scaling Due to Combined Action of Freezing and Thawing Cycling and Application of Deicing Salts

In addition to the hydraulic and osmotic pressure theories discussed above, there are a few more phenomena that are associated with the presence of deicing chemicals and are believed to contribute to the surface-scaling type of deterioration of concrete (Fig. 31.2).

B2.1. Layer-by-Layer Freezing. Differences in the salt concentration in concrete lead to corresponding differences in freezing temperatures of various layers. When ice formation occurs in such a layer-by-layer way, stresses can develop whose extent depends on the dilation difference between the frozen and unfrozen layers [5].

B2.2. Thermal Shock. Heat is required for the melting of ice and snow. When thawing takes place by the application of deicing chemicals, the heat is extracted mostly from the concrete. The great heat loss causes a rapid temperature drop on the surface of the concrete. The temperature gradient developed can cause stresses of short duration near the surface that may exceed the tensile strength of the concrete and cause damage [5].

B2.3. Supercooling Due to Preventive Salt Application. The use of deicing chemicals prevents water from freezing

FIGURE 31.2. Surface scaling of concrete caused by deicing chemicals [6].

on the surface of concrete at a temperature near 0°C. When the supercooled water near the surface of the concrete eventually freezes, the destructive effect of the phase transition will be greater than with normal freezing [5].

B2.4. Osmotic Pressure. The use of deicing chemicals will increase the concentration of the chemicals in the capillary pores near the surface of the concrete, which may build up an osmotic pressure high enough to cause a rupture of the cement paste near the surface.

B2.5. Measures to Avoid Damage Due to Deicing Salt Scaling. So far, there is no agreement that any of the above mechanisms are the primary reasons for the deterioration of concrete due to scaling. Consequently, no effective solution has been possible to prevent or to reduce the surface scaling of concrete. Research and practical experience indicate that air entrainment in concrete is effective in preventing internal deterioration; however, the scaling is never completely prevented by the air entrainment, and the critical air-void spacing factor ($\bar{L}$) concept may not be applicable to deterioration due to the scaling. According to Cordon [6], field experience has shown that linseed oil acts as an antiscaling agent. The solutions of this oil and flammable solvents are sprayed on highways, streets, and bridges to reduce damage caused by deicing salts.

C. DETERIORATION CAUSED BY ALKALI–AGGREGATE REACTIONS

For many years, aggregates were believed to be essentially inert and chemically nonreactive in concrete mixtures. Unfortunately, this often is not true, and deleterious reactive aggregates have been found in many parts of the world, including Africa, Australia, Canada, China, England, India, Japan, New Zealand, the Scandinavian countries, and the United States.

C1. Types of Reaction

There are two types of alkali–aggregate reactions:

(a) Alkali–silica reaction
(b) Alkali–carbonate reaction

Of these two reactions, the alkali–silica reaction is the most common. For this reason, the alkali–carbonate reaction will not be discussed here.

The alkali–silica reaction is a reaction in either mortar or concrete between the hydroxyl (OH^-) ions associated with the alkalies (Na_2O and K_2O) from the cement or other sources and certain mineral phases that may be present in the coarse or fine aggregates; under certain conditions, deleterious expansion and consequent cracking of the concrete or mortar may result [7].

C2. Nature of Reaction and Expansion Processes

The reaction starts when the alkaline hydroxides in the concrete fluid (Na–OH, K–OH) attack the surface of silica minerals in the aggregate. This results in an alkali silica gel and an alteration of the aggregate surface, known as "reaction rim." The resultant gel has a strong affinity for water and, consequently, a tendency to increase in volume. The expanding gel exerts an internal pressure that is sufficient to fracture the surrounding cement paste. Some of the softer gel can leach out through the voids and cracks, but expansion of the solid and semisolid products are more damaging. Figure 31.3 shows a damaged bridge structure due to the alkali–silica reaction, and Figure 31.4 shows expansion in a concrete median barrier due to the alkali–aggregate reactivity.

Table 31.1 gives a list of minerals and of rock types that have been found reactive in concrete structures. The information given in this table should, however, be used with care. For example, even if some greywackes and granites have been found to be reactive in certain parts of Canada, it does not mean that all greywackes and granites found in Canada are reactive or will react to the same degree. Petrographic analysis will generally help to identify and to determine the

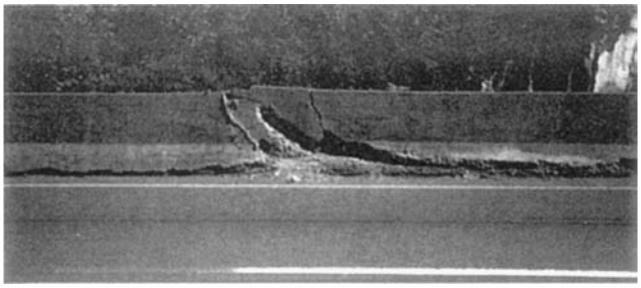

FIGURE 31.4. Cracking of a highway medium barrier caused by alkali–aggregate reactivity [8].

TABLE 31.1. Mineral Phases Susceptible to Deleterious Reactions with Alkalies in Cement and Corresponding Rocks[a]

	Alkali-Reactive Silica Minerals and Rocks
	B1.1 Alkali-Reactive Silica Minerals and Volcanic Glasses (Classical Alkali–Silica Reaction)
Reactants	Opal, tridymite, cristobalite; acid, intermediate, and basic volcanic glasses; artificial glasses; beekite
Rocks	Rock-types containing opal such as shales, sandstones, silicified carbonate rocks, some cherts and flints, diatomites
	Vitrophyric volcanic rocks; acid, intermediate and basic, such as rhyolites, dacites, latites, andesites, and their tuffs; perlites, obsidians; all varieties with a glassy goundmass; some basalts
	B1.2 Alkali-Reactive Quartz-Bearing Rocks
Reactants	Chalcedony, cryptocrystalline to microcrystalline and macrogranular quartz with deformed crystal lattice, rich in inclusions, intensively fractured or granulated; poorly crystalline quartz at grain boundaries
Rocks	Cherts, flints, vein quartz, quartzite, quartz-arenite, quartzitic sandstones that contain microcrystalline to cryptocrystalline quartz, and /or chalcedony
	Volcanic rocks such as in B1.1 (above) but with devitrified, crypto- to microcrystalline groundmass
	Micro- to macrogranular silicate rocks of various origin: Metamorphic rocks: gneisses, quartz-mica schists, quartzites, homfilses, phyllites, argillites, slates
	Igneous rocks: granites, granodiorites, charnockites
	Sedimentary rocks: sandstones, greywackes, siltstones, shales, siliceous limestones, arenites, arkoses
	Sedimentary rocks (sandstones) with epitaxic quartz cement overgrowth

[a]From Canadian Standards Association document CSA 23.1 Appendix B.

proportion of the various potentially reactive rock types in an aggregate sample from a quarried operation or a gravel deposit. However, this information alone will not permit the prediction of the magnitude of the reaction that may occur in the field.

C3. Conditions Conducive to Alkali–Aggregate Reactivity

The rate and extent of expansion due to alkali–aggregate reaction are affected by a large number of factors. These can generally be grouped as follows [8]:

(a) Inherent reactivity of the siliceous material
(b) Total alkali content of concrete
(c) Environmental considerations

C3.1. Inherent Reactivity of Siliceous Material. The nature, amount, and particle size of the siliceous phase within the rock particles play a major role on the actual rate of alkali–aggregate reaction in mortar or concrete. Poorly crystalline forms of silica such as opal and volcanic glass are very reactive because of the nature of their structure through which the alkali hydroxide ions (Na–OH and K–OH) can penetrate quickly. As little as 1% of such reactive components in an aggregate may lead to deleterious reaction and cracking and generally within 10 years of construction.

Quartz is one of the major constituents of the various rocks found in the earth's crust. Quartz has a well-organized three-dimensional crystalline structure that reacts at a much slower rate than opal and volcanic glasses. However, very small particles of quartz, because of their increased surface area, or larger particles, which have been subjected to stress in their geological history and consequently show defects in their crystalline structure, may be fairly reactive.

C3.2. Total Alkali Content of Concrete. The source of alkali for the alkali–aggregate reaction is generally considered to be derived from the Portland cement in concrete. Alkalies may also be contributed by aggregates, admixtures, supplementary cementing materials, and extraneous sources such as deicing salts and seawater. The amount of alkalies contributed by the cement for the alkali–aggregate reaction is calculated by adding the sodium oxide content to 0.658 times the potassium oxide content. The calculation provides the sodium oxide equivalent.

The minimum alkali content at which the alkali–aggregate reaction will occur will vary from one aggregate to another and the conditions to which the concrete is subjected. The alkali–aggregate reaction will generally not occur when the total alkali content is $<3\,kg/m^3$ of concrete. There may be special circumstances where one should consider alkali contents $<3\,kg/m^3$, such as where concrete is exposed to extraneous alkalies.

Generally, the higher the alkali content, the greater the expansion for a given cement content. In addition, for a given cement composition, finer grinds tend to provide a greater expansion; this may be explained by more complete hydration of the cement causing greater production of alkalies.

C3.3. Environmental Considerations. The progress of alkali–aggregate reaction is also largely influenced by the presence of accessible moisture in the pore space of the concrete, as reactions do not occur in the absence of moisture. Concrete deterioration due to alkali–aggregate reaction has often been observed to be more severe in the portions of structures subjected to cyclic conditions of wetting and drying and is accelerated at higher temperature. For example, in the southwestern Cape Province of South Africa, alkali–aggregate damage typically appears on field concrete structures after $\sim$ 4–7 years, whereas in Canada,

where the average annual temperature is much lower than in South Africa, the damage generally appears after ~ 15–20 years for a similar type of reactive greywacke aggregate. Expansion and rates of expansion are known to increase with increasing temperature and humidity conditions, but also in the presence of external alkalies such as deicing salts, seawater and seawater sprays.

C3.4. Preventive Measures Against Alkali–Aggregate Reactivity. The following are the most commonly used preventive measures against alkali–aggregate reactivity:

Use of nonreactive aggregate
Use of low-alkali cement
Limiting the alkali content of the concrete mixtures
Use of supplementary cementing materials

C4. Use of Nonreactive Aggregates

A simple solution to controlling the alkali–aggregate reactions would be to specify and use only nonreactive aggregates. However, the term nonreactive aggregate is a misnomer as most aggregates are reactive to a degree, depending on the exposure conditions and the alkali content of the concrete mixtures. Nevertheless, for very critical structures, such as offshore oil drilling platforms and nuclear reactors, the least reactive aggregate should be used. The past performance record of an aggregate in similar structures and environments as in the proposed structure can provide valuable data on the aggregate performance.

C5. Use of Low-Alkali Cement

Research and field experience have shown that the usage of cements with an alkali content (Na_2O equivalent) <0.6% will generally arrest alkali–aggregate reaction in many countries; however, the available raw materials may not be conducive to the production of cements with low-alkali contents. The alkali content of cements available in North America for normal construction purposes averages ~ 0.8% equivalent Na_2O.

C6. Limiting Alkali Content of Concrete Mixtures

Alkalies that are available for the alkali–aggregate reaction arise principally from the cement. Other sources of alkali may include aggregate, water, admixtures, and supplementary cementing materials. It is generally considered that for concrete made with potentially reactive aggregates the alkalies in the concrete should not exceed 3 kg/m^3. Critical structures such as dams and nuclear power plants may require even lower alkali contents, closer to 2.0–2.5 kg/m^3 of concrete.

C7. Use of Supplementary Cementing Materials

Laboratory and field test data available so far have shown that supplementary cementing materials such as fly ash and blast furnace slag, when used in the proper proportions, are efficient in reducing expansion of concrete incorporating reactive aggregates. As a precautionary measure, when there is a possibility that a potentially reactive aggregate may be used, concretes should be made incorporating ~ 20–30% of a fly ash. Any drop in early strength should be compensated for by reproportioning the concrete mixtures. Another approach is to use high-volume fly ash concrete [9].

Silica fume, a byproduct during the manufacture of silicon–boron steels in an arc furnace, is also being used in specific projects where high-strength impermeable concrete is desired. No well-documented data are yet available as to the long-term effectiveness of silica fume in reducing expansion due to alkali–aggregate reaction in concrete. Limited data have shown that, to be effective, one has to use between 10 and 15% silica fume by mass as a replacement for high-alkali Portland cement; however, this will depend on the degree of reactivity of the aggregate and the total alkali content of a concrete mixture.

D. DETERIORATION DUE TO SULFATE ATTACK

One of the major reasons of concrete deterioration is attack by sulfates. This type of chemical attack is widespread and has been reported from many countries in the world, including Canada, the United States, and the Middle East. The U.S. Bureau of Reclamation had cautioned civil engineers of the seriousness of this phenomenon in the early 1930s. The Bureau had emphasized that soluble sulfates in soils (>0.5%) could cause serious damage to concrete [10]. Figure 31.5 shows disintegration of a concrete element caused by sulfate attack.

FIGURE 31.5. Disintegration of concrete caused by sulfate attack [9].

D1. Mechanisms of Sulfate Attack

The sulfates of sodium, calcium, and magnesium present in alkali soils and water react chemically with hydrated lime and hydrated calcium aluminate in the cement paste (hydraulic binder) in concrete to form calcium sulfates and calcium sulfoaluminates respectively. These are expansive reactions and result in degradation of concrete. The chemical reactions involved are as follows [11]:

(A) *Sodium Sulfate Attacks (CaOH)$_2$*

$$Ca(OH)_2 + Na_2SO_4 \cdot 10H_2O \rightarrow CaSO_4 \cdot 2H_2O + 2NaOH + 8H_2O \cdot (\text{gypsum})$$

(B) *Sodium Sulfate Attacks Calcium Aluminate Hydrate*

$$2(3CaO \cdot Al_2O_3 \cdot 12H_2O + 3Na_2OSO_4 \cdot 10H_2O) \rightarrow 3C_2O \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 31H_2O + Al(OH)_3 + 6NaOH + 17H_2O$$

(C) *Calcium Sulfate Attacks Calcium Aluminate Hydrate*. Calcium sulfate attacks only aluminate hydrate forming calcium sulfoaluminate ($3\ CaO \cdot A1_2O_3 \cdot 3\ CaSO_4 \cdot 32\ H_2O$). This is known as ettringite and causes internal cracking of concrete.

(D) *Magnesium Sulfate Attacks Ca(OH)$_2$, Calcium Aluminate, and Calcium Silicate Hydrates.* The reaction with calcium silicate hydrate takes the form

$$3CaO \cdot 2SiO_2 \cdot (aq) + MgSO_4 \cdot 7H_2O \rightarrow CaSO_4 \cdot 2H_2O + Mg(OH)_2 + SiO_2 \cdot (aq)$$

The damage and expansion caused by the magnesium sulfate is more severe than by the calcium or sodium sulfates. Figure 31.5 shows concrete damaged by sulfate attack.

D2. Measures to Protect Against Sulfate Attack

D2.1. General Measures. The best protection against sulfate attack is to make concrete with very low permeability. This can be achieved by the use of low W/C ratio, use of supplementary cementing materials, and superplasticizers, adequate consolidation, and curing of concrete. When the concentration of sulfates is rather high, the use of sulfate-resisting cements can be very beneficial. The recommendations of Mehta and Monteiro [4] on the subject of control of sulfate attack are as follows:

Portland cement containing <5% C_3A (ASTM type V) is sufficiently sulfate resisting under moderate conditions of sulfate attack (i.e., when ettringite-forming reaction are the only consideration). However, when high-sulfate concentrations of the order of 1500 mg/L or more are involved, which are normally associated with the presence of magnesium and alkali cations, the ASTM type V Portland cement may not be effective against the cation exchange reactions involving gypsum formation, especially if the C_3S content of the cement is high. Under these conditions, experience shows that cements potentially containing little or no calcium hydroxide on hydration perform much better: For instance, high-alumina cements, Portland blast furnace slag cements with >70% slag, and Portland pozzolan cements with at least 25% pozzolan (natural pozzolan, calcined clay, or low-calcium fly ash).

The U.S. Bureau of Reclamation has classified severity of sulfate attacks in four degrees. Based upon this criterion, the American Concrete Institute Building Code 318 stipulates the following requirement for controlling the sulfate attack [4]:

1. *Negligible Attack*: When the sulfate content is <0.1% in soil, or < 150 ppm (mg/L) in water, there shall be no restriction on the cement type and W/C ratio
2. *Moderate Attack*: When the sulfate content is 0.1–0.2% in soil, or 150– 1500 ppm in water, ASTM type II Portland cement or Portland pozzolan or Portland slag cement shall be used, with <0.5 W/Cratio for normal-weight concrete.
3. *Severe Attack*: When the sulfate content is 0.2–2.0% in soil, or 1500–10,000 ppm in water, ASTM type V Portland cement, with < 0.45 W/C ratio, shall be used.
4. *Very Severe Attack*: When the sulfate content is > 2% in soil, or >10,000 ppm in water, ASTM type V cement plus a pozzolanic admixture shall be used, with <0.5 W/C ratio. For lightweight-aggregate concrete, the ACI Building Code specifies a minimum 28-day compressive strength of 28 MPa for severe or very severe sulfate attack conditions.

E. DETERIORATION OF CONCRETE IN SEAWATER

In recent years, the performance of concrete in seawater has become of great importance because of the construction of multi-billion-dollar offshore oil drilling platforms and other associated infrastructure. Most seawaters are characterized by the presence of ~ 3.5% soluble salts by weight. In general, the pH of seawater ranges from 7.5 to 8.4. The Mg^{2+} and SO_4^{2-} are present in concentrations of 1400 and 2700 mg/L, respectively, and are the most aggressive in their attack on the products of cement hydration. The concentration of Na^+ and Cl^- ions are ~ 11,000 and 20,000 mg/L.

TABLE 31.2. Decomposing Action of Seawater on Constituents of Hydrated Portland Cement[a]

Seawater Component That Can Enter into Deleterious Chemical Reactions with Hydrated Portland Cement	Possible Chemical Reactions	Physical Effects Associated with Chemical Reactions
Carbon Dioxide Small quantities of dissolved CO_2, derived mainly from absorption of atmospheric CO_2, always present in seawater. However, decaying vegetable matter can lead to substantially larger and harmful concentrations of dissolved CO_2, which are generally reflected by reduction of the seawater pH to values <8.	$CO_2 + Ca(OH)_2 \rightarrow \underset{\text{Aragonite}}{CaCO_3} + H_2O \xrightarrow{CO_2} \underset{\text{Bicarbonate of calcium}}{Ca(HCO_3)_2}$ $CO_2 + [Ca(OH)_2 + 3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 18H_2O] \rightarrow 3CaO \cdot Al_2O_3 \cdot CaCO_3 \cdot xH_2O + \underset{\text{Aragonite}}{CaSO_4 \cdot 2H_2O}$ $3CO_2 + 3CaO \cdot 2SiO_2 \cdot 3H_2O \rightarrow \underset{\text{Aragonite}}{3CaCO_3} + 2SiO_2 \cdot H_2O$	Both calcium bicarbonate and gypsum are soluble in seawater. Loss of material and weakening or mushiness of hardened cement paste can therefore be associated with the formation of these compounds. Since all the hydration products of Portland cement, including the calcium silicate hydrate, can be decomposed by carbonation reactions, permeable concretes in seawater containing larger than normal CO_2 concentration are likely to deteriorate.
Magnesium Salts Typically, seawater contains 3200 ppm $MgCl_2$ and 2200 ppm $MgSO_4$. Regarding cement hydration products, these magnesium salts, even in the small concentrations present, are considered harmful.	$MgCl_2 + Ca(OH)_2 \rightarrow \underset{\text{Brucite}}{Mg(OH)_2} + CaCl_2$ $MgSO_4 + Ca(OH)_2 \rightarrow Mg(OH)_2 + \underset{\text{Gypsum}}{CaSO_4 \cdot 2H_2O}$ $MgSO_4 + [Ca(OH)_2 + 3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 18H_2O] \rightarrow Mg(OH)_2 + 3CaO \cdot Al_2O_3 \cdot \underset{\text{Ettringite}}{3CaSO_4} \cdot 32H_2O$ $MgSO_4 + [Ca(OH)_2 + 3CaO \cdot 2SiO_2 \cdot 3H_2O] \rightarrow 4MgO \cdot SiO_2 \cdot 8H_2O + CaSO_4 \cdot 2H_2O$	$CaCl_2$ and gypsum, being soluble in seawater, lead to material loss and weakening. Formation of ettringite is associated with expansion and cracking. It is reported that the conversion of $3\,CaO \cdot 2\,SiO_2 \cdot 3\,H_2O$ to $4\,MgO \cdot SiO_2 \cdot 8\,H_2O$ is associated with brittleness and strength loss.

[a]From [12].

The decomposing action of seawater on the constituents of hydrated Portland cement as given by Mehta [12] is reproduced in Table 31.2. Figure 31.6 shows the physical and chemical processes responsible for deterioration of reinforced concrete element exposed to seawater.

The presence of large amounts of sulfates in seawater may lead one to consider the possibility of sulfate attack. This is not so because the ettringite formed because of the reaction between sulfate ions and both C_3A and C–S–H is soluble in the presence of chlorides and is leached out and thus does not cause deleterious expansions. This explains why the use of sulfate-resisting cement in concrete exposed to marine environment is not warranted [11].

E1. Requirements of Concrete for Marine Exposure

The selection of concrete for marine exposure must have the lowest possible W/C or water/cementitious ratio to ensure very low permeability. Where possible, the supplementary cementing materials such as fly ash or slag or silica fume and chemical admixture such as superplasticizers should be incorporated in mixture proportioning. The use of sulfate-resisting cement is not essential for concrete exposed to seawater, but the Portland cement should have C_3A content of <8%, when SO_3 content of the cement is < 3%; cements with C_3A contents of up to 10% may be used where the SO_3 content does not exceed 2.5 [10]. Figure 31.7 shows the concrete test specimens at Treat Island (Maine), an outdoor exposure site for determining the long-term performance of concrete exposed to seawater. The concrete blocks cast from well-proportioned concrete are in excellent condition even after 20 years of severe exposure to seawater. Figure 31.8 shows the recently constructed \$1 billion Confederation Bridge in eastern Canada. The bridge is about 14 km in length and connects the province of New Brunswick with the province of Prince Edward Island. The prestressed concrete structure is exposed to severe seawater attack and is subject to >100 freezing and thawing cycles a year. The bridge has a design life of 100 years. The high-performance, air-entrained concrete for the bridge was made using silica fume blended cement and incorporates up to 30% fly ash in parts of the foundation elements and piers. Hopefully, the bridge will not suffer major deterioration during its design life.

F. CARBONATION OF CONCRETE

The term carbonation refers to the reaction of atmospheric carbon dioxide with cement hydrates in concrete. This reaction can have serious implications as regards to durability of reinforced concrete if the concrete is not properly made. The various aspects of carbonation including its mechanism, its rate, and the various factors that influence it are discussed below.

F1. Mechanism of Carbonation

The concentration of CO_2 can vary from 300 ppm (parts per million by volume), that is, 0.03% in nonindustrialized areas to ∼3000 ppm, that is, 0.3% by volume in large cities. The CO_2, even in small concentration, may penetrate into poorly made concrete with high W/C ratio. This is accompanied by the reaction with the cement hydrates, particularly with calcium hydroxide, $Ca(OH)_2$, resulting in the formation of calcium carbonate. The reaction with other hydrates can also take place with the resulting production of silica, alumina, and ferric oxide.

The carbonation of concrete reduces the pH of the pore water in the hydrated cement paste from ∼13 to a value approaching ∼9. If all the calcium hydroxide is carbonated (this can take many years), the pH of the hydrated paste can

reach as low as 8.3. When this happens, the durability of Portland cement is compromised in a manner described below.

In reinforced concrete, the steel reinforcement is surrounded by an alkaline environment (pH 13). Under these conditions, a submicroscopic thin oxide film of ferrous oxide is formed on the steel that renders it passive; that is, it gives the steel complete protection from reaction with oxygen and water. The maintenance of the passivity of the steel is dependent on the availability of the high pH pore water solution surrounding the passive layer of ferrous oxide. When the pH of the pore water of the hydrated paste is reduced because of the carbonation, and when this low-pH solution approaches the surface of the steel reinforcement, the passive oxide film is destroyed. The steel reinforcement is then open to corrosion subject to the availability of moisture and oxygen. Thus, though the carbonation per se does not attack reinforcing steel, it contributes considerably to creating an environment in which corrosion of steel reinforcement can take place.

F2. Factors Affecting Carbonation

The most significant factor affecting carbonation of concrete is the diffusivity of the hardened cement paste in concrete. This, in turn, depends on the composition of concrete, its W/C ratio, and the type of cement used and its curing. All these factors have to be taken into account when investigating the rate of carbonation. Several researchers used the compressive strength of concrete as a parameter for determining the carbonation, primarily because this is a parameter that can be determined easily.

F3. Rate of Carbonation

A most commonly used relationship between depth of carbonation and time depth is as follows [13]:

$$d = k\sqrt{t}$$

where d = depth of carbonation in millimeters (mm)
t = time of exposure in years
k = coefficient of carbonation in millimeters per $\sqrt{\text{year}}$ (mm/year$^{0.5}$)

The values of k can range from <1 for low W/C ratio concrete to >5 for high W/C ratio concrete.

F4. Carbonation of Concrete-Containing Supplementary Cementing Materials

The environmental issues and energy considerations have led to increased use of supplementary cementing materials (SCMs) concrete. These include fly ash, blast furnace slag, and silica fume. The hydrated cement paste in the concrete incorporating supplementary cementing materials contains lower amounts of $Ca(OH)_2$ because some of it is taken up by reaction with the silica from the supplementary cementing materials. This implies that a relatively smaller amount of CO_2 is required to remove all of the $Ca(OH)_2$. But this is offset by the fact that the use of SCMs results in a denser microstructure of the hardened paste, resulting in reduced permeability. Provided the concrete incorporating SCMs is properly proportioned and adequately cured, carbonation is not an issue.

F5. Measures to Prevent Carbonation

Deterioration of concrete as it relates to carbonation effects is not a serious problem provided that concrete is properly proportioned, has low W/C ratio, and is properly consolidated and adequately cured. In such concrete the depth of carbonation is unlikely to exceed 15–20 mm over a period of 50 years. Thus, concrete cover of 35–50 mm over reinforcing steel should provide sufficient protection against corrosion due to carbonation.

G. CONCLUDING REMARKS

Good-quality concrete that is proportioned properly, is transported and consolidated correctly, is cured adequately, incorporates supplementary cementing materials, and has a low W/C ratio need not deteriorate provided the environment for which it has been designed does not change drastically. Unfortunately, unlike steel, a factory-made product, concrete is normally made at a construction site, and it does deteriorate because all the above requirements are not generally followed. When this happens, concrete cracks giving oxygen and water access to the reinforcing steel results in corrosion of the reinforcing bars and damage to the reinforced concrete structure. As cracking of concrete is very difficult to control, the only alternative then to stop deterioration of reinforced concrete is to use reinforcing bars that do not corrode. No such products are yet available on the market at a reasonable cost. It is therefore imperative that major research efforts be initiated to develop low-cost stainless steel reinforcement or other composite reinforcing materials that have very low tendency for corrosion.

A. INTRODUCTION

Concrete is one of the most widely used materials in construction and has applications in most modern infrastructure, including highways, bridges, and tunnels, and transport of drinking and wastewater, with an approximate consumption rate of 6 billion tons per year. An understanding of the physical performance of concrete materials is vital in order to assess their durability in service under natural conditions. Corrosion or deterioration of concrete has important economic consequences, especially when replacement or repair of infrastructures, such as bridges or municipal sewer systems, is involved [1–8]. However, concrete corrosion is a complex phenomenon involving chemical, physicochemical, electrochemical, and biological processes. Microorganisms have long been implicated in the corrosion of concrete [9–14], but their involvement is probably the least understood among all the processes indicated above. Bacteria in the genus *Thiobacillus* were initially identified as the major culprits through biologically produced sulfuric acid. Other groups of microorganisms involved in the corrosion process have also been implicated, including nitric acid–producing bacteria [15–17], fungi [6, 11], and exopolymer-producing bacteria [2, 11, 18]. Macroscopic fouling organisms also participate in degradation of concrete in submerged structures, but no detailed studies have been reported [19, 20].

Protection against biologically induced corrosion involves modification of the local environment. Corrosion of sewer pipes has been controlled by aeration of stagnant wastewater to decrease the concentrations of H_2S and/or to inhibit populations of sulfate-reducing bacteria (SRB) through addition of specific metal ions, including iron (Fe) compounds [21]. A new generation of technologies using fiber-reinforced resin sheets [22] to coat concrete and addition of polymers [23–25] offer some advantages over conventional methods by providing a physical barrier. However, in addition to concern over cost of these new technologies, polymeric resin–coated concrete was reported to be susceptible to microbial deterioration during exposure in sewer

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

systems [26]. Furthermore, microbial degradation of polymeric materials has been reported [12, 27–32]. Fiber-sizing chemicals and plasticizers and the small quantities of organic residues present in composite resins [12, 27, 31, 33–35] can support the active growth of natural populations of microorganisms, including bacteria and fungi [28, 29, 36–38] (also see related chapter 30 in this book). In addition, Slow-growing bacteria cause much greater damage to polymers than the fast-growing ones [35], suggesting that current test methods that focus on fast-growing microbial populations may underestimate the extent of degradation.

B. A BRIEF HISTORY

Corrosion of concrete sewer pipes by hydrogen sulfide, an anaerobic product of sulfur-containing organic compounds and reduction of SO_4^{2-} during microbial metabolism, was identified as the cause of corrosion in 1900 by Olmstead and Hamlin [39]. The corrosion reaction was initially regarded as a purely chemical process [40] in which hydrogen sulfide produced under anaerobic conditions in wastewater is oxidized chemically to sulfuric acid in the presence of molecular oxygen [41]. The sulfuric acid then reacts with calcium in concrete to form $CaSO_4$ or gypsum. Parker and his coworkers established the relationship between acidophilic thiobacilli and concrete degradation by isolating *Thiobacillus concretivorus* (renamed *Thiobacillus thiooxidans*) and another *Thiobacillus* species from corroded concrete (*T. neaopolitanus*) [9, 10, 42–47]. The extent of corrosion correlates positively with the population of these microorganisms, providing sound evidence for their role in the corrosion process.

In the early 1980s, rapid deterioration of newly replaced sewer systems in Hamburg, Germany, renewed the scientific interest in these corrosion processes [8, 26]. In these investigations, positive correlations were observed again between the extent of concrete corrosion and the numbers of *T. thiooxidans*. Sand also observed that *Thiobacillus ferrooxidans* was associated with oxidative activity of H_2S [48]. In the presence of sodium thiosulfate, dominant microorganisms were *Thiobacillus neaopolitanus*, *Thiobacillus intermedius*, and *Thiobacillus novellus*, whereas mercaptan, a S-containing compound, did not support any population of thiobacilli, but heterotrophic bacteria and fungi were commonly found.

Biological corrosion of sewer pipes can be a serious problem in coastal cities due to the high abundance of SO_4^{2-} in the wastewater. At the time of the Hamburg failure, coastal U.S. cities faced similar problems with newly installed concrete sewer systems, especially the city of Los Angeles [7]. A reason for the reemergence of the problem was the advent of the National Pollution Discharge Elimination Systems (NPDES) in 1972, which banned discharge of toxic metals and chemicals into sewers. As a result of this legislation, inorganic and organic toxic wastes are no longer permitted to be discharged directly to sewers, with a resultant increased activity of microorganisms, particularly the SRBs, producing large quantities of H_2S [49–52]. In addition to the sewers, concrete corrosion problems today involve highway bridges, aquaducts, water distribution systems for drinking and wastewater, historic buildings and monuments [53–56], river hydropower dams [57], and nuclear depositories [58, 59] where corrosion rates are unacceptably high. The recognized failure of highways and bridges recently in developed countries has renewed the discussion on concrete corrosion and protection [60, 61].

C. CONTRIBUTIONS BY AIR POLLUTION

Corrosion of concrete is not always caused by microorganisms. Air pollution from industralization and other exhaust systems contributes directly and indirectly to the deterioration of highways and bridges and inorganic building materials such as stone [53, 62, 63], quartz [64, 65], marble [66], mortar, and even glass [67, 68]. Emission of oxides of sulfur and nitrogen contributes to acid rain [69, 70], which dissolves surface materials of concrete, stone, cement, and glass with noticeable effects. Analyses showed that 60–70% of acidic precipitation is due to sulfuric acid, 30–40% to nitric acid, and approximately 5% to hydrochloric acid [71].

Microorganisms participate actively in the degradation process by utilization of atmospheric deposits as nutrient sources for their growth [72, 73]. The predominant groups of microorganisms are those capable of sulfur oxidation [48, 74], nitrification of nitrogen oxides [15, 16, 66, 75–77], and ammonia oxidation [78]. Organic acids, particularly from fungi, are suspected to contribute to concrete corrosion [3, 30]. At the same time, bacterial exopolysaccharides are of equal importance in corrosion [30, 78–80]. Chemical and biological processes interact, resulting in the corrosion of materials [4, 81]. However, a systematic approach integrating the role of both acid deposition and microbial activity to the degradation of inorganic materials has not been attempted in the literature. Data describing stone degradation in the presence of various natural microbial populations are available [13, 24, 25, 82–87]. Pollutants in the air may become a source of microbial substrates in the form of not only sulfurous and nitrogenous oxides but also hydrocarbons and other sulfur- and nitrogen-containing compounds [72].

D. MICROBIAL PROCESSES

The role that microorganisms play in concrete corrosion is linked primarily to the sulfur and/or nitrogen cycle in which biogenically produced inorganic acids, SO_4^{2-} and NO_3^{-},

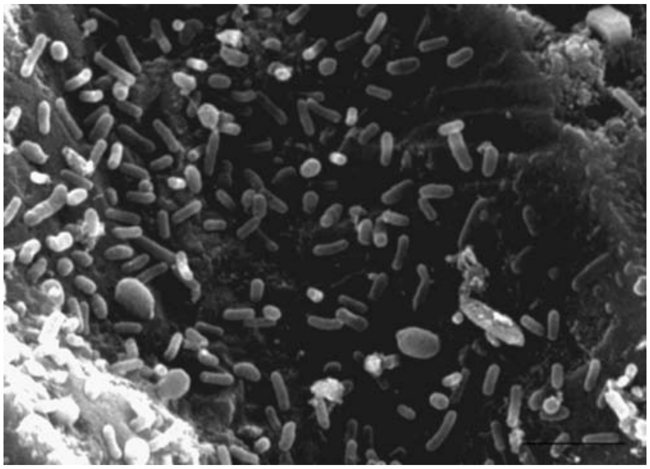

FIGURE 32.1. Scanning electron micrograph of biofilm consisting of *Thiobacillus intermedius* on surfaces of concrete after exposure under laboratory condition for 120 days (scale bar, 5 μm).

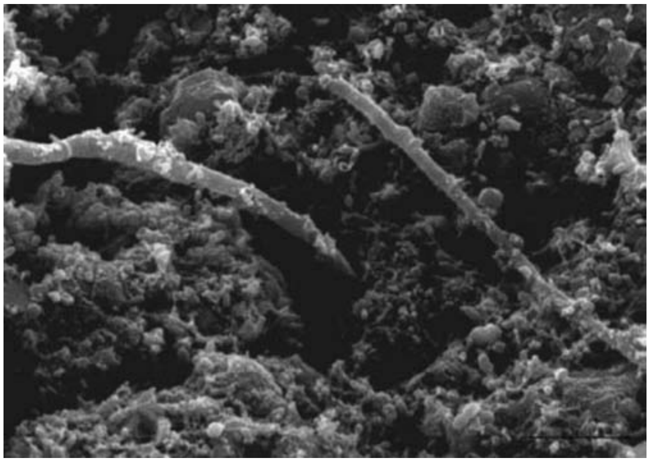

FIGURE 32.2. Scanning electron micrograph of a mixed biofilm containing the fungus *Fusarium* species and bacteria before isolation of the *Fusarium* species (scale bar, 10 μm).

are the result of microbial metabolism. In these processes, sulfate reduction and then oxidation and ammonia oxidation and nitrification are the key reactions involved. Nitrifying bacteria have only recently been reported to facilitate the degradation of concrete and building materials under natural conditions [88–90]. Furthermore, fungi also attack concrete at rates comparable to those by sulfur-oxidizing bacteria [11, 84], but no information is available on the contribution of ammonia-oxidizing archaea to corrosion.

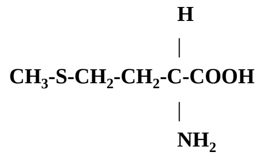
Microorganisms are known to form biofilms and produce exopolysaccharides which are also of importance in the corrosion of concrete (Fig. 32.1), specifically through complexation by organic acids and acidic functional groups of the exopolymeric materials. Microbial activity on surfaces and their metabolites affects the susbtratum materials. Degradation and deterioration of materials often occur in the presence of SRBs, sulfur-oxidizing bacteria [91], acid-producing bacteria [92], fungi [11], and microbial exopolymers [4, 78, 79, 81, 93]. Thiobacilli have long been implicated as the culprit for such destruction of concrete materials [1, 26, 57]. For example, *T. intermedius* forms thick biofilms and is capable of etching concrete. The organic acids or multifunctionality molecules may serve as chelating agents, dissolving surface Ca^{2+} into solution. A *Fusarium* species was found to corrode concrete, and the fungal hyphae penetrated into concrete matrices [11] (Fig. 32.2). The mechanism is most likely due to organic metabolites produced by the fungus that form complexes with Ca in the concrete matrix. Milde et al. suggested that a succession of different thiobacilli that are metabolically active under neutral and acidic conditions are responsible for the complete degradation of concrete in natural systems [26]. Similar results were also reported [94]. Other groups of microorganisms have also been implicated for their role in the biodeterioration of granite and limestone, including lichens [95] and cyanobacteria [96, 97].

D1. Sulfate in Natural Environments

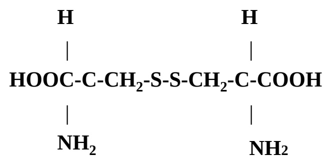
Sulfur exists in various oxidative states from $+6$ in SO_4^{2-} to -2 in H_2S (Table 32.1) and is an essential element for all living cells. Living orgamisms contain approximately 1% S in various proteins. Examples of amino acids containing S are methionine, cystine, and cysteine (Fig. 32.3). Living cells contain these amino acids, which decompose upon death of the organisms. Among the different states of S-containing compounds, including the mercaptan family, hydrogen sulfide is the most noticeable because of the nuisance odor at a concentration as low as 0.2 ppm. Under natural conditions sulfate is widely present in aquatic and marine environments, wastewater treatment facilities, and sewers. The largest reservoir is seawater. Hydrogen sulfide is chemically reactive and the characteristic black color

TABLE 32.1. Oxidation States of Sulfur-Containing Compounds

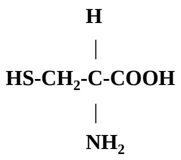
Form	Formula	Oxidative State (S)
Sulfate	SO_4^{2-}	$+6$
Sulfite	SO_3^{2-}	$+4$
Thiosulfate	$S_2O_3^{2-}$(—S—SO_3^-)	$-2, +6$
Tetrathionate	$S_4O_6^{2-}$	$+2.5$
Thiocyanide	S—C—N^-	-2
Trithionate	$-O_3SSSO_3$—	$+6, +2, +6$
Elemental S	S^0	0
Disulfite	HS^-	-2
Sulfide	S^{2-}	-2



Methionine



Cystine



Cysteine

in sediments is due to the formation of FeS in anoxic zones [98, 99].

Reduction of sulfate in marine environments by SRBs causes serious corrosion problems for shipping, oil-drilling platforms, and other coastal and offshore infrastructures. In addition, production of hydrogen sulfide has a detrimental effect on marine life [100].

D2. Sulfate-Reducing Bacteria

Production of H_2S from SO_4^{2-} in wastewater systems was recognized in 1864 by Meyer [68], who proposed that the reaction was mediated by algae. A few years later, Cohn claimed that the filamentous gliding microorganism *Beggiatoa* was responsible for the reduction of SO_4^{2-} in wastewater to H_2S. In 1895 Beijerinck demonstrated definitively the process of microbial S reduction by isolating *Vibrio desulfuricans* in pure culture (later renamed *Desulfovibrio desulfuricans*). The genus name *Desulfovibrio* is reserved for non-spore-forming sulfate reducers, usually with a curved, motile rod and a limited capability to utilize carbon. Preferred substrates include lactate and pyruvate. Microorganisms in this group also include some species which utilize recalcitrant hydrocarbons.

Other microorganisms capable of sulfate reduction include *Desulfovibrio, Desulfobulbus, Desulfomonas, Desulfobacter, Desulfococcus, Desulfonema, Desulfosarcina, Desulfobacterium, Desulfotomaculum,* and *Thermodesulfobacterium* [51]. *Desulfotomaculum* is the only spore-forming genus of SRB. These SRBs carry out dissimilatary processes during sulfate reduction in which S from SO_4^{2-} is a source of electrons and energy for microbial growth rather than being assimilated into the cells. At the same time, organic compounds are oxidized.

Sulfate-reducing bacteria are widespread in natural and polluted environments. They are strictly anaerobic microorganisms, and molecular O_2 is toxic to them. Special culturing techniques and laboratory equipment are required for isolation and handling of these bacteria [101]. Their growth covers a wide spectrum of environmental conditions, ranging from psychrophilic (4°C) to extremely thermophilic (90°C and higher). SRBs are found not only in wastewater but also in oil fields, nuclear power plants, and biofilms on surfaces of a wide range of materials. Ecologically, SRBs are important microorganisms scavenging molecular hydrogen produced by anaerobic fermentation because interspecies H_2 transfer is thermodynamically vital to the anaerobic microbial community, as the process essentially removes an inhibitory metabolite (H_2) [102, 103].

D3. Sulfur-Oxidizing Bacteria

As early as 1887, Winogradsky demonstrated that certain groups of bacteria are capable of obtaining their energy for growth from oxidizing S^0 to SO_4^{2-} [104]. The biologically catalyzed reactions are as follows:

$$2H_2S + O_2 \rightarrow S_2 + 2H_2O + 80\ \text{kcal}\ (= 334.4\ \text{kJ}) \quad (32.1)$$

$$S_2 + 3O_2 + 2H_2O \rightarrow 2H_2SO_4 + 240\ \text{kcal}\ (= 1003.2\ \text{kJ}) \quad (32.2)$$

The microorganisms belong to a group called chemoautotrophs, utilizing CO_2 for carbon and S as a source of electrons. There are eight species in the genus *Thiobacillus*. They differ in their ability to tolerate acidity. *Thiobacillus thiooxidans* and *T. ferrooxidans* are capable of functioning at pH levels as low as 2–3.5, while *Thiobacillus thiopurus* and *Thiobacillus denitrificans* prefer slight acidity for optimal growth. *Thiobacillus ferrooxidans* and *T. thiooxidans* are particularly important for their role in leaching of mining ores.

All thiobacilli are obligate autotrophs except *T. novellus*. Although the heterotrophic bacteria *Arthrobacter*, *Micrococcus*, *Pseudomonas*, and *Bacillus*, in addition to some actinomycetes and fungi, can oxidize sulfur compounds, no energy is derived from these transformations [105].

D4. Ammonia-Oxidizing Microorganisms

In the 1870s, Pasteur postulated that oxidation of NH_4^+ to NO_3^- was a microbiological process. The first experimental evidence was presented by Schloesing and Muntz in 1877. Subsequently, Warrington at the Rothamsted Experimental Station in England claimed that the nitrification process was a two-step transformation. Winogradsky then isolated

TABLE 32.2. Chemoautotrophic Nitrogen Oxidizers

Genus	Species	Habitats
Nitrosomonas	*europaea*	Soil, water, sewage
Nitrosospira	*briensis*	Soil
Nitrosococcus	*nitrosus*	Marine
	oceanus	Marine
	mobilis	Soil
Nitrosovibrio	*tenuis*	Soil

	(*agilis*)	Soil, water
Nitrospira	*gracilis*	Marine
Nitrococcus	*mobilis*	Marine
	marina	Marine

nitrifying bacteria in pure culture; however, the purity of his cultures is still debatable [75, 106].

Nitrifying bacteria are chemoautotrophs (Table 32.2). They obtain carbon from CO_2 or carbonate and energy from oxidation of NH_4^+ or NO_2^-. During the processes of nitrification, NH_4^+ is converted to hydroxylamine (NH_2OH) by an endothermic reaction. The next reactant has not been identified but is hypothesized to be a nitroxyl radical. The NO_3^- is proposed to react with this radical to form nitrohydroxylamine before breaking down to HNO_2. Transformation of HNO_2 to NO_3^- requires the presence of oxygen, but the role of O_2 is confined to electron transport [107]. The oxygen in NO_3^- is actually from H_2O. The overall reaction produces energy for growth resulting in a free energy change of -65 and -18.2 kcal/mol for oxidation of 1 mol of NH_4^+ and NO_2^-, respectively according to the following equations:

$$NH_4^+ + 1.5O_2 \rightarrow NO_2^- + H_2O + 2H^+ + 76\,\text{kcal}\ (= 317.7\,\text{kJ}) \tag{32.3}$$

$$NO_2^- + 0.5O_2 \rightarrow NO_3^- + 24\,\text{kcal}\ (= 100.3\,\text{kJ}) \tag{32.4}$$

In addition to chemoautotrophic metabolism, heterotrophs are capable, to a lesser extent, of carrying out nitrification. However, the process does not appear to be ecologically significant.

Bock and Sand [108] found that the nitrifying bacteria play an important role in the degradation of concrete as a result of nitric acid production during nitrification [15]. Nitrifying bacteria were also found to be the predominant contributors to the deterioration of other stone materials [91, 109, 110]. These bacteria differ from the thiobacilli in that the former are capable of growth on nonimmersed surfaces such as buildings, while the latter require an aqueous environment in the presence of sulfate.

More recently, ammonia-oxidizing archaea have been widely detected in environmental samples [78]. This discovery changes our traditional view that bacteria are responsible for the transformation of NH_4^+ available in the environment. However, the limited information currently available also demonstrates some weaknesses in the molecular-based techniques used for detecting this group of archaea. In situ activity of the archaea has not been fully established even though they are widely detected in environmental samples at high abundance.

D5. Role of Fungi

This is a new twist in the deterioration of concrete because fungi differ from bacteria taxonomically and are eukaryotes while bacteria are unicellular prokaryotes. Fungi are well known for their metabolic versatility and are capable of attacking a wide range of organics, including engineered polymeric materials [12, 31, 32]. They are also notorious for their secondary metabolites, the mycotoxins [111]. One of the reactions carried out by fungi is the production of peroxide through peroxidase. This enzyme enables fungi to attack complex organics, including polyaromatics and chlorinated aromatics [112]. In comparison, very little information is available on the role of fungi in the degradation of inorganic materials, particularly stone and concrete. A *Fusarium* species has been isolated that is capable of attacking concrete [3, 11]. The fungus and *T. intermedius* caused almost identical weight loss after 120 days of incubation [11].

Several possible mechanisms of fungal attack of concrete exist. Fungi are known for their production of organic acids, including citric, oxalic, and gluconic acids [85, 86, 113, 114], which react with calcium in the concrete, leading to subsequent dissolution and degradation. They are also physiologically capable of etching the material and extending their hyphae into the interior of the concrete, resulting in enlargement of the damaged area and an increase in porosity. Both bacteria and fungi may form synergistic associations in concrete degradation (Fig. 32.4), and this may be

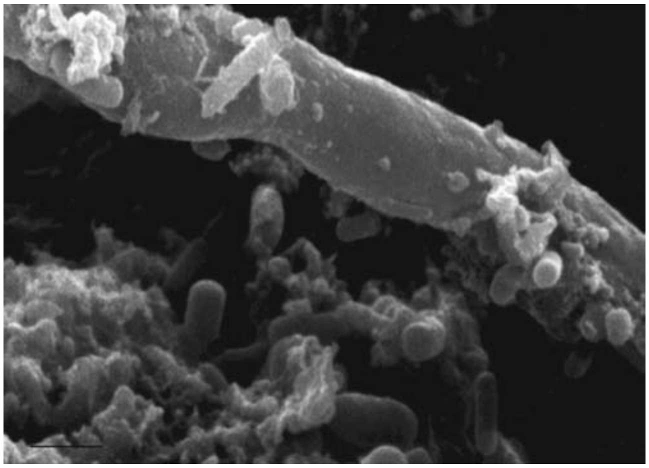

FIGURE 32.4. Scanning electron micrograph of *Fusarium* species hypha with bacteria attached (scale bar, 2 μm).

most pronounced under natural conditions where pure cultures of microorganisms are impossible. Studies of concrete weight loss indicated that precipitates formed with organic acids were responsible for the measured changes in weight. These precipitates, which easily detach, are usually calcium–organic complexes. Fungal activity occurs over a wide range of environmental conditions. Therefore the damage caused by these organisms may be much larger than expected.

D6. Microbial Exopolymers

Microorganisms produce large quantities of exopolymeric materials in late growth phases and/or environments with high carbon/nitrogen (C/N) ratios or during adhesion to and growth on surfaces (Fig. 32.5). These polymeric materials are important carbon and energy reserves and are utilized during periods of nutrient deficiency. Bacterial exopolymeric materials also play an important role in the formation of microbial biofilms [94], subsequent corrosion of metals, and transport of metal ions in porous media [4, 78–81, 115]. They are multifunctional group molecules [93, 116]. The activity of these molecules and their functional groups in chelation and dissolution of calcium from concrete is still poorly understood. Ford and Mitchell [115] and Geesey et al. [117] proposed that bacterial exopolymers bind metals and promote formation of ionic concentration cells, accelerating dissolution and corrosion of metallic materials. Similarly, negatively charged carboxylic and hydroxyl groups of exopolymeric materials from thiobacilli may form complexes with calcium and hence leach the calcium from concrete matrices. This process may contribute to concrete degradation, particularly when biofilms grow in close proximity to the surface. Further research is needed to identifiy a possible role for these exopolymers in concrete degradation.

E. CORROSION OF REBAR

Concrete is formulated for different purposes using steel reinforcement. Reinforcement of concrete with steel bars may increase susceptibility to corrosion because of the growth of SRBs and the resultant production of H_2S, which can penenatre into concrete. The corrosion products from both metals and also concrete constituents may expand in volume, generating stress for the surrounding concrete materials and resulting in formation of cracks [118, 119]. In such situations, both biological and physicochemical processes act in concert. Preventive measures involve the use of polymers to prevent moisture reaching the steel-reinforcing bars and incorporation of biocides. Microbial activity is significantly reduced at low moisture levels [37].

Hydrogen-producing bacteria may also contribute to the stress cracking of high-strength steel. Ford and Mitchell [92] reported that bacteria were found in the cracking areas of a high-strength steel bar under loaded conditions. Cracks did not develop in the absence of hydrogen- and acid-producing bacteria (sterile controls), suggesting that bacterial metabolites could contribute to a significant weakening in the strength of steel rebars due in part to permeation of microbially produced hydrogen into steel [120]. Protection of concrete structures is a significant challenge for both engineers and applied microbiologists because of the multiple applications of reinforced concrete under a variety of different environments (Fig. 32.6).

FIGURE 32.7. Photograph of an open aquaduct structure under construction for drinking water transport from mainland China to Hong Kong.

F. PREVENTIVE MEASURES

Protection of concrete from biological corrosion has been impeded because of the difficulty in eradicating microorganisms from the materials when the structures are part of the environment and compeletely exposed (Fig. 32.7). In a study conducted by Sand et al. [17], oxygenation of sewer systems was proposed as a means of alleviating the propagation of SRBs in wastewater systems and slowing the subsequent degradation of concrete. Numerous other approaches have been investigated, including precipitation of microbially produced H_2S by ferrous chloride ($FeCl_2$) [21], competition by heterotrophs for displacement of *Thiobacillus* [121], and the use of microbial biocides [122, 123]. However, none of these preventive measures has proven to be successful due to the incomplete understanding of the microbial community under natural conditions [6] and also the plasticity of microorganisms in adapting themselves to the changing environment both physiologically and genetically [124–126].

G. CONCLUSIONS

It is apparent that the microbiology and ecology of concrete corrosion processes are not well understood. Current information on microbial corrosion of concrete is limited to the microorganisms that have been successfully isolated in pure culture from natural environments, particularly *Thiobacillus* species and the nitrifying bacteria. The role of other microorganisms, for example, fungi, acetogenic bacteria, and ammonia-oxidizing archaea, in concrete degradation needs further investigation to improve our knowledge. Fungi are capable of deterioration of concrete, but the synergistic association between bacteria and fungi has not been fully established. Culture-independent molecular techniques start to show the metabolic diversity of the natural community on concrete and should be utilized in future studies to confirm the specific groups of microorganisms involved in the degradation process. Furthermore, dissolution products from such exposure experiments need to be thoroughly characterized to establish the chemical reactions that are taking place. The roles of many uncultured bacteria shown through molecular biology to be present on deteriorating concrete have yet to be understood.

ACKNOWLEDGMENTS

We thank Ed Seling of the Museum of Comparative Zoology, Harvard University, for taking the scanning electron micrographs used here in Figures 32.1, 32.2, 32.4, and 32.5 and Jessie Lai for assistance in organizing and archiving documents.

A. INTRODUCTION

Before discussing microbial degradation, it should be noted that, in the absence of any one of the critical requirements for decay (described later in this chapter), wood is a remarkably stable material. Some of the longest lived of all organisms are the bristlecone pines of California and these can be >4700 years old. There are numerous examples of temples in Japan with wood components that have remained intact for hundreds of years because they have been kept dry. Treatment of wood with preservatives can extend the service life of wood products for many decades, and this subject is covered in detail in Chapter 34.

It should also be recognized that microbial degradation is only one facet of biodegradation of wood. Biodegradation of wood in terrestrial environments can be caused by a range of microorganisms and insects. In marine environments, there are crustacea and molluscs that will also attack wood. This chapter will focus on microbial degradation of wood in terrestrial environments for a variety of reasons. Damage caused by insects, crustaceans, and molluscs is more readily identifiable with the naked eye than microbial degradation and quite unrelated to corrosion. It typically takes the form of tunneling by biting or abrasion. In contrast, microbial degradation occurs at the microscopic level and is mediated by enzymes and nonenzymic free-radical generation systems, through processes that are more analogous to the corrosion of other materials. Furthermore, while insects, specifically termites and beetles, cause the most damage to wood products in tropical and subtropical regions, microbial degradation is more economically important in temperate climates.

To begin to understand microbial degradation of wood, it is first necessary to understand something about the structure and chemical makeup of wood. The critical requirements for decay will then be detailed and the microorganisms involved will be categorized. The diagnosis of decay types will be covered in some detail and procedures for the elimination of fungal infection will be outlined. Finally, the effects of wood decay on corrosion of metals will be briefly discussed.

B. STRUCTURE AND CHEMISTRY OF WOOD

The structure of wood is related to its functions in supporting the crown of the tree, transporting water from the roots to the crown and storage of food reserves. Wood is a cellular material and most of the water-conducting cells (tracheids and, in hardwoods, vessels) are aligned vertically in the tree (Fig. 33.1), longitudinally in lumber, and in various orientations in an engineered wood products made from veneers, strands, or chips. The cells are connected by pathways

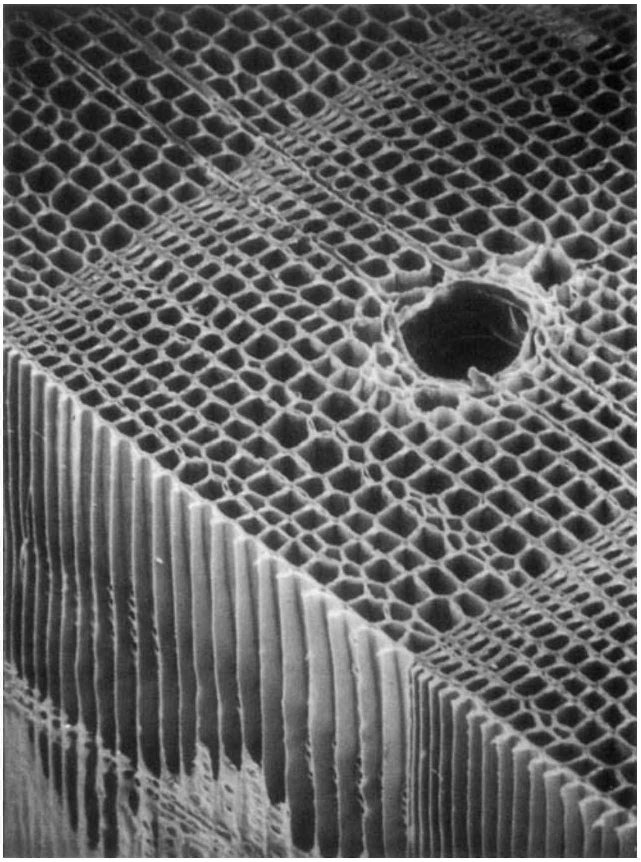

FIGURE 33.1. Scanning electron micrograph of a softwood showing cellular structure (×100 approx.)

through the cell walls that allow for the longitudinal and lateral movement of water. These pathways can also allow the passage of microorganisms from cell to cell. In addition to the longitudinally aligned cells, there are bundles of cells arranged in radial orientation (rays) that conduct soluble materials from the outer to the inner parts of the tree and vice versa. Some of these ray cells are also specialized for storage of food reserves to be used for future growth. The walls of all the cells are constructed from the same basic materials.

Wood cell walls are made up of two major chemical components and many minor ones. The major components are cellulose and lignin, which in combination are referred to as lignocellulose. Cellulose is a long-chain polymer of glucose units and provides the strength properties of wood. Lignin is a three-dimensional resin made up of a range of aromatic monomers. Cellulose chains are aligned into bundles, with crystalline and noncrystalline regions, laid down in a spiral around the walls of each cell. Each cell wall has several layers with a different orientation of the cellulose, resulting in cross-banding. Lignin permeates the entire cell wall but the cellulose–lignin ratio varies between layers. Hemicelluloses, composed of branched chains of sugars, are also part of the matrix.

In the live tree, the cell walls are fully swollen with water, equivalent to ~ 27% of the dry weight of wood. The sapwood cell voids may also be full of water, resulting in a sapwood moisture content of 150–200%. The heartwood moisture content is typically 30–80%. Shrinkage of wood occurs as a result of drying from 27% to the in-service moisture content. The moisture content of wood inside heated buildings ranges from 4 to 10%. Wood at equilibrium moisture content with exterior air ranges from 12 to 18%. Consequently, wood products must be dried prior to use in construction or allowed to air dry during or after construction if they are to be dimensionally stable and remain free from decay. The critical moisture contents for colonization and breakdown of lignocellulose by microorganisms are considered in the following section.

C. CRITICAL REQUIREMENTS FOR MICROBIAL DEGRADATION OF WOOD

In the forest, microorganisms play a key role in the natural cycles of death, decay, recycling of nutrients, and regrowth. When mankind wishes to use wood as a structural or decorative material, it is necessary to break or delay these natural cycles for the desired life of the structure. This can be done by eliminating one of the critical factors necessary for microbial degradation. Temperature is an important factor, but this mainly affects the speed at which colonization and decay occur. The critical factors are a susceptible wood substrate, the presence of a microorganism capable of decaying wood, oxygen, and water.

Wood-degrading microorganisms have similar temperature optima to humans; consequently, wood in buildings is at an ideal temperature for decay. The fastest growth rates for many wood-inhabiting fungi occur between 20 and 30°C (68–86°F). Most are halted, but not killed, at ~35°C (95°F). They will, however, be killed after several hours at 60°C (140°F) or minutes at 70°C (158°F) or higher. Moderate growth still occurs down to 15°C (59°F) and growth does not stop until the temperature gets very close to 0°C (32°F).

The susceptibility of the natural wood substrate to microbial degradation depends on the part of the tree it comes from. In the living tree, the inner heartwood is dead, but it is protected to a certain extent by its natural durability. This is provided by natural toxins and blockages laid down by the tree as each annual ring is converted from sapwood to heartwood. This natural durability varies widely among tree species. The sapwood of the living tree transports water from the roots to the crown and stores starches, proteins, and lipids required for future growth. It is protected by the bark and by active response to wounding or invasion. When the tree is converted to wood products, the heartwood retains its natural durability but the sapwood dies and can no longer react to protect itself. Because it contains no natural toxins and has a

considerable amount of readily available storage products, the sapwood of all wood species is highly susceptible to fungal colonization and decay. Fortunately, this has been recognized for many years and there are a variety of effective wood preservation technologies to reduce the decay susceptibility of sapwood and enhance the durability of heartwood (see Chapter 34). Some wood species consist largely of heartwood, for example, old growth Douglas fir. Others consist largely of sapwood, for example, plantation-grown southern pine.

Microorganisms reproduce and are disseminated through the production of microscopic spores, smaller than pollen grains, which can be moved short distances by rain splash, carried by insects or blown over long distances by the wind. They can be present in the atmosphere at almost any time of the year but are particularly prevalent in the fall. Wood-degrading organisms can be kept out of the living tree by the barrier effect of the bark, the defense responses of the sapwood, and the natural durability of the heartwood. If they have managed to invade the living tree through wounds, some of these organisms may be able to survive processing into a wood product if the wood remains in a green (wet) condition. However, conventional and high-temperature kiln drying schedules will kill these organisms, as will the temperatures typically encountered in the manufacture of wood-based panels and engineered wood products. Most wood products used for construction are therefore free from infection at the point of manufacture. They will, however, be repeatedly exposed to microorganisms during storage, transportation, and construction and over the entire service life. As a result, the potential for the presence of wood-degrading microorganisms must be assumed.

Oxygen is almost ubiquitously available and many wood-degrading microorganisms are capable of tolerating relatively low oxygen levels. Even in some apparently anaerobic lake sediments, there are bacteria capable of breaking down wood at an extremely slow rate. Attempting to seal the oxygen out of wood is not a successful strategy for preventing microbial degradation.

The requirement for water is by far the most fundamental, and moisture management is by far the best means to prevent microbial degradation. Water is required for fungal cells to remain hydrated and for fungal enzymes, nonenzymic breakdown systems, and breakdown products to move within the wood. Wood products in service can be protected against microorganisms by drying the wood to <20% moisture content and keeping it dry. At moisture contents between 20 and 26%, established decay can continue but it is almost impossible for new infections to be initiated by spores. Some fungi, such as the true dry-rot fungus (see Section E2), can transfer moisture from a wet piece of wood to relatively dry wood, thus creating suitable conditions for decay. Between 27 and 30% moisture content, colonization and decay can occur but the growth of fungi is slow. Above 40% and <80% are ideal for growth and decay by wood-rotting fungi. Thus, rapid decay of wood is generally reliant on a supply of liquid water (for exceptions see Section E3). The maximum moisture content for rapid decay is between 80 and 120% moisture content depending on density of the wood and the fungus. At these levels, fungal activity is limited by oxygen diffusion rather than by excessive moisture, as such.

In summary,

$$\text{Susceptible wood} + \text{wood-degrading organisms}$$
$$+ \text{oxygen} + \text{water} = \text{decay}$$

Take any one of these parameters out of the equation and decay does not occur. Preservative treatment can reduce the susceptibility of wood to decay, allowing it to remain in service for many decades. Wet wood can remain sound in a bristlecone pine for thousands of years if microorganisms are kept out. Archeological wood can be recovered from lake sediments after hundreds of years when oxygen is excluded and wood in temples can remain sound for hundreds of years if it stays dry.

D. WOOD-INHABITING MICROORGANISMS AND COLONIZATION SEQUENCE

Discolored and shrunken wood, recognizable as rotten, is almost the last stage of a colonization sequence that begins when sterile wet wood is exposed or dry wood becomes wet. This sequence continues to progress as long as all the critical requirements are in place. Each microorganism changes the environment to make it less favorable for itself, for example, by using up a certain nutrient, and more favorable for subsequent colonizers, for example, by increasing permeability.

The microorganisms that live in wood can be divided into the bacteria and the fungi. Wood-inhabiting bacteria are single-celled organisms (though some grow in chains) which use organic material as a food source. They multiply by cell division and have limited motility so their ability to penetrate wood is very restricted. Wood-inhabiting fungi grow by extension of microscopic multicelled tubes known as hyphae. These hyphae are capable of growing through the existing pathways within the wood and, in some cases, creating new pathways. The entire branching network of hyphae looks something like the root system of a tree and is known as fungus mycelium. The fungi can be further subdivided into molds, staining fungi, soft-rot fungi, and wood-rotting basidiomycetes. The order in which they are listed above is the order in which they invade wood.

The wood-inhabiting bacteria can be separated into early colonizers and wood-degrading bacteria. The early-colonizing bacteria probably develop within hours of a sterile

piece of wet wood being newly exposed or a dry piece of wood becoming wet. They live on nonstructural storage products and their only effect is to increase the permeability of wood. However, if other organisms are excluded by unfavorable conditions, wood-degrading bacteria can dominate. These cause extremely slow strength loss over hundreds of years and are a primary cause of failure only in archeological wood and certain types of preservative treated wood.

Mold fungi develop on damp sapwood within days and they also live on nonstructural storage products. They grow rapidly and some produce antifungal antibiotics that help them to compete for the available resources. They have transparent or white mycelium and colored spores. They discolor the surface of the wood with their spores, but these can be wiped off and the effects are hardly noticeable if the wood is dried out. Large quantities of mold spores, particularly of certain species, can cause health problems if they are inhaled by susceptible individuals. Some molds can grow to a limited extent at wood surface moisture contents between 19 and 26%, too low for decay. However, exuberant growth of molds is indicative of conditions that could lead to the next stage of colonization and eventually to decay.

Staining fungi are closely related to mold fungi, and their main distinguishing feature is dark mycelium. They can be further subdivided into those causing sapstain and those causing black-stain in service, although there is considerable overlap between the two groups.

Sapstain fungi can be present in the standing tree and in summer they develop within weeks on felled logs or freshly sawn lumber. Some are capable of growing up to 20 mm/day under ideal conditions. They compete with the molds and bacteria for nonstructural storage products. Their dark brown or black mycelium gives a blue or black color to the wood, and this can penetrate the full depth of the sapwood. Sapstain fungi do disfigure the wood, but they cause little or no structural damage unless the wood stays wet and other organisms are excluded, for whatever reason. Under these circumstances, sapstain fungi can cause detectable reductions in impact bending strength.

The fungi causing blackstain in service also disfigure wood surfaces. They occur on painted and unpainted wood and are particularly problematic when they grow underneath transparent film-forming finishes. Under the latter conditions and on unpainted wood, they may be able to utilize the products released from the breakdown of wood by ultraviolet (UV) light. The aromatic rings in lignin make it a very effective absorber of UV light, but UV light and water produce free radicals which can initiate rapid breakdown of lignin. On unpainted wood, these breakdown products are washed off, leaving delignified cell remnants consisting almost entirely of cellulose. The refraction of light from these delignified cells gives the wood a silvery sheen. Good examples of this appearance can be seen on driftwood. When blackstain fungi and single-celled algae (simple plants) grow on such surfaces, they darken the wood to a gray "weathered appearance." The combined effects of UV light, rainfall, and microbial degradation lead to a slow erosion of wood surfaces. This process can be slowed by surface finishes or pressure treatments that exclude one or more of these three factors (see Chapter 34). Conditions conducive to the continued growth of staining fungi are likely to lead to the next stage of colonization.

FIGURE 33.2. Soft rot on the surface of an 80-year-old creosoted utility pole below the soil surface.

Soft-rot fungi are closely related to mold and staining fungi. Some do not discolor the wood and others can give blue or black discoloration. They are the first of the colonizers that are capable of using lignocellulose as a food source, but they are commonly prevented from colonizing earlier by competition from the bacteria, molds, and staining fungi. Soft-rot fungi erode or tunnel within the cell wall, causing gradual strength loss. They only cause serious damage if the wood-rotting basidiomycetes are kept out by unfavorable conditions such as preservative treatment or high moisture content (Fig. 33.2). In treated wood in the ground, their rate of attack depends on the type of preservative (see Chapter 34) and the amount in the wood. It is typically measured in millimeters per year starting at the wood–soil interface. In untreated wood exposed above ground the soft-rot fungi are normally replaced very quickly by the wood-rotting basidiomycetes, which can cause much more rapid strength loss.

Wood-rotting basidiomycetes typically take months to become established, probably because they too are out-competed by the bacteria, molds, and staining fungi. Once they do become established, their effects on the wood are much more rapid and severe than the soft-rot fungi. Wood-rotting basidiomycetes can be divided into two groups: the white-rot fungi and the brown-rot fungi based on their mode of attack on wood. White-rot fungi erode away the surface of the cell walls, causing strength loss faster than soft-rot fungi but much slower than brown-rot fungi. Brown-rot fungi cause

rapid strength loss by depolymerizing the cellulose before there are any visible signs of discoloration or shrinkage.

Because of this rapid strength loss and their predominance on structural softwoods, brown-rot fungi have the greatest economic impact of all decay types. Under ideal conditions, which rarely occur in nature, brown-rot fungi can grow up to 10 mm/day. Once established in a piece of sapwood, they can cause up to 40% strength loss in compression parallel to the grain (important for studs and piling) and up to 60% strength loss in compression perpendicular to the grain (important for wall plates and bearing points for horizontal timbers) in 1 week. This means that it is extremely important to stop the colonization sequence by drying the wood or treating it before it gets to the point where wood-rotting basidiomycetes become established.

E. DIAGNOSING DECAY

Determining the type of decay in a wood structure is not a straightforward procedure and is best left to a specialist. Having said this, the most common type of decay in structural softwood products is brown rot and this is the type of decay that most people will recognize.

E1. Major Types of Decay

Bacterial decay typically begins at the surface of wood in contact with soil or fresh water and gradually progresses inward. Visibly, the wood may remain unchanged or it may become paler in color and have the texture of a crumbly English cheese. When the affected wood is dried, it may take on a honeycomb appearance. Some types of bacterial decay can be recognized under the light microscope, but an electron microscope is needed to be certain of this type of decay. The probability of encountering this type of damage is low unless one is dealing with archeological material, old foundation piling, or wood harvested from man-made lakes, decades after flooding.

Soft rot also tends to begin at the surface of wood in contact with soil or fresh water and gradually progresses inward (Fig. 33.2). The appearance of the wood may remain unchanged despite considerable strength loss. The early effects of soft-rot fungi often cannot be diagnosed without looking at thin sections of wood under the microscope. However, there is a tool available that estimates the depth of soft rot by measuring the depth of penetration of a pin fired into the wood with a known force. Some indications of early strength loss can be ascertained by inserting a knife blade at a shallow angle to the surface, at right angles to the grain, and levering up a splinter. A fibrous splinter indicates sound wood and a brash fracture indicates decay (this also works for decay by wood-rotting basidiomycetes). At more advanced stages, soft rot can take on the appearance of white rot or brown rot. The biochemistry of the breakdown of wood by soft-rot fungi is barely understood compared to our understanding of the other two decay types.

White rot and brown rot are rarely obvious on the surface of a structure until they produce a fruiting structure such as a conk or bracket. In wood in ground contact, they do not compete well with soil fungi so they tend to be confined to deeper within the wood. In wood exposed above ground, the surface is often painted, hiding any underlying damage. Exposed unpainted surfaces may never stay wet long enough to support growth and decay. The first signs of decay in painted wood are usually collapse and cracking of the paint film as the underlying wood shrinks and cracks. When a structure with suspected problems is opened up, such as by removing the cladding or drywall in a building, wood-rotting basidiomycetes can be seen growing on the surface of wood provided the atmosphere in voids within the structure has been at a high relative humidity (RH), close to 100% RH for some time. The fruiting structures and mycelium of white-rot and brown-rot fungi cannot be distinguished without the involvement of a trained mycologist.

White rot and brown rot can be readily distinguished by their effect on the wood. White-rot fungi degrade both lignin and cellulose, leaving the wood with a bleached and often stringy appearance (Fig. 33.3). This can be confused with the effects of chemical bleaching agents (see Chapter 34). White-rot fungi possess a battery of cellulose- and lignin-degrading enzymes, several of which contain metals or are metal dependent. White-rot fungi tend to attack hardwoods, such as aspen and maple, rather than softwoods.

Brown-rot fungi degrade the cellulose and modify the lignin, giving a darkened, almost charred appearance, referred to as cubical cracking (Fig. 33.4). This can also be confused with the electrochemical deterioration that occurs when a galvanic cell forms between two types of metal used

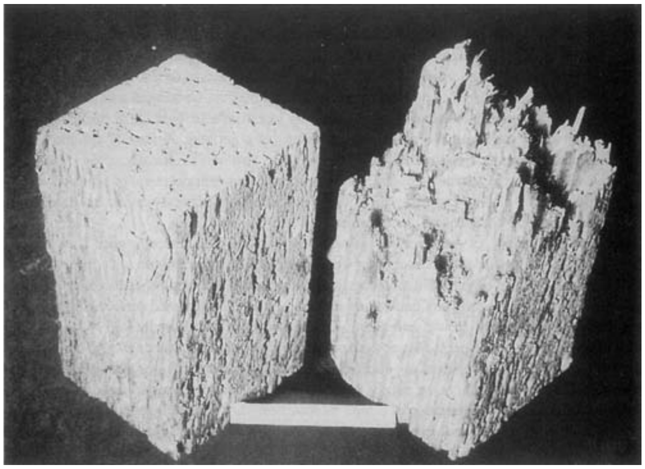

FIGURE 33.3. White rotted wood blocks showing typical bleaching and stringy texture.

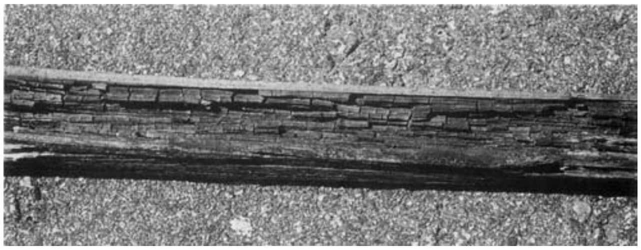

FIGURE 33.4. Brown rotted lumber showing typical darkening and cubical cracking.

as fasteners, commonly known as nail sickness (see Chapter 34). There may indeed be a link between the two. It has been suggested that Fenton-type (iron redox) reactions with or without mediation by fungal chelators are involved in the production of free radicals that initiate depolymerization of cellulose and modification of lignin by brown-rot fungi. Brown-rot fungi tend to attack softwoods more than hardwoods. They are the most important fungi causing decay in buildings because softwoods are more commonly used for structural purposes. The brown-rot fungi include those commonly referred to as dry-rot and wet-rot fungi.

E2. Dry Rot, Wet Rot, and Tolerance to Drying

Dry rot is a commonly misused term. It does not refer to wood that is rotted and dried out, nor does it refer to rot that can take place in dry wood. There is, however, a true dry-rot fungus called *Serpula lacrymans*, which is capable of transporting water from wet, rotting wood through mycelial cords to relatively dry wood. When the wood is wetted up, this fungus can colonize and decay it. The true dry-rot fungus is common in Europe, eastern North America, and northern Japan. It is relatively rare in western North America where it is replaced by another fungus, *Meruliporia incrassata*, which also has some water-transporting capabilities. The true dry-rot fungus is particularly prevalent in wood in brick or stone buildings. This may be partly due to a requirement for calcium and partly to a need for relatively constant temperature and humidity. Brick, stone, and concrete tend to retain moisture and slow the drying rate of adjacent wood products. Part of the reason this fungus is so much of a problem is that is can survive in wood hidden within brick, stone, or concrete walls and reemerge to infect new wood if the moisture sources that caused the decay problem in the first place are not completely eliminated.

Wet rot includes decay caused by other wood-rotting basidiomycetes. Two of these, *Gloeophyllum sepiarium* and *Gloeophyllum trabeum*, are particularly tolerant of drying out and of high temperatures. They are particularly prevalent in wood products in above-ground exterior exposure, such as window joinery, siding, and decking. Most of the others require more consistent moisture conditions to thrive. Having said this, it should be noted that many wood-rotting basidiomycetes can survive for years in wood with ~12% moisture content only to become active again if the wood rewets. Simply drying out a structure will not kill the decay fungus.

E3. Identification and Elimination of Wood-Rotting Basidiomycetes

If it becomes important to know which fungus caused the damage, this is best left to a mycologist with specific training in this field. However, with the possible exception of the true dry-rot fungus, it is rarely critical to know which fungus caused the problem; the recommended course of action is the same. Cut out all visibly decayed wood plus 2 ft in the longitudinal direction and the full cross section where the decay occurred. This action is necessary to eliminate wood that may have been colonized by the wood-rotting basidiomycete but not yet visibly changed. Not only will this region have lost considerable strength, but it could act as a source of infection if the moisture sources were not all eliminated or if a new leak arises. The search for moisture sources should consider not only obvious or primary moisture sources, such as a leaky building envelope or a flood, but also possible secondary sources, such as condensation. While wood-rotting basidiomycetes generally need liquid water to become established, they can continue to cause decay supported only by water vapor. Wood-rotting basidiomycetes create their own moisture as they decay the wood. Cellulose is a carbohydrate and the fungus converts it to carbon dioxide and water. If there is the possibility that all infected wood and all sources of moisture have not been eliminated, the remaining wood should be treated with a diffusible preservative and any new wood installed should be pressure treated (see Chapter 34).

E4. Determining Start Date of Decay Problem

When decayed wood is found in buildings or other structures, the question most often asked is, "How long has this been going on?" Unfortunately, this question is almost impossible to answer. The rate of growth and decay by wood-rotting basidiomycetes is affected by the species of fungus, the natural durability of the wood, the wood moisture content, the temperature, the presence and competitive abilities of other fungi, and interactions among these parameters. Too many of these parameters cannot be determined retroactively.

E5. Corrosion of Metals by Wood-Rotting Fungi

The metals, such as manganese and iron, needed by wood-rotting basidiomycetes for their metabolic processes are limiting micronutrients in wood. Both white-rot and brown-rot fungi appear to have specific mechanisms for securing and accumulating these resources. To do this, they produce metal chelators, known as siderophores. Brown-rot

fungi also reduce the pH of wood early in the decay process through the production of organic acids. As a result, corrosion of metals can be induced by contact with decaying wood over and above that expected based on the moisture availability.

F. FURTHER READING

More detailed information on the subject of wood biodegradation in general can be obtained from two textbooks by Eaton and Hale [1] and Zabel and Morrell [2] The first is written from a European perspective, whereas the second is written from a North American perspective. A classic textbook in this field was authored by Cartwright and Findlay [3]. More specific information on microbial breakdown mechanisms is covered by Eriksson, Blanchette, and Ander [4]. Inspection of buildings and diagnosis of deterioration problems are covered by Bravery et al. [5] and Levy [6].

A. INTRODUCTION

As discussed in Chapter 28, wood is a biodegradable, natural, renewable resource. Over the centuries wood has supported community life in a variety of ways, including construction of buildings for shelter; providing heat, cooking food, and furnishings to improve lifestyle; and as raw material for artisans. When Europeans first came to North America wood was plentiful and could easily meet the demands. In Europe, with the rapid development of shipbuilding in the sixteenth to eighteenth centuries, wood began to be used on such a large scale that Samuel Pepys noted in his diary that there was a shortage of seasoned oak for the navy's ships. The development of large-scale ironworks saw even more destruction of forests for production of smelting charcoal.

Compounding this shortage of wood were the problems of material failure due to rot. In the late-eighteenth century the loss of the Royal George at Portsmouth, with over 800 lives lost, stimulated the Royal Society of the Arts to offer a gold medal for the discovery of the cause of the dry rot in the hulls of wooden ships and a reliable method of eliminating it [1]. Soon several chemicals were considered to enhance wood durability, and in 1770, Sir John Pringle drew up the first list of wood preservatives. By 1810 the *Encyclopedia Britannica* published these lists as a reference. The early preservatives were generally metal salts such as copper sulfate, mercuric chloride, and zinc chloride.

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie
Copyright © 2011 John Wiley & Sons, Inc.

One of the problems of these simple salt treatments was their ready loss from treated wood, a problem that was solved when in 1841 Payne was granted a patent for a two-stage treatment involving ferrous sulfate and calcium sulfide which caused the ferrous sulfide to precipitate in the wood. However, lack of efficacy caused the treatment to be abandoned. About the same time, in 1838, John Bethell was granted a patent for his "creosoting" process, which employed solutions of metallic salts and bituminous chemicals. The term creosote was actually used in a patent granted to Moll in 1836 for his process in which wood was injected with extracts of coal tar in closed iron vessels. Moll called the heavier fraction "Kreosot." So in the late-nineteenth century creosote to preserve railway ties and marine timbers began to be used. It is remarkable that the basic creosote preservative and the treatment process proposed by Bethel have remained largely unchanged to the present day. However, as multisalt inorganic-based wood preservatives for utility poles in North America began to be used in the late 1940s alternative processes were required to ensure an effective treatment. The past 20 years have been a number of pressure and nonpressure processes for impregnating timber with preservative, and these will be briefly reviewed in this chapter. Perhaps the biggest single influence on the development of preservatives and processes during the last two decades has been concern over the environmental impact of industrial processes and their products. This has stimulated the industry to create new wood preservatives and process modifications to minimize the environmental impact of treated wood.

B. PRESERVATIVES CURRENTLY STANDARDIZED IN NORTH AMERICA

B1. Creosote

Despite considerable pressure to use alternative preservatives, creosote remains the most important preservative rather than dominant preservative for protection of wood placed in the marine environment and for treatment of wooden railway ties. Information on the properties of creosote can be found in the wood-preserving standards developed by the American Wood Protection Association (AWPA) in the United States [2] and the Canadian Standards Association Wood Preservation Standard 080 in Canada [3]. Over the last two decades, the focus on creosote has been to reduce or eliminate the soluble tar acid fraction and to reduce the benzopyrene content. The tar acid fraction is reduced (eliminated) by washing the creosote and the acids recovered for other uses. The benzopyrene content has been reduced due to its toxic effects on humans. A number of excellent reference papers on creosote and its uses may be found in the proceedings of the AWPA [4–6]. In 1994, $0.26 \times 10^6\,m^3$ of creosote-treated wood was produced. Since then the trend has been to a gradually reduce volume of production due to lack of key end uses, such as retail lumber, as well as increased competition from alternative materials for one of the major products—piling. Creosote remains supported for both marine timbers and piles provided that the best management practices guide developed in 1996 by the American Wood Preservers Institute supports its use [7–9].

B2. Pentachlorophenol

Pentachlorophenol was developed in mid-1930s as part of a general interest in the potential of chlorinated phenols [10]. The higher chlorinated phenols were found to have greater efficacy than the trichlorophenol and tetrachlorophenol products. The pentachlorophenol also possessed a higher melting point. Although originally produced either by chlorination of phenol using an aluminium chloride catalyst or by hydrolysis of hexachlorobenzene, the potential for dioxin formation in the latter process has resulted in it being discontinued. Early uses of pentachlorophenol included protection of millwork in which a 5% pentachlorophenol solution in a light organic solvent was applied to wood by either a double-vacuum process in the larger industrial plants, and by spray or dipping in small scale operations. During the 1940s the availability of creosote was limited due to the war, and pentachlorophenol in heavy oil was employed to protect utility poles in North America. Field tests quickly established it to be a very effective broad-spectrum biocide capable of preventing not only decay but also insect attack. It was however unsuitable for protecting wood in the marine environment. It rapidly became the preservative of choice for utility poles and by the mid-1960s it dominated pole protection.

In the mid-1970s the U.S. Environmental Protection Agency (EPA) introduced a review of all wood preservatives, and pentachlorophenol became the focus of attention because of the small amounts of dioxin and furan impurities found in technical-grade material. Concern has also been expressed over the potential for pentachlorophenol-treated wood to produce dioxins in service, although this has not been demonstrated. Perhaps the most important impact of the dioxin impurity is on the disposal of pentachlorophenol-treated waste. Until the last few years the disposal of treated wood recovered from service was not an issue [11]. Since all treated wood as it is still considered to be not hazardous according to EPA. It can be disposed of in a regular landfill. This is now under review and the United States and Canada have limited the procedures that govern the disposal of pentachlorophenol-treated wood can be disposed. Incineration has been proved to be an effective option, provided that the temperature of the process is above 1000°C [12]. Although a "clean" version of pentachlorophenol was developed during the 1980s, cost prevented its use by industry. The importance of the solvent system on the performance of pentachlorophenol has been widely studied and several

alternative treatments have been commercialized. These include ammoniacal copper pentachlorophenate and water-soluble forms of pentachlorophenol using emulsifying agents. Perhaps one of the most widely used alternatives was liquefied gas treatment, in which pentachlorophenol was dissolved in an inert liquefied gas such as methylene chloride or butane, often with the aid of a small amount of a cosolvent. The advantage of this treatment was that it could be used to produce treated wood without the color change normally associated with the use of the heavy oil solvent. However, with the passage of time the loss of preservative from wood treated by the liquefied gas processes was found to be too great and the service life of the product was not acceptable. None of these alternative pentachlorophenol-based preservatives or processes are in use today.

In 1994, 0.07 m^3 of pentachlorophenol-treated wood was produced. The principal products were utility poles and cross-arms. Its market share of treated wood has been declining since it is not used for retail lumber and many utility companies have changed to using fixed waterborne preservatives. Although initially there was interest in using an oil-borne copper naphthenate in place of pentachlorophenol, the well-publicized failures of copper naphthenate–treated southern pine poles negatively impacted its use.

B3. Chromated Copper Arsenate

Chromated copper arsenate (CCA) was proposed to the AWPA for standardization in 1949 as Greensalt [10]. It was accepted in 1953. The formulation known also as CCA type A was revised in 1968, and in 1969 the formulation was specified in the standards on an oxide basis when it contained 65.5% chromium (expressed as CrO_3), 18.1% copper (expressed as CuO), and 16.4% arsenic (expressed as As_2O_5). A second formulation, known as Boliden K-33, or simply as K-33, had been in use commercially in Sweden since 1950, having been patented in 1947 [10]. It was proposed for inclusion in the AWPA Book of Standards in 1963, as CCA type B. The formulation standardized on an oxide basis in 1969 contained 35.3% chromium (expressed as CrO_3), 19.6% copper (expressed as CuO), and 45.1% arsenic (expressed as As_2O_5). In the mid-1960s the AWPA wished to reduce the complexity of the preservative standards by eliminating obsolete preservatives. A single standard for CCA was proposed which had a formulation which was approximately the average of the two existing CCA formulations [10]. Data were presented to show that such a formulation would have the best leaching resistance. In 1969 a standard for CCA type C was published and the preservative contained 47% chromium (expressed as CrO_3), 19% copper (expressed as CuO), and 34% arsenic (expressed as As_2O_5). From 1970 all three formulations were employed with the industry often switching from one to the other depending on the cost or availability of chromic acid or arsenic acid. However, in the last decade types A and B have given way to the almost exclusive use of the better balanced type C formulation.

From 1980 to 2003 CCA became the dominant preservative worldwide. In 1994 over $2 \times 10^6\, m^3$ of CCA-treated wood was produced in the United States. Indeed, over 85% of sawn wood was treated with CCA. This dramatic change in market dynamics from that of the early 1970s reflected the adoption of residential preservative-treated wood which was marketed through retail outlets for use on projects around the home. This market had been taken up exclusively by CCA. With the development of these specialty products for the do-it-yourself market, the use of additives has become much more prevalent. These additives include polyethylene glycol or emulsified oil for improving the climbability of utility poles, dyes and pigments to alter the color of CCA-treated wood, and water-repellant additives to reduce the checking behavior of decking. Despite concerns over surface hardness in CCA-treated southern pine, CCA-treated poles are widely accepted by the industry with a current market share of almost 70%.

In the 1990s the wood-treating industry focused on improving the fixation of CCA before the treated wood leaves the treating plant. Relatively simple tests such as that based upon chromotropic acid were developed which allow both producer and user to confirm that CCA-treated wood does not contain unreacted chromium. Research showed that the rate of reaction of chromium is slower than that of either copper or arsenic so that tests based on the chromium reaction can be used to follow the overall fixation rate. Consistent with the current focus on the environmental impact of wood treatment, greater attention is now given to ensuring that the treated wood is free of surface deposits, and this too has become part of the CSA and AWPA book of standards. The methods used to enhance the fixation rate will be discussed briefly in the following section on treatment processes.

In 2003 the use of CCA dramatically changed. The suppliers of CCA agreed to withdraw its use from the residential treated wood market. It is still allowed for use for industrial products such as poles and piling. It is also allowed for residential uses such as shingles and shakes, plywood, and the preserved wood foundation components. However, for most traditional residential uses, such as fenceposts, decking, fencing, and cladding other preservatives based on copper and organic co-biocides have been introduced and now dominate those markets.

B4. Ammoniacal Copper Arsenate and Ammoniacal Copper Zinc Arsenate

Ammoniacal copper arsenate (ACA, patented by Gordon in 1939) as a preservative was adopted by the AWPA in 1953 [10]. It was formulated as 49.8% copper (expressed as CuO) and 50.2% arsenic (expressed as As_2O_5). This formulation tended to lose unfixed arsenic so that an improved

formulation, ammoniacal copper zinc arsenate (ACZA), was developed and replaced ACA in the book of standards [13]. ACZA is formulated as 50% copper (expressed as CuO), 25% zinc (expressed as ZnO), and 25% arsenic (expressed as As_2O_5). Ammoniacal copper-based preservatives have traditionally been preferred for wood species that are refractory to treatment, for example, spruce and Douglas fir. Consequently ACA and ACZA were more common in Canada and the west coast of the United States than in southern United States. Currently, neither ACA nor ACZA are approved in Canada. ACZA remains allowed for use in the United States where its principal uses are the treatment of piles, timber, and utility poles.

B5. Copper and Zinc Naphthenate

Naphthenic acids, by-products of the petroleum industry, can be reacted with copper and zinc salts to produce copper and zinc naphthenates. First used as wood preservatives in Europe, where they were sold under the trade name Cuprinol, they were not introduced into the United States until 1948 [10]. Their principal use was as brush treatments sold at retail outlets to the general public or as dip treatments for commercial products such as fence posts. Their relatively high cost prevented their commercial acceptance for pressure treatment until the last decade, when the utility pole industry became increasingly under pressure to introduce an alternative to pentachlorophenol. It was introduced into the AWPA commodity standards in the early 1990s solubilized in a P9-type oil. However, with the increasing acceptance of fixed waterborne preservatives, its use in this market remains very small. In Europe its main use has been for the double-vacuum treatment of millwork (window joinery and doors), cladding, fencing, and so on, for above-ground exposure. Zinc naphthenate is not used for pressure treatment in North America. The volume of copper naphthenate–treated wood in North America remains relatively small. In Europe the lack of availability of naphthenic acid has stimulated research on the production of synthetic copper and zinc soaps from versatic and octanoic acid. These products have not been introduced into North America.

B6. Bis-tributyltin Oxide

Tributyltin oxide (TBTO) was principally employed for the dip treatment of window joinery and doors. However, following research in the 1970s, which revealed that TBTO rapidly degraded upon impregnation into wood, its use has declined and it is now no longer used.

B7. Copper-8-quinolinolate

Pure copper-8-quinolinolate (oxine copper) is insoluble in light organic solvents. A solubilized form can be produced with nickel hexanoate. Its use remains limited in North America, with its principal advantage being that wood treated with oxine copper at one time could be used in contact with foodstuffs. It was introduced into the AWPA commodity standard for sawn wood exposed above ground but was restricted to the protection of several pine species, including southern pine, western red cedar, and hem-fir [2].

B8. Alkylammonium Compounds

The potential of alkylammonium compounds (AACs) as wood preservatives has been recognized for more than 30 years [14]. However, following early failures of problems of decay in wood treated benzalkonium compounds in New Zealand in the early 1980s their main use has been as a co-biocide in formulations of ammoniacal or amine copper preservatives, such as ammoniacal copper quat (ACQ). They remain standardized as a stand-alone preservative, and if this use is to be realized, it is likely to be formulated with other organic co-biocides for wood exposed above ground. At present only didecyldimethylammonium chloride (DDAC) and DDA didecyldimethylammonium carbonate have been standardized in North America [2]. An important commercial application for DDAC is as a co-biocide in NP-2, a formulation widely used for protecting unseasoned wood in transit and storage. In Europe and Japan other AACs have been commercialized. They include trimethylcocoammonium chloride and alkyldimethylbenzylammonium chloride.

B9. Alkaline Copper Preservatives: Alkaline Copper Quat

Almost universally there has been environmental pressure to reduce the use of CCA in high-volume residential applications. One of the first preservatives to be developed without arsenic or chromium was ACQ (types A and B) where the quat (or quaternary ammonium compound) was DDAC [15]. The preservative consisted of copper (basic copper carbonate) solubilized in ammonium hydroxide and formulated with a quaternary ammonium compound. This preservative combination was commercialized in Scandinavia and was introduced into the AWPA standard in 1992. In 1995, a version of ACQ type B formulated with monethanolamine as the solvent in place of ammonium hydroxide was standardized. The use of amine in place of the ammonium hydroxide provided product improvements including enhanced surface cleanliness and better color to allow penetration of the retail lumber market.

Currently four ACQ formulations are accepted treatments for most commodities in the AWPA [2] and CSA [3] book of standards. The variations include the addition of some ammonia to assist in the penetrability of the preservative in refractory wood species. This preservative has replaced CCA for the treatment of wood for residential applications and is

one of two main preservatives commercialized in Canada and the United States for this application.

B10. Alkaline Copper Preservatives: Alkaline Copper Azole

In addition to ACQ a second formulation based on alkaline copper has been widely accepted for use in protecting residential products. Copper azole was standardized in 1995 [16]. This is alkaline copper azole, in which the copper is solubilized in monoethanolamine and formulated with a triazole [2, 3]. The most common triazoles used are tebuconazole and propiconazole. The former is used in North America while the latter has been used in European copper azole formulations. Initially, boric acid was also included in the formulation (CB-A), but this early preservative has since been replaced by one containing only copper and tebuconazole (CB-B).

B11. Micronized Copper Wood Preservatives

Because of concern over the leaching of copper from alkaline copper–treated wood at high retentions as well as enhanced corrosion compared to that from earlier preservatives such as CCA, new innovations continue to be introduced by the industry. The most recent innovation involves the use of small solid particles of copper carbonate which are suspended in aqueous solution together with a co-biocide as a wood preservative [17]. Two formulations have been standardized in North America [2, 3]. They are micronized copper quat (MCQ) and micronized copper azole (MCA). Because the copper is placed into the wood as basic copper carbonate and then is only solubilized by its reaction with the wood components, large concentrations of mobile copper are not present in the treated wood. This is perceived to be an advantage in minimizing the environmental impact and reducing the corrosive effects of the treated wood. In addition, the need to stabilize, or "fix," the preservative after treatment has been eliminated. Currently the micronized copper preservatives are being widely accepted by retail outlets supporting residential use of treated wood. The formulation of the product remains the same as that for the alkaline solvent–based preservatives.

B12. Copper Bis(dimethyldithiocarbamate)

The beneficial value of carbamates has been known for many years and several biocides based on this class of chemical have been commercialized in other industries. In the mid-1990s a new preservative was based on a two-stage treating process involving sequential impregnation of timber with a copper ethanolamine solution and a sodium dimethyldithiocarbamate solution. The two chemicals react in the wood to produce the highly insoluble copper dimethyldithiocarbamate [18]. This preservative has been discontinued in the United States and was never commercialized in Canada.

B13. Ammoniacal Copper Citrate

Ammoniacal copper citrate was standardized [2] for the protection of sawn wood for both in-ground as well as out-of-ground exposures. Its use has been discontinued.

B14. 3-Iodo-2-propynyl Butyl Carbamate

3-Iodo-2-propynyl butyl carbamate (IPBC) is a new generation of organic wood preservatives that has been standardized by the AWPA [2]. Currently its main application is in a formulation NP-2, which is designed to prevent degradation of unseasoned wood during storage and transit. As interest in totally organic-based wood preservative formulations increases, the use of IPBC may well increase to protect wood used in above ground.

B15. Triazoles

Triazoles represent a new group of chemicals that have been shown to provide good protection against decay for timber exposed in above ground. Research has suggested that due to cost and the lack of broad-spectrum activity it is likely that they will be formulated with other biocides to produce an effective preservative, particularly for the protection of residential wood products. Two triazoles have been standardized since 1994: tebuconazole and propiconazole [19]. A third cyproconazole has also been studied both in Europe and North America and has potential for future use in preservative formulations. As with other organic wood preservatives discussed in this chapter, their main use is likely to be for protecting wood used in above ground.

B16. 4,5-Dichloro-2-*N*-octyl-4-isothiazolin-3-one

Isothiazolinones represent a new class of organic wood preservative that has been standardized in both Europe and North America [2]. Like many of the other organic preservatives, the isothiazolinones are likely to find most use for protecting wood exposed in above ground or as co-biocides in formulations to enhance biocidal performance.

B17. Chlorothalonil

Chlorothalonil was introduced into the AWPA standard in 1993 [2]. It is not currently commercially used in wood preservation.

B18. Inorganic Boron

Borate treatment of wood has been well established in New Zealand for the diffusion treatment of unseasoned timber. Indeed, a small amount of borate-treated wood was produced in Canada for supply to the U.K. market for

protection against the house longhorn beetle (*Hylotrupes bajulus*). During the past three or four years, there has been increasing interest in the use of borate treatments to prevent insect attack in wood not exposed to liquid water. Examples of such exposures include sill plates and studs in termite-infested regions of the world. Historically, the process involved dipping unseasoned timber in high concentrations of borate followed by long-term storage to allow diffusion to proceed. More recently it has been demonstrated that acceptable treatments can also be achieved by pressure treatment of wood with borate solutions of moderate strength. Consequently, in 1995 inorganic boron was added to the AWPA book of standards [2, 3], and in 1998 borate treatments were added to a number of commodity standards.

B19. Acid Copper Chromate

Acid copper chromate (ACC) was proposed to the AWPA for standardization in 1950 and accepted in 1953 [10]. While it still remains in the book of standards, its use is relatively minor and limited to those industrial products where CCA is not accepted due to the presence of arsenic.

B20. Copper HDO

A recent addition to the array of preservative formulations based on alkaline copper is copper–HDO (where HDO is *N*-cyclohexyl-diazeniumdioxide). The preservative has been widely used in Germany and Scandinavia for over a decade. It was standardized in the United States in 2005 [2] but has not yet been approved in Canada. It is anticipated that its standardization will take place during 2011. The solvent system is monoethanolamine.

B21. Impralit-KDS

Another alkaline copper preservative recently approved and standardized in the United States is Impralit-KDS [2, 20]. This preservative combines the basic copper carbonate and boric acid solubilized in monoethanolamine with a polymeric betaine. The polymeric betaine is a complex borate ester which, once impregnated into wood, breaks down to produce boric acid and a quaternary ammonium like compound. KDS has been used extensively in Europe for more than a decade.

C. PROCESSES

Although several treatment processes have been established in many countries, in North America the main standard-writing organizations have focused on pressure treatment processes. The dip treatment of sawn wood found in many other countries for protection against insect attack is not practiced in North America. (Dip treatment has been widely used for protection of commodities such as window joinery, but neither the AWPA nor CSA standards currently cover it.)

The treatment process for timber can be divided into four main stages [10]: material conditioning, pretreatment steps designed to improve the quality of the protection, the actual pressure process, and the final conditioning/fixation process. For most commodities it is essential to remove the water from the cell lumen to allow the treating solution to enter the wood cell structure. From here it can diffuse into the cell wall. In general, the conditioning of the wood is by air seasoning, although accelerated drying by steam conditioning or kiln drying is increasingly being practiced. Target moisture contents for most treatments are around 25%. An exception to this is where the wood is to be Boultonized prior to treatment, in which case the moisture content may be as high as 35%. Following seasoning, the commodity is cut to the correct size or shape. This is important since during treatment wood is not treated throughout the cross section. Rather the preservative process provides an outer shell of treated wood. The protection of the untreated core is then dependent on maintaining the integrity of this outer shell. To assist in the treatment of refractory heartwood, techniques such as incising are employed. Incising is the creation of fine openings in the wood surface that allows the preservative solution to penetrate immediately to the required depth from the surface. By arranging these incisions in a suitable pattern, the enhanced longitudinal flow of solution allows an integral shell of preserved wood to develop. In round wood techniques such as through boring at the ground line have been commercialized for difficult-to-treat pole species such as Douglas fir.

For oil-borne preservatives such as pentachlorophenol or creosote, the treatment solution is usually applied at high temperature [10]. This has two beneficial effects. First, it sterilizes the wood, eliminating any incipient decay already present. Second, if a vacuum is applied to the treatment system when the timber is immersed in the hot oil, the water present in the wood can be removed. This forms the basis of the Boultonizing of wood, a pretreatment process often practiced with utility poles.

Following the pretreatment processes the products are then subjected to the pressure impregnation stage. While traditionally two main types of processes have been used, these have become modified during the past 10–20 years so that modern processes often depend upon the specific product and chemical combination being considered. The two main processes are the full cell process (sometimes called the Bethel process [10]) and the empty-cell process [10]. In the full cell process the wood is placed in the treatment cylinder and subjected to an initial vacuum of 75 kPa. The preservative solution is then introduced into the cylinder and the pressure then gradually raised to a maximum of 1050 kPa. This pressure is then maintained for 1–16 h depending on the commodity and wood species being treated. Southern pine schedules are generally very short whereas those for

refractory species such as Douglas fir tend to be long. Following the pressure phase, the solution is pumped out of the retort and a final clean-up vacuum is applied. This is designed to remove excess preservative solution from the product and prevent dripping of the solution when the product is removed from the cylinder and placed into temporary storage. The full cell process has traditionally been used for waterborne preservatives and creosote treatment of marine piling.

Two versions of the empty-cell process have traditionally been used [10]: the Lowry process and the Rueping process. In the Lowry process, the timber is placed in the treating cylinder and the preservative solution added without any initial vacuum. At the end of the pressure phase the trapped air in the wood assists in recovering much of the creosote or oil-borne preservative, thus preventing overtreatment of the product. For wood species, which has a large amount of sapwood, even the Lowry process can result in excess preservative solution being taken up. In the Rueping process, an initial air pressure is applied to the cylinder containing the timber. The preservative solution is then allowed to enter the cylinder while maintaining the cylinder pressure. As before, the pressure is then increased during the pressure phase. At the end of the pressure phase, the entrapped air then assists in the recovery of the preservative solution, preventing overtreatment.

During the past two decades, the wood-preserving industry has developed several posttreatment processes designed to minimize potential for environmental contamination. These include special sealed concrete surfaces covered from the rain where treated wood can be held before moving into general yard storage. However, some of the most important innovations relate to the treated wood itself. For example, for CCA which undergoes a reaction with the wood components resulting in insolubilization of the components, posttreatment heating is an integral part of the process at many treating plants. This heating stage can be achieved in many ways [21]. Processes based on the application of hot water under pressure, high-temperature steam [22], humid air at moderate temperatures, and the use of radio frequency [23] kilns are just some techniques reported in the literature. Even treating plants using ammoniacal copper preservatives have adopted different posttreatment processes designed to minimize surface deposits on commodities. These include posttreatment washes with ammonia solution.

For oil-borne products including creosote-treated piling, it is recognized that an increase in the moisture content which takes place when the commodity is placed in service causes the fibers to swell and the wood to lose preservative. To counter these effects, posttreatment steaming of oil-borne-treated wood is now recommended to reduce surface loading at the treating plant, thereby reducing the potential for loss to the environment.

While the major focus of the AWPA and CSA standards is on the pressure impregnation of wood, the use of thermal treatments with oil-borne preservatives is also described. In this process the wood is subjected to immersion in a hot preservative solution followed by immersion in a cold preservative treating solution. During the first stage, the air in the wood cells expands and some is lost from the wood surface. In the cold treating solution, the air contracts, creating a partial vacuum which assists the preservative penetration into the wood. The thermal treatment process is restricted to roundwood.

D. STANDARDS

In North America the principal standards governing the production of treated wood are the AWPA [2] and CSA080 [3] standards. These standards have traditionally been based on a "results-type" approach in which a number of pieces in the charge or load of wood are sampled and the acceptability of the treatment depends on the analysis of penetration and retention exceeding set threshold values. The threshold values are established for preservatives through field exposure tests, in which the performance of the new preservative is compared to a reference preservative. During 2009 the AWPA and CSA have begun to explore whether a process specification could be useful for certain types of products. The concept would be to control the process sufficiently to ensure a reliable quality control on the product. Such a process specification would apply to noncritical building components such as fencing boards and deck boards. Currently no process specifications have been standardized.

The AWPA book of standards is updated annually. In earlier versions it contained five sections. The first section described the preservative compositions. The second section was the largest and outlined how different commodities must be treated using pressure processes. This section identified the limits of the various treatment parameters. The objective of this part of the commodity standard is to prevent damage occurring to the product during treatment through the use of excessive pressure or heat. The third section described in detail how treated wood and preservative solution can be analyzed to ensure quality of treatment. A fourth section contained a number of miscellaneous standards, some of which discuss how to establish the quality control of treated wood and of treating plants. The fifth section outlined the procedures that must be followed to evaluate wood preservatives. These include laboratory as well as field tests. Finally, there was a listing of conversion factors.

Until 1998 the AWPA book of standards was based upon Imperial units, but in 1998 the standard was converted to metric units. The Canadian wood-preserving standard converted to metric units in 1989.

A major change in the way the wood preservation commodities are standardized was made in 2003 in North America [2, 3, 24, 25]. Instead of focusing on standards for different commodities with specific details on how to treat wood, the new approach focuses on the different biological hazards that exist. This new system is called the Use Category System (UCS). Under this system different commodities are grouped under a number of categories depending on the degree of biological hazard. Five use categories have been adopted. The first, UC1, covers material not in contact with the ground and protected from exterior weather. UC2 describes interior construction material that is used above ground but which may be expected to become damp in use. The third use category (UC3) is for wood used above ground outdoors and has two subcategories. UC3A covers wood that is coated and not in contact with the ground, for example, windows and cladding. UC3B is for wood that is not coated but is not in ground contact. Typical products might be decks or railings. UC4 covers wood in ground contact. It is divided into several subcategories depending on the degree of criticality. UC4A is for normal ground or freshwater uses, such as fence posts, but excluding wood in critical uses or unusually high hazards. UC4B is for severe ground contact exposure and important construction material that would be difficult to replace, such as preserved wood foundation components. The third subcategory, UCC, is for wood in ground contact but where the biological hazard is unusually high or the end use is structural and failure would be hazardous. Examples of such uses would be freshwater piling and utility poles. The fifth category, UC5, focuses on the marine environment where higher preservative retention is usually required, for example, marine piling. There is in addition a category, UCF, which covers protection of wood against fire rather than biological hazards. This category is further divided into interior and exterior exposure conditions. The intent of this new approach to defining preservative requirements is to make the standards more easily understood by the end user and to ensure consistency between commodities. The adoption of a use category system to describe preservative requirements for commodities is not new, with different versions already in place in Europe, Australia and New Zealand, and Japan.

In the latest versions of the AWPA [2] and CSA [3] book of standards, the structure has been revised to incorporate the information shown previously but centered around the UCS concept. The CSA book of standards mirrors the structurtre of the AWPA book of standards. In the first section of the current AWPA book of standards (U1-08), the user specifications for treated wood are outlined. In addition to describing the various use categories, it also includes a table providing a guide to commodity specifications. The intent is to assist the user in selecting the appropriate treatment type for the product of interest. The table directs the reader to the appropriate "commodity specification" section for additional information. Other tables identify the wood species and treatment combinations standardized by the AWPA (and CSA). It also includes a listing of all preservatives standardized by the AWPA (and CSA). The processing and treatment standard (T1-08) describes all of the technical requirements for successful treatment of wood with preservatives. In a recent development all preservatives have been assigned a separate standard, rather than being grouped together by preservative type, as was previously done. The analytical methods section follows this approach as well, so that each analytical method is now described in its own standard. The evaluation and miscellaneous standards remain as before as separate sections. In general, the analytical and evaluation standards of the AWPA [2] are adopted by the CSA as appendices to the Canadian standard [3].

E. RECOMMENDED SOURCES OF INFORMATION

Several excellent sources of information on wood preservation are available. The Proceedings of the American Wood Protection Association and the Canadian Wood Preservation Association can provide updated information on preservatives and processes. The books of standards produced by the American Wood Protection Association and the Canadian Standards Association are important sources for identifying changes in requirements. A number of texts have been written which can provide more in-depth information on topics covered only superficially in this review. A recommended overall source on wood preservation and biodeterioration from a European perspective is written by Eaton and Hale (1993) [26], while the industrial aspects of preservation have been comprehensively described by Wilkinson (1979) [27]. More detailed information on some of the established preservatives and processes can be found in *Wood Deterioration and Its Prevention by Preservative Treatments* [10]. For up-to-date information on wood preservation research the International Research Group on Wood Protection should be consulted. Internet access is available for many of these organizations (e.g., www.awpa.com, www.irg-wp.com, cwpa.ca).

A. INTRODUCTION

The first metal–matrix composites (MMCs) were created in the 1960s, [1] and new types are still being developed today. MMCs are metals that are incorporated with either discontinuous or continuous reinforcements usually in the form of whiskers (W), particles (P), short fibers (SF), fibers (F), or monofilaments (MF). The reinforcements can be either metal

(e.g., tungsten), nonmetal (e.g., carbon, silicon), or ceramic (e.g., silicon carbide or alumina). A variety of MMCs have been developed with matrices such as aluminum, magnesium, lead, depleted uranium, stainless steel, titanium, copper, and zinc for experimental and commercial applications. Aluminum MMCs are the most extensively available [2]. The reinforcement constituents, usually ranging from 10 to 60 vol %, have included boron (B), graphite (Gr), silicon (Si), silicon carbide (SiC), boron carbide (B_4C), titanium diboride (TiB_2), alumina (Al_2O_3), mica, quartz, tungsten, yttria, and zircon. The selection of the matrix metal and reinforcement constituent is usually chosen to increase the specific strength [3] and stiffness [3] of the MMC; however, MMCs have also been developed for other unique properties such as improved thermal conductivity [4], neutron shielding [5], and vibration damping capacity [6] and to reduce thermal expansion [2], friction [7], and wear [7]. Some MMC properties are governed by the rule of mixtures [8], but this does not generally apply to corrosion resistance. In fact, corrosion resistance of MMCs is usually less than that of their monolithic matrix alloys due to the presence of the reinforcements that alter the microstructure, electrochemical properties, and corrosion morphology.

B. MMC TYPES AND APPLICATIONS

MMCs can also be categorized as being discontinuous reinforced (DR) with particulate reinforcements [Fig. 35.1(a)] or continuous reinforced (CR) with fibers or monofilaments [Fig. 35.1(b)]. The MMC notation that is used in this chapter is as follows: matrix type/reinforcement composition/vol % reinforcement type. Hence, Al/Al_2O_3/50 P MMC denotes an aluminum matrix MMC reinforced with 50 vol % of Al_2O_3 particles.

DR MMCs generally have isotropic properties and lower reinforcement and fabrication costs in comparison to CR MMCs. For structural-grade DR MMCs, reinforcement content ranges from approximately 15 to 25 vol %, and uniform reinforcement and reinforcement-size distributions are preferred for optimal mechanical properties. These MMCs come in a variety of structural shapes (Fig. 35.2). In one example regarding the catamaran "Stars and Stripes'88" [2], Al/SiC/20 P MMC tubes were used to replace monolithic aluminum tubes to reduce tube weight by 20%. Structural-grade DR MMCs are also being used with greater frequency in the automotive sector for components such as engine pistons, piston-connecting rods, rear-wheel driveshafts, break calipers, cylinder liners, push rods, rocker arms, and valve guides [5]; in the sports industry for high-performance bicycle frames and components, golf clubs, and baseball bats [5]; and in the aircraft industry for fan exit guide vanes in

turbine engines, ventral fins, helicopter blade sleeves, and fuel access covers [9]. For electronic-grade DR MMCs used in electronic packaging, reinforcement content generally exceeds 30%. The reinforcement and reinforcement-size

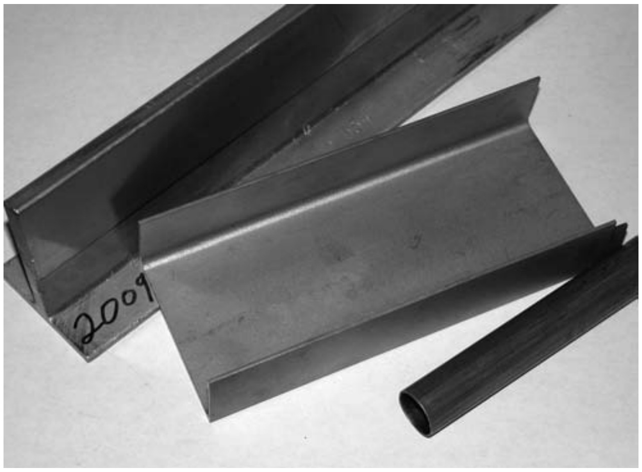

FIGURE 35.2. MMC structural T-section, channel, and tube.

distributions are often not uniform [Fig. 35.1(a)] to maximize the reinforcement volume fraction. The electronic-grade MMCs are usually loaded with ceramics of low coefficient of thermal expansion (CTE) to lower the MMC CTE to levels closer to that of electronic materials such as silicon and gallium arsenide. One MMC example for electronic packaging is the low-CTE Al/Si/43 P MMC, which is also machinable and lightweight. For thermal management applications, copper MMCs are reinforced with milled graphite fibers that have negative CTEs and thermal conductivities exceeding that of copper [10]. DR copper MMCs have also been developed for sliding electrical contact materials [11] and improved machinability for lead-free copper alloys [12]. DR Al/Gr MMCs have been developed for potential use in tribological applications due to good resistance to wear and seizure [13–15]. DR titanium MMCs are candidate materials for gears, bearings, and shafts [16]. Porous DR titanium MMCs have potential use as surgical implant materials, owing to the compatibility of titanium and bone growth [17]. Porous titanium is a good surgical implant material because bone growth is enhanced by the relatively low elastic modulus of titanium, and bone ingrowth is allowed by the porous structure. Porous titanium, however, has poor tribological properties and, therefore, MMCs that incorporate graphite to reduce friction and titanium carbide to improve wear resistance are of interest [17].

CR MMCs are either reinforced with continuous fibers or monofilaments, generally resulting in anisotropic properties with enhancements in the longitudinal direction of the reinforcement [Fig. 35.1(b)]. The reinforcement diameter generally varies from 10 µm for fibers to 150 µm for monofilaments. The reinforcement and fabrication costs of CR MMCs are usually much higher than those of DR MMCs. Examples of CF MMCs are Al/B/MF MMC structural tubes used in the Space Shuttle that resulted in 44% reduction in weight over aluminum alloys in the original design [18] and Al/Gr/F MMCs, which have unique properties such as negative to near-zero coefficient of thermal expansion, that were used as antenna booms in the Hubble space telescope [2]. Al/Al_2O_3/F MMCs have been used in the automotive industry to replace cast iron components due to MMC properties such as low weight, low thermal conductivity and expansion, good wear resistance, and improved high-temperature tensile and fatigue strengths [19]. Other types of Al/Al_2O_3/F MMCs with low weight, high strength, and high damping capacity are used for automotive push rods [6]. Structural Ti/SiC/MF MMCs have been used in prototype drive shafts, turbine engine discs, compressor discs, and hollow fan blades and were also candidate materials for the skin of the National Aerospace Plane [20]. CR copper MMCs have been developed for applications requiring reduced weight and high thermal conductivity [21].

C. FACTORS INFLUENCING MMC CORROSION

The nonhomogeneous microstructure of MMCs due to the presence of the reinforcement constituents can lead to higher corrosion rates and different corrosion morphologies in comparison to their monolithic matrix alloys. Corrosion in MMCs may originate from electrochemical, chemical, and physical interaction between MMC constituents due to intrinsic properties or those induced by processing. Corrosion can be accelerated by galvanic interaction between the reinforcement, matrix, and interphases. The interphases and reinforcements may also undergo chemical degradation that are not electrochemical in nature. The presence of the reinforcements may also influence the MMC microstructure by inducing segregation, intermetallic formation, and dislocation generation. Processing deficiencies may result in unexpected forms of corrosion.

The parameters affecting MMC corrosion that will be discussed are (1) electrochemical effects related to the primary MMC constituents, (2) electrochemical effects of the interphases, (3) chemical degradation in MMCs, and (4) secondary effects caused by the microstructure and processing.

C1. Electrochemical Effects of Primary MMC Constituents

One of the major factors in MMC corrosion is galvanic action between the matrix and reinforcement if the reinforcement material is conductive or semiconductive. When using polarization diagrams to depict galvanic corrosion, the intersection of the anodic polarization curve of the matrix metal and the cathodic polarization curve of the reinforcement indicates the magnitude of the galvanic corrosion current density (i_{GALV}) (Fig. 35.3) for a galvanic couple with equal matrix and reinforcement area fractions. When matrix and reinforcement area fractions are not equal, the polarization diagrams must be plotted using the electrode current rather than the current density to account for the unequal area fractions. Galvanic corrosion in MMCs is governed by the reinforcement resistivity, electrochemistry, photoelectrochemistry, and area fraction and the matrix metal, environment, and microstructure.

C1.1. Common Reinforcement Types. Common reinforcement types used in MMCs are summarized in the following paragraphs.

C1.1.1 Boron. Although pure boron is an insulator and cannot support cathodic currents, the conductivity of boron monofilaments (B MFs) is many orders of magnitude greater than that of pure boron due to tungsten and tungsten borides in the MF core [22] (Table 35.1). Boron MFs consist of

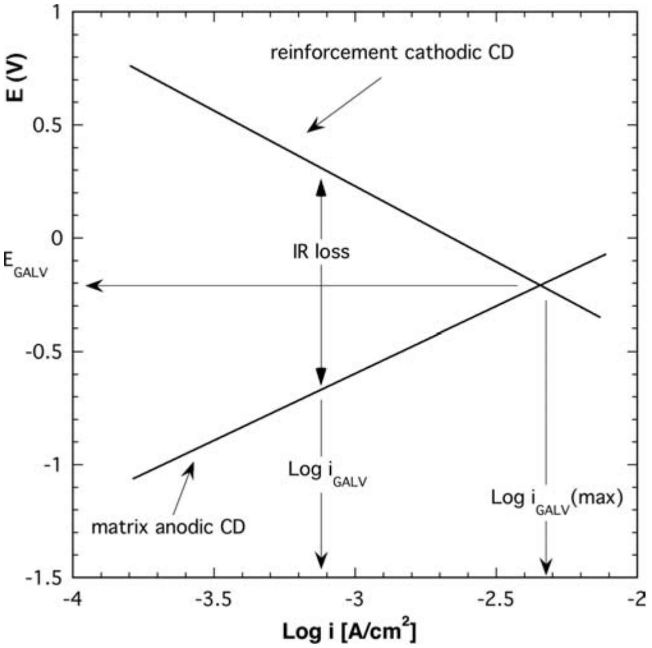

FIGURE 35.3. Anodic and cathodic polarization curves showing galvanic corrosion parameters.

polycrystalline boron with a core of tungsten and tungsten borides [22]. Hence, while pure boron cannot support cathodic currents, B MFs can serve as efficient cathodes.

C1.1.2 Graphite. Graphite reinforcement usually comes in the form of short or continuous fibers. Graphite has relatively low resistivity (Table 35.1) and therefore serves as very efficient cathodes for oxygen and proton reduction.

C1.1.3 Silicon Carbide. SiC reinforcement comes in the form of particles, whiskers, continuous fibers, or monofilament. The electrical resistivity of SiC increases with purity and can range from approximately 10^{-5} to 10^{13} Ω·cm [23]. SiC particles can be either of the high-purity green type or low-purity black type. Green SiC, which has higher thermal conductivity (in addition to higher electrical resistivity) than black SiC, is preferred for MMCs used in electronic packaging where high thermal conductivity is needed. SiC fibers have resistivities ranging from 10^3 to 10^6 Ω·cm depending on the fiber grade [24]. SiC MFs have carbon cores and carbon-rich surfaces with resistivities on the order of 10^{-2} Ω·cm [25] (Table 35.1). Consequently, due to the vast difference in electrical resistivities of SiC, variations in corrosion behavior may result. Hence, galvanic corrosion cannot be ruled out, and SiC can serve as an inert electrode for proton and oxygen reduction.

C1.1.4 Alumina. Alumina reinforcement comes in the form of particles, short fibers, or continuous fibers. The resistivity of Al_2O_3 (99.7 wt % pure) is greater than about 10^{14} Ω·cm [26], and therefore galvanic corrosion between Al_2O_3 and aluminum is not possible.

C1.2. Reinforcement Resistivity. Reinforcement materials generally fall into the categories of insulators, semiconductors, and conductors. For reinforcements that are insulators,

TABLE 35.1. Resistivities of Reinforcement Materials

Material	Resistivity (Ω·cm)	Temperature. (°C)	Notes	References
Al_2O_3	$>10^{14}$	30	99.7% Al_2O_3	[26]
Mica	10^{13}–10^{17}	—	Muscovite $KAl_3Si_3O_{10}(OH)_2$	[27]
SiC	10^{-5}–10^{13}	—	Function of purity	[23]
SiC fiber	10^3–$>10^6$	25	Nicalon™, dependent on grade	[24]
B	6.7×10^5	25	Pure	[28]
B_4C	10^0	—	—	[29]
Si	10^{-2}–10^5	—	Function of purity	[26]
P100 Gr fiber	2.5×10^{-4}	—	Thornel	[30]
P55S Gr fiber	7.5×10^{-4}	—	Thornel	[30]
SiC MF (ends)	4×10^{-2}	25	The "end" indicates that electrical contact was made with the end of the MF exposing the core; the "circumferential surface" indicates that electrical contact was made with only the MF circumferential surface (excluding the core). SiC MFs have carbon cores and BMFs have tungsten cores.	[31]
SiC MF (circumferential surface)	2×10^{-2}	25		
B MF (ends)	2×10^{-1}	25		
B MF (circumferential surface)	5×10^{-1}	25		

galvanic corrosion is not possible. For semiconductors, the degree of galvanic corrosion will be restricted by the magnitude of ohmic losses (IR) through the reinforcements (Fig. 35.3). The larger the IR loss, the lower will be the galvanic current. Assuming one-dimensional current flow through a reinforcement particle, the IR loss can be approximated as $i\rho l$, where the parameter i is the cathodic current density, ρ is the reinforcement resistivity, and l is the thickness of the reinforcement through which the current is assumed to be flowing. Since reinforcements are usually on the order of several micrometers, their resitivities have to be relatively high to significantly impede galvanic corrosion. For example, for an i_{GALV} of approximately 10^{-4} A/cm^2 and a 5-μm-thick reinforcement having a resistivity of 10^5 Ω·cm, the IR loss will be only 5 mV, which would have a negligible effect on galvanic corrosion. Hence, if IR losses are to limit galvanic corrosion, reinforcements having relatively high resistivity are needed. In addition, resistivity needs to be higher as the particle sizes decrease since ohmic losses decrease with particle size (i.e., IR loss = $i\rho l$). Many semiconductors do not have resistivities high enough to stifle galvanic corrosion. For example, the resistivity of SiC may vary by approximately 18 orders of magnitude depending on its purity [23]. Most particulate SiC-reinforced MMCs utilize black SiC, which has lower cost, purity, and resitivity than green SiC. The resistivities of various reinforcement materials are shown in Table 35.1. The treatment above for the ohmic losses through reinforcement particles should only be considered as an approximation since one-dimensional current flow was assumed. In the actual case, the ohmic drop through the edges of the particle could be much less than through the thickness.

C1.3. Reinforcement Electrochemistry. Although, as discussed above, the reinforcement resistivity is important, the rate of galvanic corrosion is also highly dependent on the catalytic properties of the reinforcements for proton and oxygen reduction. A low-resistivity reinforcement with poor catalytic properties for proton and oxygen reduction could induce less galvanic corrosion than a higher resistivity reinforcement with facile kinetics for the reduction reactions. For example, in the case of aluminum in aerated 3.15 wt % NaCl (Fig. 35.4) where galvanic corrosion is under cathodic control, the galvanic corrosion rate shows a strong dependency on the reinforcement type. The galvanic corrosion rates between the aluminums and various reinforcements ranked from highest to lowest as P100 Gr > SiC MF (ends exposed) > SiC MF (circumferential surface exposed) > B MF (ends exposed) > hot-pressed (HP) SiC > B MF (circumferential surface exposed) > Si. It should also be noted that ceramic reinforcements may vary in purity and structure, and some reinforcements are in themselves composites. For example, SiC MFs have carbon-rich outer layers and carbon cores, and their polarization diagrams have a stronger resemblance to P100 Gr than HP SiC. In addition, since the MFs often have cores that are of a different material than their surfaces, the orientation of the reinforcements may also affect corrosion behavior. The polarization behavior of MF electrodes with the circumferential surface exposed (MF^S) is different compared to the behavior of MF electrodes with the ends exposed baring the cores (MF^E). Compare cathodic curves for SiC MF^S versus SiC MF^E and B MF^S versus B MF^E in aerated (Fig. 35.4) and deaerated (Fig. 35.5) 3.15 wt % NaCl.

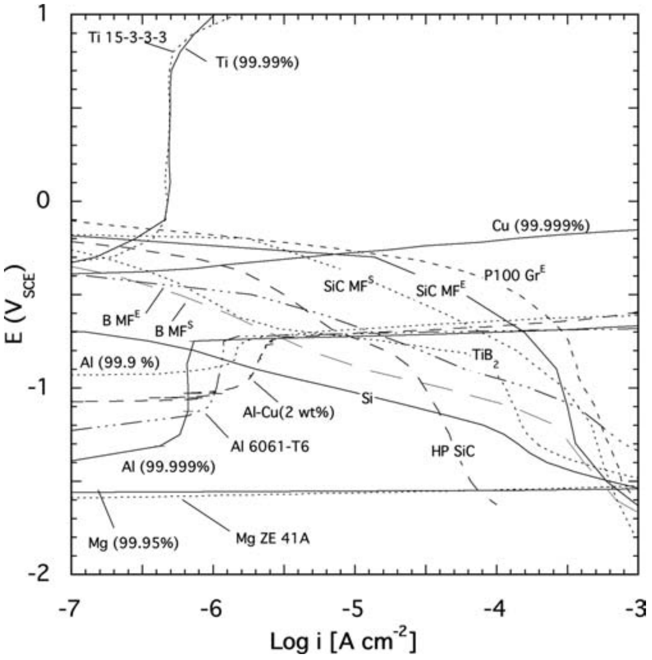

FIGURE 35.4. Collection of anodic polarization diagram of ultrapure Al (99.999%) [32], pure Al (99.9%) [33], Al–2 wt % Cu [34], Al 6061-T6 [32], ultrapure Ti (99.99%) [35, 36], Ti 15-3 [35, 36], ultrapure Cu (99.999%), pure Mg (99.95%) [37], and Mg ZE 41A [37]. Cathodic polarization diagrams of P100 Gr^E [32], HP SiC [32], SiC$_{MF}$^{E} [38], SiC$_{MF}$^{S} [38], Si [33], TiB_2 [32], B$_{MF}$^{E} [31], and B$_{MF}$^{S} [31] exposed to aerated 3.15 wt % NaCl at 30°C.

C1.4. Reinforcement Photoelectrochemistry. If the MMC reinforcements or constituents are semiconductors, galvanic currents between the matrix metal and the semiconductor could be suppressed under illumination if the semiconductor is n type or accelerated if the semiconductor is p type.

An n-type semiconductor is photoanodic and can promote photooxidation reactions under illumination. One such reaction is the oxidation of water. Hence, when an MMC containing n-type semiconductors is wet and under illumination, photogenerated electrons from the n-type semiconductor could polarize the MMC to more negative potentials inducing cathodic protection [39]. Accordingly, anodic

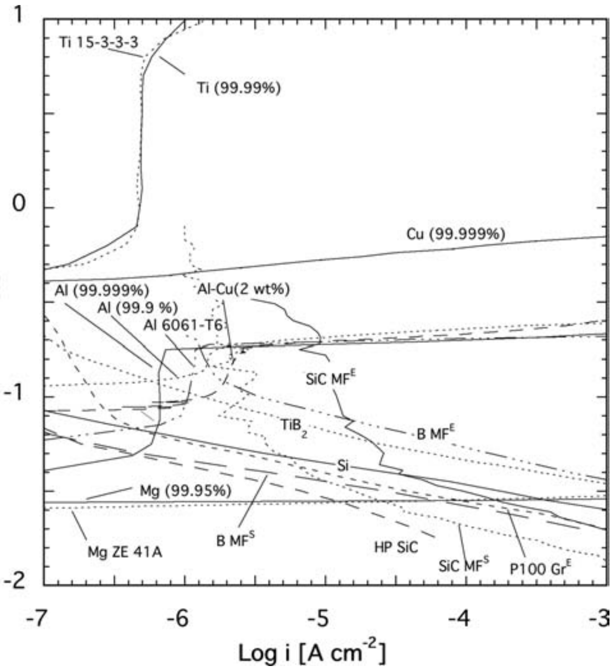

FIGURE 35.5. Collection of anodic polarization diagram of ultrapure Al (99.999%) [32], pure Al (99.9%) [33], Al–2 wt % Cu [34], Al 6061-T6 [32], ultrapure Ti (99.99%) [35, 36], Ti 15-3 [35, 36], ultrapure Cu (99.999%), pure Mg (99.95%) [37], and Mg ZE 41A [37]. Cathodic polarization diagrams of P100 Gr^E [32], HP SiC [32], $SiC_{MF}{}^E$ [38], $SiC_{MF}{}^S$ [38], Si [33], TiB_2 [32], $B_{MF}{}^E$ [31], and $B_{MF}{}^S$ [31] exposed to deaerated 3.15 wt % NaCl at 30°C.

current densities on Al 6092/Al_2O_3/20 P-T6 MMCs immersed in air-exposed 0.5 *M* Na_2SO_4 solutions increased sharply under illumination, which was attributed to photo-anodic currents generated by water oxidation on *n*-type TiO_2 particles in the microstructure that were likely introduced with the Al_2O_3 reinforcements [40]. The open-circuit potentials also decreased upon illumination, indicating that the *n*-type TiO_2 induced cathodic protection. Outdoor exposures of these Al 6092/Al_2O_3/20 P-T6 MMCs showed that corrosion films were thinner on the topside of specimens exposed to sunlight as compared to the backside of the specimens not exposed to sunlight [41]. Interestingly, MMCs containing *p*-type semiconductors had thicker corrosion films on the sunlit surfaces as apposed to the shaded surfaces [41].

A *p*-type semiconductor is photocathodic and under illumination promotes photoreduction reactions. Depending on the electrolyte conditions, proton or oxygen reduction may be enhanced at the *p*-type semiconductor. In the presence of moisture and illumination on MMCs that contain *p*-type semiconductors, photoreduction causes the cathodic current to increase, raising the corrosion potential and inducing greater dissolution of the matrix [39]. Accordingly, during cathodic polarization of Al 6092/SiC/P-T6 MMCs [39] that were immersed in air-exposed 0.5 *M* Na_2SO_4 solutions, cathodic current densities and open-circuit potentials increased sharply during illumination. In these MMCs exposed to the outdoors, corrosion films were also thicker on the sunlit surfaces as apposed to the shaded surfaces [41].

C1.5. Reinforcement Area Fraction. If the galvaniccorrosion rate is under cathodic control, galvanic corrosion should increase as the reinforcement area fraction increases. The catchment area principle [42] can be used to determine i_{GALV} as a function of the area fraction of the cathodic reinforcement [32]:

$$i_{GALV} = i_C \frac{X_C}{1 - X_C} \tag{35.1}$$

where the parameter i_{GALV} is the dissolution current density of the matrix (i.e., I_{GALV}/anode area), i_C is the current density of the cathode, X_C is the area fraction of the cathode, and $1 - X_C$ is the area fraction of the anode. The value of i_C can be set equal to the current density of the cathodic constituents at the galvanic couple potential. For Cu (99.999%), Al (99.999%, 99.9%, Al–2 wt % Cu, and 6061-T6 Al), and Mg (99.95%, ZE41A) coupled to P100 Gr, the i_C values are approximately 10^{-5}, 2.5×10^{-4}, and 7.9×10^{-4}, respectively, in aerated 3.15 wt % NaCl at 30°C (Fig. 35.4). By plotting Eq. 35.1, a graph (Fig. 35.6) was generated from which i_{GALV} of Cu, Al, and Mg can be obtained as a function of the area fraction of P100 Gr^E for exposure to aerated 3.15 wt % NaCl at 30°C. Note that i_C for Cu was in the Tafel regime and that for Al and Mg was in the diffusion-limited oxygen reduction regime (Fig. 35.4). Hence, galvanic corrosion rates for Al and Mg could increase significantly with convection, whereas that for Cu should not. The diagram

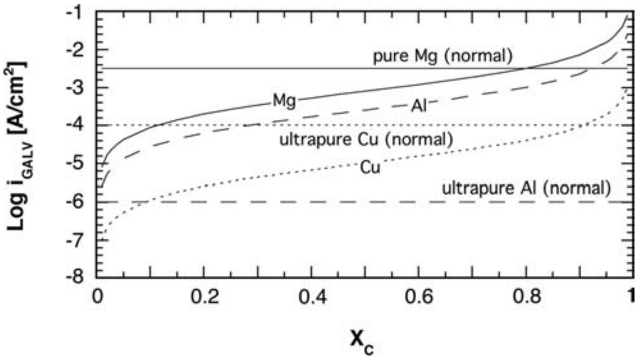

FIGURE 35.6. Graphs showing galvanic corrosion current density i_{galv} of Mg [i.e., pure Mg (99.95 %), Mg AZ41A], Al [i.e., ultrapure Al (99.999%), pure Al (99.9%), Al–2 wt %Cu-T6, or Al 6061-T6], and ultrapure Cu (99.999%) as a function of the area fraction of X_C of P100 Gr^E in aerated 3.15 wt % NaCl at 30°C. Normal corrosion rates of pure Mg, ultrapure Al, and ultrapure Cu are also plotted as horizontal lines.

(Fig. 35.6) also shows the normal corrosion rates of ultrapure Cu, ultrapure Al, and pure Mg. Hence, the area fraction of P100 Gr at which the galvanic corrosion rate would exceed the normal corrosion rate of the matrix metal varies with the type of metal.

C1.6. Matrix Metal. The matrix alloy plays a significant role in galvanic corrosion. In matrix alloys with noble open-circuit potentials, the effect of galvanic corrosion is generally attenuated. Notice that in deaerated 3.15 wt % NaCl (Fig. 35.5), titanium and copper are virtually immune to galvanic corrosion, whereas magnesium is highly susceptible.

C1.7. Environment. The environment can also have a significant effect on galvanic corrosion rates. For matrix alloys that corrode galvanically under cathodic control, galvanic corrosion rates can increase markedly when dissolved oxygen levels increase. The anodic polarization diagrams of several alloys are plotted with the cathodic polarization diagrams of various reinforcements in aerated (Fig. 35.4) and deaerated (Fig. 35.5) 3.15 wt % NaCl at 30°C. Marked increases in galvanic corrosion rates result from aeration (compare Figs. 35.4 and 35.5) for the various types of aluminum when they are galvanically coupled to P100 graphite, SiC MF, B MF, HP SiC, and TiB_2. Notice that galvanic corrosion rates do not increase for the aluminums coupled to Si since the polarization curves intersect in the passive aluminum regime, making galvanic corrosion under anodic control. In halide-free environments such as in 0.5 *M* Na_2SO_4, aluminum passivates and galvanic corrosion is also under anodic control; hence, aeration (Fig. 35.7) would not increase galvanic corrosion rates higher than that of the passive aluminum current density based on the polarization diagrams. The breakdown of passivity due to the presence of aggressive ions such as chlorides can also significantly increase galvanic corrosion rates (compare Figs. 35.4 and 35.7).

C1.8. Microstructure. The corrosion of the MMC is also affected by the physical presence of the reinforcements, even if they are inert. As the matrix alloy corrodes, the reinforcements are often left in relief, leaving behind a network of fissures that trap corrosion products and exacerbate corrosion. The initiation and propagation of corrosion sites are generally influenced by the electrical resistivity and volume fraction of the MMC constituents, including the reinforcements, interphases, and intermetallics. The corrosion behavior of MMCs in the open-circuit condition can be quite different from what might be expected based on their anodic polarization diagrams. For example, in near-neutral 0.5 *M* Na_2SO_4 solutions, various aluminum MMCs passivate during anodic polarization [43, 44], but in the open-circuit condition, the same MMCs are susceptible to localized

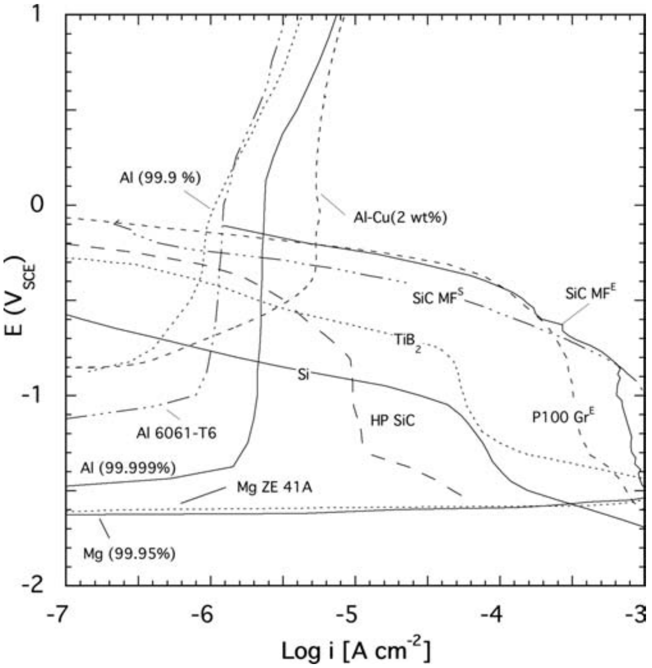

FIGURE 35.7. Collection of anodic polarization diagram of ultrapure Al (99.999%) [32], pure Al (99.9%) [33], Al–2 wt % Cu [34], Al 6061-T6 [32], pure Mg (99.95%) [37], and Mg ZE 41A [37]. Cathodic polarization diagrams of P100 Gr^E [46], HP SiC [46], $SiC_{MF}{}^E$ (oxygenated solution) [47], $SiC_{MF}{}^S$ (oxygenated solution) [47], Si [33], and TiB_2 [46] exposed to aerated 0.5 *M* Na_2SO_4 at 30°C.

corrosion. At the open-circuit potential, localized cathodic sites can become alkaline, and localized anodic sites can become acidified [45]. If the matrix metal is amphoteric like that of aluminum, dissolution may occur in the alkaline cathodic and acidic anodic regions [45]. Corrosion at alkaline cathodic regions usually occurs in aluminum MMCs when the cathodic constituents are of low area fraction, which concentrates the cathodic current and hydroxide ion buildup over a few cathodic sites. Hence, when predicting MMC corrosion behavior, polarization studies alone may be misleading.

An example of where corrosion was induced by localized cathodic currents was in Al 6092/Al_2O_3/20 P-T6 MMCs. In these MMCs, the Al_2O_3 reinforcement particles are insulators and cannot serve as cathodes; however, the microstructure also contained several types of titanium suboxides with compositions close to that of Ti_6O, Ti_3O, Ti_2O, and TiO; TiO_2 (likely doped); Ti–Zr–Al-containing oxides; and Fe–Si–Al intermetallics [40]. Of these particles, the titanium suboxides, TiO_2, and the Fe–Si–Al intermetallics supported significant cathodic activity [40]. The area fraction of the non-Al_2O_3 particles in the MMCs was estimated to be on the order of 0.01 using image analysis [43]. In the open-circuit condition, these sites were observed to be corrosion initiation sites in aerated 0.5 *M* Na_2SO_4, where the MMC passivates during anodic polarization.

C2. Electrochemical Effects of Interphases

During the fabrication processing of MMCs, reactions between the reinforcement and matrix may lead to the formation of an interphase at the reinforcement–matrix interface. The presence of the interphase may lead to corrosion behavior different from what might be expected based on virgin MMC constituents. For example, Pohlman [48] could not measure galvanic currents between virgin B MFs and Al 2024 or Al 6061 in 3.5% NaCl solutions, indicating that galvanic corrosion between aluminum matrices and B MFs should be negligible. In actual Al/B/MF MMCs, however, galvanic corrosion takes place between the aluminum matrix and the aluminum boride interphase on the surface layers of the B MFs [48]. Pohlman measured galvanic currents between the aluminum alloys and B MFs that were extracted from the matrix. A 4-μm-thick layer of aluminum boride enveloped the extracted B MFs. Galvanic currents measured between the aluminum alloys and aluminum boride were similar to those between the alloys and the extracted B MFs. When the layer of aluminum boride was removed from the extracted B MFs, the galvanic current ceased, which indicated that the aluminum boride interphase was necessary for galvanic corrosion.

C3. Chemical Degradation of Reinforcements and Interphases

MMCs may also degrade by chemical reactions that cannot be directly assessed by electrochemical methods. Reinforcement phases and interphases may undergo chemical degradation which cannot be detected by polarization techniques.

Muscovite mica $KAl_3Si_3O_{10}(OH)_2$ particles of approximately 70 μm in size [49] used in Al MMCs appeared to have absorbed moisture, swelled, and then exfoliated [50] during exposure to non-deaerated 3.5 wt % NaCl solutions.

The aluminum carbide Al_4C_3 interphase which is present in some aluminum MMCs may hydrolyze in the presence of moisture, forming methane and aluminum hydroxide. The rate of Al_4C_3 hydrolysis was measured to be approximately 1% per hour for hot-pressed Al_4C_3 (78% of theoretical density and porous) exposed to pure water at 30°C [46]. Methane evolution has been detected from Al/Gr MMCs containing Al_4C_3 [51, 52]. Buonanno [52] reported that Al_4C_3 hydrolysis in Al/Gr MMCs leaves fissures at fiber–-matrix interfaces. The hydrolysis of Al_4C_3 therefore could result in rapid penetration into the MMC microstructure through reinforcement–matrix interfaces, leading to the formation of microcrevices. Al_4C_3 can form by the reaction of aluminum and carbon [53], SiC [54], or B_4C [55] at elevated temperatures that could be encountered during MMC processing. Hence, if processing conditions are not properly controlled, MMCs containing Al and carbon compounds could contain this deleterious interphase.

C4. Secondary Effects

Corrosion in MMCs is also influenced by factors that are not directly caused by the reinforcement, matrix, or interphase but result due to their presence. For example, the reinforcement phase in the MMC may alter the microstructural features in the matrix metal in ways that do not occur in the monolithic matrix alloy. Examples discussed below are the effects of intermetallic phases which may form around the reinforcements by solute rejection during solidification [56], dislocation generation by the mismatch in CTE between the reinforcement and matrix [57], and the susceptibility of the MMC microstructure to physical damage. In addition, problems related to processing deficiencies are disused.

C4.1. Intermetallics. In MMCs, the presence of the reinforcement phases may affect the normal precipitation characteristics of intermetallic phases in comparison to those of the monolithic matrix alloy. The intermetallics also have their own characteristic electrochemical properties (e.g., corrosion potentials, pitting potentials, and corrosion current densities [58]). Noble intermetallics may induce galvanic corrosion of the matrix, whereas active intermetallics may go into dissolution and leave fissures or crevices. Hence, the difference between the corrosion characteristics of the MMC and its monolithic matrix alloy is also dependent on the extent to which the reinforcement phases affect the amount, distribution, and morphology of the intermetallics in the MMC.

In Al/Al_2O_3 MMCs, Al_8Mg_5 and Mg_2Si intermetallics provided corrosion paths along fiber–matrix interfaces [59]. Pits in Al/Al_2O_3 MMCs exposed to NaCl solutions containing H_2O_2 were attributed to the dissolution of $MgAl_3$, which is rapidly attacked at low potentials [60]. In Al/mica MMCs, a dendritic phase which was probably Mg_2Al_3 or Al_8Mg_5 and spheroidized $CuMgAl_2$ were preferentially attacked in non-deaerated 3.5 wt % NaCl [61].

C4.2. Dislocation Density. The high strength of particulate MMCs in comparison to their monolithic alloys is generated by high dislocation densities caused by a mismatch in the CTE between the reinforcement and matrix and heating and cooling histories [57]. Since cold working, which is the result of generating high dislocation densities, is known to change the corrosion behavior of metals such as steel [62] and aluminum [63], the corrosion behavior of MMCs may also be affected by high dislocation densities [31]. It has been suggested that corrosion near the SiC–Al interface in Al/SiC MMCs could be caused by high dislocation density due to a mismatch of the CTE between SiC and Al [64, 65].

C4.3. Physical Damage. MMCs can also be more susceptible to corrosion initiation at sites of physical damage in comparison to their monolithic alloys. Impacting the MMC

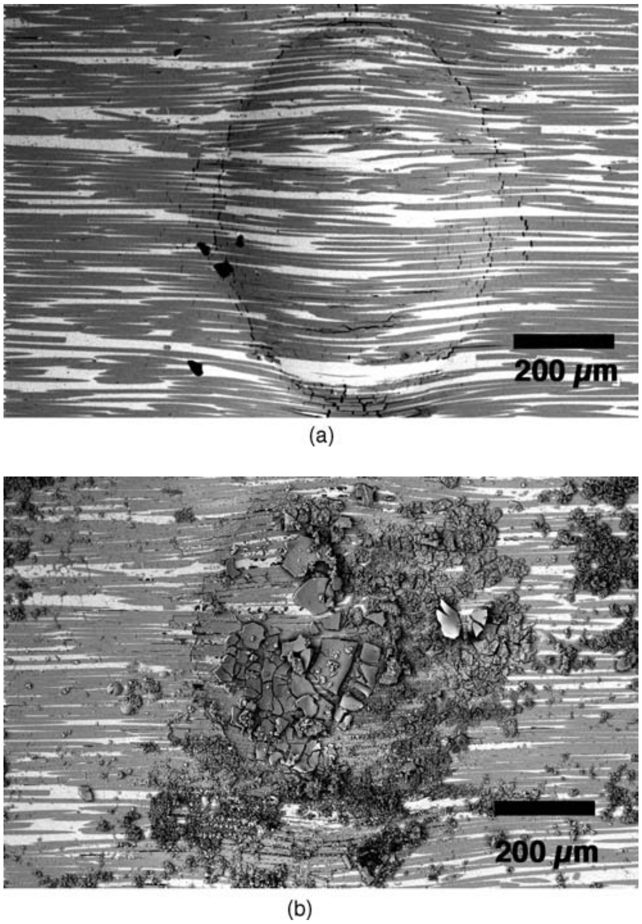

FIGURE 35.8. Al–2 wt % Cu/Al_2O_3/F 50 MMC with localized deformation induced using a 1.58-mm-diameter Si_3N_4 ball (a) before and (b) after immersion in aerated 3.15 wt % NaCl at 30°C for five days. Notice (a) broken fibers and (b) enhanced corrosion initiation over deformed region. (Photos courtesy of Shruti Tiwari.)

surface may debond the matrix from the reinforcement or fracture the reinforcement (Fig. 35.8) with both cases creating microcrevices that can lead to corrosion initiation sites. In Al-2 wt % Cu/Al_2O_3/50F MMCs, regions of localized deformation corroded preferentially when the MMCs were exposed to aerated 3.15 wt % NaCl. Significant amounts of Cu precipitated on the surface of the deformed region, where corrosion was exacerabated. For similar levels of localized deformation, pure Al/Al_2O_3/50F MMCs were much less susceptible to preferred corrosion initiation at locally deformed regions.

C4.4. Processing Deficiencies. Processing-induced corrosion is not inherently caused by the primary components of the MMC system but result from processing deficiencies such as too low or too high processing temperatures, contamination, and so on. Some cases that were observed in various MMCs were (1) low-integrity diffusion bonds that induced crevice corrosion between B MF and the aluminum matrix [66, 67], (2) microstructural chloride contamination originating from $TiCl_4$ and BCl_3 processing gases [68] that induced pitting [69] in some types of Al 6061/Gr/50 F-T6 MMCs in chloride-free environments, and extraneous carbon particles in Al 6092/B_4C MMCs [70], exacerbating galvanic effects.

Unlike the case with many types of metal alloys, MMCs cannot be always reprocessed to regain optimal properties. If an MMC had been subjected to high temperatures that lead to interphase formation, reprocessing the MMC to reverse the interphase formation would be unlikely. Also, fractured or damaged reinforcement constituents cannot be repaired. Therefore, it is very important to know the source and history of MMC products.

D. CORROSION OF MMC SYSTEMS

The corrosion behavior of aluminum, magnesium, titanium, copper, stainless steel, lead, depleted uranium, and zinc MMCs is discussed.

D1. Aluminum MMCs

Aluminum is a reactive metal with a high driving force to revert back to its oxide, but it generally has good resistance to aqueous corrosion in near-neutral solutions due to the formation of a passive film [71]. In acidic and basic solutions, the passive film is not thermodynamically stable and thus corrosion rates are high [71]. Aluminum pits in halide-containing solutions and the pitting potential (E_{pit}) is linearly dependent on the logarithm of the halogen anion concentration [72]. However, in order for aluminum to pit in the open-circuit condition, it must be polarized to potentials noble to E_{pit} by a cathodic reaction. Proton and oxygen reduction are two possible cathodic reactions, but in neutral, chloride-containing solutions, oxygen reduction is necessary to initiate pitting. Pits do not nucleate on aluminum in the open-circuit condition if solutions are deaerated [73]. In aerated solutions, ultrapure aluminum (99.999 wt %), which is a poor catalyst for oxygen reduction, does not pit in the open-circuit condition. The slow oxygen reduction kinetics on ultrapure aluminum is believed to be caused by the high resistivity of aluminum oxide which restricts electron migration through the passive film [74, 75]. In aluminum alloys, however, noble precipitates and conducting reinforcements can polarize the alloy to E_{pit} in aerated solutions. Corrosion of aluminum MMCs reinforced with boron, graphite, SiC, Al_2O_3, and mica will be discussed. Studies on stress corrosion and corrosion fatigue are also discussed.

D1.1. Aluminum/Boron MMCs. Al/B/MF MMCs are usually fabricated by diffusion bonding B MFs between aluminum foils [76]. Aluminum borides (i.e., AlB_{12} and AlB_2)

have been found at B MF matrix interfaces [77]. Both the B MF ends and circumferential surfaces can support cathodic currents (Figs. 35.4 and 35.5) and therefore can induce galvanic corrosion. Hence, shielding the MFs from environmental exposure is a likely provision for corrosion control of these MMCs.

D1.2. Aluminum/Graphite MMCs. Al/Gr MMCs are usually reinforced with either continuous or chopped fibers. The MMCs reinforced with continuous fibers have anisotropic properties with high specific tensile strength and stiffness along the fiber axis, but limitations of shear, compression, and transverse strengths generally excludes their use in structural applications [2]. The high thermal conductivity, negative coefficient of thermal expansion, and high stiffness of graphite, however, has made ultralow expansion Al/Gr MMCs ideal for thermally stable space structures.

The advantages of graphite for enhancements in mechanical and physical properties, however, are tempered with negative characteristics regarding corrosion resistance that graphite imparts due to its low electrical resistivity, catalytic properties for oxygen reduction, and reactivity with aluminum at high temperatures. Severe galvanic corrosion is induced in Al/Gr MMCs in aerated solutions (Fig. 35.4), with the main cathodic reaction being oxygen rather than proton reduction [78]. At elevated temperatures, graphite reacts with aluminum, forming the Al_4C_3 interphase, which readily decomposes in water [46] to produce CH_4 and aluminum hydroxide $Al(OH)_3$ [51]. Also see Section C3.

Al/Gr MMCs should therefore be carefully processed to avoid or minimize Al_4C_3 formation, and microstructures free of chlorides [69] should be ensured (see Section C4.4), either by careful control of processing parameters if chlorinated gases are used or using fabrication methods that do not use chlorinated gases [68]. Due to the reactivity of Al/Gr MMCs, they are more suited for use in dry environments. Certain corrosion-resistant procedures used for monolithic Al such as anodization may not be suitable for Al/Gr MMCs since the graphite fibers can be easily oxidized at positive potentials [79].

D1.3. Aluminum/Silicon Carbide MMCs. The Al/SiC MMCs have been reinforced with particles, whiskers, fibers, or monofilament. Due to the vast difference in electrical resistivities of SiC, variations in corrosion behavior may result. Hence, galvanic corrosion cannot be ruled out, and SiC can serve as an electrode for proton and oxygen reduction.

The degree of galvanic corrosion is strongly dependent on the type of SiC reinforcement. The anodic polarization diagrams (Fig. 35.4) of ultrapure Al (99.999%), pure Al (99.9%), Al–2 wt % Cu, and Al 6061-T6 with the cathodic polarization diagrams of HP SiC, SiC MF (with either carbon cores or carbon-rich surface exposed) in aerated 3.15 wt % NaCl shows that the galvanic current density of the aluminums coupled to SiC MF is approximately 15 times that when coupled to HP SiC of equal surface area. The influence of the carbon core and carbon-rich surface of the SiC MF is clearly seen (Fig. 35.4) where the polarization diagram of the SiC MF has a stronger resemblance to that of pitch-based graphite (P100 Gr) than that of HP SiC [25]. Galvanic current between a type of Nicalon™ SiC fiber and an aluminum alloy was also measured in an aerated NaCl solution [80], but the galvanic current was only 15% of that between carbon fiber and the aluminum alloy.

Experimental results have generally indicated that the corrosion rate of particulate and whisker Al/SiC MMCs are higher than the monolithic matrix alloy [81–84] and increase with SiC content [84, 85] in aerated, chloride-containing environments. Weight loss data of 6092/SiC/P-T6 Al MMCs showed an increase in the corrosion rate as the SiC content increased from 5, 10, 20, 40, to 50 vol % for various 90-day humidity chamber tests [86]. At the 50 vol % SiC content level, the corrosion rate for an MMC with high-purity, high-resistivity green SiC was noticeably lower than that of the MMC with low-resistivity black SiC [86]. The black SiC is likely to support more cathodic currents leading to higher corrosion rates in comparison to green SiC. The large variation in resistivity of the SiC may be the cause for conflicting results in the literature on the corrosion of Al/SiC MMCs. For example, no obvious evidence of galvanic corrosion was found in Al 6061/SiC MMCs with 17–27 vol % SiC particles [87].

The presence of SiC particles does not have a significant effect on the aluminum matrix passive current densities [84, 86, 88, 89] and pitting potentials [80, 86–88, 90–95]. Pit morphology, however, is indirectly affected by the presence of SiC particles. Pits on Al/SiC/W MMCs were notably more numerous and much smaller in size [96] compared to pits on wrought and powder-compacted monolithic alloys during anodic polarization in 0.1 N NaCl. The pits nucleated at intermetallic particles (not SiC), which are smaller and more numerous in the MMCs than in the monolithic matrix alloys [96]. SiC whiskers [96] and particles [87] can enhance the precipitation of the intermetallic phases. Pitting has also been observed at dendrite cores [97], near-eutectic silicon [94, 98], and intermetallic particles [98] in various Al/SiC MMCs. In the open-circuit condition, pits have also been observed to initiate at SiC–Al interfaces and could be caused by galvanic action with the SiC particle if the resistivity of SiC is relatively low or the hydrolysis of Al_4C_3 at the SiC–Al interface [43].

Since the corrosion behavior of Al/SiC MMCs is dependent on the microstructure, the corrosion characteristics can be altered by processing. In the MMC, void content [99], dislocation density [100], agglomeration of SiC particles [101], and the precipitation of active phases [102] are affected by processing conditions. Certain solution heat

treatments and high extrusion ratios improved the corrosion resistance of an Al 7091/SiC/20 P MMC [99]. Extrusion improved the corrosion resistance of cast MMCs by reducing the amount of pores and agglomerates of SiC particles [101]. Corrosion resistance was also improved by a finer, more homogenous distribution of secondary phases at the T4 temper in comparison to the O and F tempers [103]. It has been suggested that corrosion near the SiC–Al interface could be caused by high dislocation density due to a mismatch of the coefficient of thermal expansion between SiC and aluminum [25, 64, 65], segregation of alloying elements to the SiC–Al interface [104], or the formation of Al_4C_3, which hydrolyzes in water. Aluminum carbide has been identified as a source of corrosion for MMCs reinforced with particles [105] and SiC Nicalon™ fibers [80]. Also see Section C3.

The formation of micro crevices caused by reinforcement particles left in relief as the matrix corrodes also exacerbates corrosion by localized acidification in anodic regions and alkalinization in cathodic regions in Al6092/SiC/P-T6 MMCs [45, 106]. The aluminum matrix loses its ability to passivate when the solution becomes either acidic or alkaline. Also See section C1.8.

D1.4. Aluminum/Alumina MMCs. Particles and both short and continuous Al_2O_3 fibers have been used to reinforce aluminum alloys. Characteristic properties of Al/Al_2O_3 MMCs are low-weight, high-temperature tensile and fatigue strengths, low thermal conductivity and expansion, and superior wear resistance. Galvanic corrosion between Al_2O_3 and aluminum is not possible since Al_2O_3 is an insulator.

The Al_2O_3 reinforcements usually do not have significant effects on pitting potentials [43, 80, 90, 92–94, 107] in chloride solutions. Passive current densities below the pitting potential have been reported to increase with Al_2O_3 content [107], although this may be related to processing since passive current densities for a particulate Al6092/Al_2O_3/20P-T6 MMC were consistent with other MMCs in sodium sulfate solutions and in chloride solutions under the pitting potential [86]. Microbial corrosion was also reported to be more significant on particulate MMCs in comparison to the monolithic alloy, indicating that the Al_2O_3–Al matrix interface or Al_2O_3 particles may have aided biofilm formation [108].

In Al/Al_2O_3 MMCs, corrosion initiation usually occurs at intermetallic particles or contaminants introduced with the Al_2O_3 reinforcements. Hence, Al/Al_2O_3 MMCs with pure Al matrices usually have excellent corrosion resistance due to minimal amounts of intermetallic precipitates that can serve as cathodic sites [34]. Only slight corrosion damage was observed on pure Al/Al_2O_3/50 CF MMCs exposed to marine atmosphere 0.5 mile from the coastline for an 11-month period [79]. The presence of intermetallics and segregation of alloying elements may contribute to localized corrosion near reinforcements. Preferential corrosion near fibers [34, 60, 109, 110] and particles [94, 110, 111] is sometimes noticed in chloride-containing solutions. In a 2 wt % Mg aluminum alloy MMC, Fe and high levels of Mg (10 wt %) were detected near fibers [60]. It was suspected that the presence of Mg originated from Mg_2Al_3. Pitting near fibers was attributed to corrosion of Mg_2Al_3, which is rapidly attacked at low potentials [60]. The Al_8Mg_5 and Mg_2Si intermetallics have also been reported to induce corrosion in Al/Al_2O_3 MMCs [59]. In Al–2 wt %Cu/Al_2O_3/50 CF MMCs, corrosion initiation occurred at copper-rich precipitates on the fiber–matrix interface [34]. In Al 6092/Al_2O_3/20 P-T6 MMCs, cathodic sites were identified as Fe–Si–Al intermetallics and low-resistivity Ti oxide or suboxide particles (likely introduced with the alumina reinforcement) [40].

D1.5. Aluminum/Mica MMCs. Muscovite ($KAl_3Si_3O_{10}(OH)_2$) mica particles less than about 70 µm in size have been used in Al/mica MMCs [112] for potential use in applications where good antifriction, seizure resistance, and high-damping capacity are required [113]. Since muscovite is an insulator with resistivities that range from approximately 10^{13} to 10^{17} Ω·cm [27], galvanic corrosion should not be a problem. Muscovite is insoluble in cold water [114], but it has also been reported to absorb moisture and then swell [115]. Mica particles were cast in various aluminum alloys [115, 116]. In 3.5 wt % NaCl solution, the Al/mica MMCs had pitting potentials approximately 20–30 mV lower than the monolithic matrix alloys. In addition, intermetallics were preferentially attacked, regions around and away from mica particles pitted, mica–aluminum interfaces corroded, and mica particles exfoliated [50]. Also see Section C3.

D1.6. Stress Corrosion Cracking of Al MMCs. There have been only a few studies on stress corrosion cracking and corrosion fatigue of DR and CR Al MMCs.

D1.6.1 Discontinuous Reinforced MMCs. Stress corrosion cracking studies for alternate exposure and immersion in NaCl solutions have been conducted on aluminum MMCs reinforced with Al_2O_3 particles [117] and SiC particles [117–119] and whiskers [117]. The Al2024/Al_2O_3/P MMC was susceptible to stress corrosion cracking while subjected to three-point beam bending and alternate exposure or continuous immersions in a NaCl solution [117]. Under the same conditions, however, the 6061 Al MMCs reinforced with SiC particles and SiC whiskers were not susceptible to stress corrosion cracking [117]. Similarly, Al2024/SiC/P MMCs were not prone to stress corrosion cracking under constant strain at 75% of ultimate tensile strength while exposed to an aerated NaCl solution [118]. Slow strain rate tension testing of Al 2024/SiC/P MMCs indicated that the MMC lost up to 10% of failure strength compared to exposure in air [119].

D1.6.2 Continuous Reinforced MMCs. Stress corrosion cracking studies for the immersed state have been conducted on aluminum MMCs reinforced with unidirectional, graphite fibers [120], boron monofilaments [66], and Nextel 440 (Al_2O_3, SiO_2, B_2O_3) fibers [121]. Al6061/Gr/F MMCs were stressed parallel to the fiber axis in natural seawater. Failure was stress dependent at high stress levels and occurred in less than 100 h. At lower stresses, failure was primarily caused by extensive corrosion and therefore was relatively independent of stress levels. Al2024/B/MF MMCs stressed parallel to the fiber axis at 80% fracture strength in an NaCl solution did not fail in 1000 h but failed after 500 h when H_2O_2 was added to the NaCl solution. Extensive intergranular matrix corrosion and broken filaments at random sites were observed. The monolithic matrix alloy failed within 10 h under similar conditions. For Al2024/B/MF MMCs stressed perpendicular to the fiber axis at 90% yield strength in NaCl and NaCl with H_2O_2 solutions, failure occurred by intergranular matrix corrosion and separation at diffusion-bonded fiber–matrix interfaces. Failure times decreased with increasing B MF content; therefore, the presence of the MF was deleterious when stresses were perpendicular to the fiber axis. For the Al6061/Nextel/F MMCs, specimens were exposed to a pH 2 NaCl solution in the stressed and unstressed states [121]. The composite strength was measured before and after exposure to assess damage. The prevailing mode of failure was attributed to extensive corrosion along the fiber–matrix interface and not stress corrosion cracking.

D1.7. Corrosion Fatigue in Al MMCs. Corrosion fatigue studies have been conducted on Al MMCs reinforced with graphite fibers [120], SiC whiskers [122–125], and SiC particles [123, 126]. Processing conditions and type of reinforcement affect corrosion fatigue behavior. Unnotched Al6061/Gr/F MMCs were exposed to natural seawater and stressed parallel to the fiber axis. The MMCs were processed with either silica (SiO_2)–coated or TiB_2-coated graphite fibers. For a given stress amplitude, the MMC with TiB_2-coated fibers had the longest corrosion fatigue life, followed by the MMC with the SiO_2-coated fibers and the monolithic matrix alloy. At low stress amplitudes corresponding to longer exposure times, the MMC with the SiO_2-coated fibers suffered premature failure due to extensive corrosion. In Al/SiC MMCs, fatigue crack rates of compact tension specimens are usually higher in NaCl solutions as compared to air [122] or argon [126]. Loading frequency affects corrosion fatigue crack rates [126], but no consistent trends were observed. Fatigue [122] and corrosion fatigue [126] crack rates are influenced by loading and extrusion or rolling direction. The nucleation of a crack was also observed at the bottom of a corrosion pit [125]. The shape of the reinforcement constituent may also have significant effects on stress corrosion and corrosion fatigue, based on modeling that considers crack-tip strain rate [124]. The model predicts that crack rates are reduced by increasing the reinforcement length-to-diameter ratio, which implies that MMCs reinforced with whiskers are more resistant to stress corrosion and corrosion fatigue than those reinforced with particles. This is in agreement with results on Al6061/SiC/W MMCs that were found to have longer corrosion fatigue lives than Al6061/SiC/P MMCs in salt-ladened moist air [123].

D2. Magnesium MMCs

Magnesium is the lightest (density of only 1.7 g/cm^3) and most active structural metal in the electromotive series [127]. Therefore, it has a very high driving force for corrosion, making it particularly susceptible to galvanic corrosion if it is coupled to noble reinforcement constituents. The normal corrosion of Mg is generally not affected significantly by dissolved oxygen [127] since the primary cathodic reaction in Mg corrosion is proton reduction. Hence, noble impurity elements that have low hydrogen overvoltage (e.g., iron, nickel, cobalt, and copper) [128] can significantly accelerate the corrosion rate of Mg, which is highly dependent on metallic purity [127]; for example, ultrapure Mg corrodes at the rate of 0.25 mm/y in seawater, but commercial Mg corrodes at about 100–500 times faster due to impurities [127]. If Mg is reinforced with constituents that are catalytic to oxygen reduction, MMC corrosion rates may significantly increase with aeration whereas that of the monolithic matrix alloy may not. Corrosion studies have been conducted on magnesium MMCs reinforced with B MF, graphite fibers, SiC MF, SiC particles, and Al_2O_3 fibers. The stress corrosion cracking behavior of an Mg/Al_2O_3 MMC has also been investigated.

D2.1. Magnesium/Boron MMCs. Galvanic corrosion between Mg and pure boron is not a concern since pure boron is an insulator [129, 130]. However, tungsten core B MF is not an insulator due to the formation of tungsten boride [130]. Galvanic currents between virgin B MF (tungsten cores either shielded or exposed) and Mg [130] or an Mg alloy [129] were measurable in NaCl solutions. Galvanic currents were higher when tungsten cores were exposed [129, 130] since pure tungsten is an effective cathode [129]. Galvanic current densities increased approximately five times when Mg was coupled to B MF extracted from the matrix [129]. Corrosion rates of actual Mg alloy (MA2-1)/B/MF MMCs in 0.005 N and 0.5 N NaCl solutions were 12.5 and 81.7 g/m^2 day, respectively, which were about six times the values of the monolithic matrix alloy in respective environments.

D2.2. Magnesium/Graphite MMCs. The cathodic polarization diagrams of pitch-based graphite (cross section exposed) in aerated (Fig. 35.4) and deaerated (Fig. 35.5) 3.15 wt % NaCl with the anodic polarization diagrams of pure magnesium and Mg ZE41A in deaerated 3.15 wt %

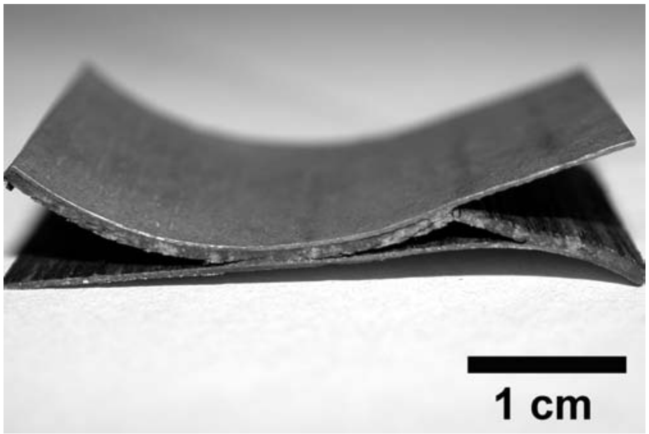

FIGURE 35.9. Exfoliated Mg AZ91C/Gr/12.7 F MMC with AZ31B Mg skins after a 20-year exposure period in an air-conditioned environment.

NaCl show that galvanic corrosion rates with graphite fiber will increase in aerated solutions. In addition, galvanic corrosion of magnesium is cathodically controlled, and therefore galvanic corrosion rates should increase with increasing area fraction of cathodic reinforcement material (Fig. 35.5). Actual MMCs immersed in air-exposed 0.001 *N* NaCl suffered severe degradation within five days [131]. Comparisons between a Mg AZ91C/Gr/40 P MMC and monolithic Mg AZ91C showed that the MMC open-circuit potential was approximately 0.3 V more noble and corrosion rate 40 times greater than that of the monolithic alloy in a deaerated 50-ppm chloride solution [132]. Even in relatively dry, air-conditioned environments an Mg AZ91C/Gr/12.7 F MMC with AZ31B Mg skins exfoliated over a 20-year period (Fig. 35.9).

D2.3. Magnesium/Silicon Carbide MMCs. Galvanic corrosion between magnesium and SiC depends on the type of SiC reinforcement and on the presence of dissolved oxygen in solution. Anodic polarization diagrams of pure magnesium and Mg ZE41A with cathodic polarization diagrams of HP SiC and SiC MF exposed in aerated (Fig. 35.4) and deaerated 3.15 wt % (Fig. 35.5) show that galvanic corrosion rates (as determined by the mixed-potential theory) are greater in aerated solutions due to oxygen reduction [47, 133]. Galvanic corrosion rates are lower for couples with HP SiC as opposed to the SiC MF which have carbon cores and surfaces. Studies conducted on particulate Mg ZE41A alloy reinforced with 12 vol % SiC particles ranging in size up to approximately 20 μm did not show preferential attack between SiC particles and the matrix in salt spray tests [134]. Instead, macroscopic anodic and cathodic regions developed. Corrosion spread over the MMC surface much more rapidly than on the monolithic alloy, but the local corrosion rates were approximately only three times greater on the MMC. The authors [134] speculated that the higher corrosion rates on the MMCs could have been caused by iron contamination of the magnesium matrix during processing in a steel crucible. Studies on a model MMC consisting of high-purity magnesium and well-separated SiC particles exposed to 3.5 wt % NaCl also did not show evidence of galvanic corrosion between the particles and matrix [135].

D2.4. Magnesium/Alumina MMCs. Galvanic corrosion should not be expected between magnesium and Al_2O_3 since Al_2O_3 is an insulator. The corrosion rates of an Mg AZ91C/Al_2O_3/CF MMC [136] was approximately 100 times greater than that of the matrix alloy in 3.5 wt % NaCl at 25°C but similar to that of the matrix alloy in distilled water at 20°C. The significantly higher corrosion rates of the composites in the chloride solution appear to be caused by the presence of the Al_2O_3 fibers. Although galvanic corrosion is not expected between magnesium and Al_2O_3, conducting interphases or precipitates could potentially form due to the presence of the Al_2O_3 fibers. The open-circuit potential of a Mg AZ91C/Al_2O_3/CF MMC was more noble than that of the matrix alloy in a 50-ppm Cl^- solution [137], indicating that noble precipitates or interphases could have been present.

Stress corrosion tests [138] of Mg ZE41A/Al_2O_3/CF MMC in an NaCl–potassium chromate (K_2CrO_4) solution showed that notched and unnotched specimens stressed parallel to the fiber axis and exposed for approximately 100–1000 h in the NaCl–K_2CrO_4 solution retained approximately 90% of the strength in air. The matrix alloy and the MMC with the stress direction aligned perpendicular to the fiber axis retained only approximately 40–60% of the strength in air.

D3. Titanium MMCs

Titanium MMCs are being developed for aerospace, commercial, and biomedical applications. Titanium has a density of 4.5 g/cm^3.

D3.1. Titanium/Graphite MMCs. Porous titanium/Gr MMCs were processed and heat treated to fabricate a porous titanium/titanium carbide (TiC)/Gr MMC [17]. Polarization tests were conducted in 0.9 wt % NaCl and lactated Ringer's solution for in vitro use. The anodic polarization current densities of the MMCs were significantly higher than that of pure monolithic titanium, which passivated. The authors attributed the higher corrosion rates of the Ti/TiC/Gr MMC to its porosity, which may have prevented complete passivation of the titanium matrix. Another possibility for the higher current densities could be the oxidation of graphite particles (see Section D3.2).

D3.2. Titanium/Silicon Carbide MMCs. Corrosion studies on titanium alloy Ti–15V–3Cr–3Sn–3Al (Ti 15–3) [36] and titanium aluminide α_2-Ti_3Al (14 wt % aluminum, 21 wt %

niobium, balance titanium) [139] reinforced with SiC MF have been conducted. The corrosion behavior of Ti 15-3/SiC/MF MMC was investigated in 3.15 wt % NaCl. There was excellent agreement in the polarization diagrams of the actual MMC and that of a model utilizing the polarization diagrams of the individual constituents and the mixed-potential theory [36]. The matrix passivated and the carbon cores and carbon-rich outer surface of the SiC MF oxidized, likely forming CO_2 similar to that observed in graphite fibers under anodic polarization [69]. In the open-circuit condition, the galvanic current density between Ti 15-3 and SiC MF cannot exceed that of the passive current density of Ti 15-3 based on their polarization diagrams (Fig. 35.4), and zero-resistance ammeter results confirmed that galvanic currents between Ti 15-3 and SiC MF were negligible. The corrosion behavior of the α_2-Ti_3Al/SiC/MF MMC [139] was somewhat similar to that of the Ti 15-3/SiC/MF MMC [36], with the exception that the α_2-Ti_3Al matrix is less resistant to pitting. During anodic polarization, the α_2-Ti_3Al/SiC/MF MMC pitted at approximately 1 V_{SCE} in 0.5 N NaCl, which was approximately 0.5 V less than that of the monolithic matrix alloy. Some matrix pitting and crevice corrosion around the SiC MFs were also observed after anodic polarization. The galvanic current density of the α_2-Ti_3Al/SiC/MF MMC was negligible and limited to the passive current density of the α_2-Ti_3Al matrix [139].

D3.3. Titanium/Titanium Carbide and Titanium/Titanium Diboride MMCs. Particulate pure Ti/titanium carbide (pure Ti/TiC/P) and pure Ti/titanium diboride (pure Ti/TiB_2/P) MMCs were fabricated by cold isostatic pressing following by sintering [140]. No interphase products were identified in the pure Ti/TiC/P MMC after processing, whereas TiB intephase products were identified in the Ti/TiB_2/P MMC after processing. Composites reinforced with 2.5, 5, 10, and 20 vol % TiC or TiB_2 were anodically polarized in deaerated 2 wt % HCl in the temperature range of 50–90°C. The passive current density for pure titanium was approximately 10^{-5} A/cm^2 throughout the temperature range. Generally, dissolution currents of the pure Ti/TiC/P and pure Ti/TiB_2/P MMCs increased with increasing temperature and reinforcement content, and maximum values were about 20 times and 100 times, respectively, higher than that of pure titanium. For both types of MMCs, microscopy revealed that the titanium matrix was virtually uncorroded, whereas, the TiC particles underwent some degradation, and the TiB_2 particles and TiB interphase were corroded significantly.

D4. Copper MMCs

Copper MMCs have been investigated for use in marine, electronic, and thermal applications. Copper is relatively heavy, with a density of 8.96 g/cm^3. Reinforcements are typically chosen to impart strength and stiffness, reduce weight, enhance thermal and electrical properties, improve machinability, and enhance wear resistance. Initial studies [1] were conducted on a wide variety of experimental copper and copper alloy MMCs reinforced with graphite, SiC, TiC, silicon nitride, boron carbide, and Al_2O_3 for marine applications. The MMCs generally showed corrosion behavior that was similar to that of the monolithic alloys, although corrosion rates were higher for some of the MMCs. Other studies have focused on copper MMCs for electronic, thermal, and tribological applications.

D4.1. Copper/Graphite MMCs. The corrosion behavior of pure copper MMCs reinforced with 1.2–40 vol % graphite particles and 50 vol % graphite fibers in deaerated and aerated 3.5 wt % NaCl solutions [141] were investigated. The corrosion potential of the particulate-reinforced MMCs became more noble with increasing graphite content in both deaerated and aerated solutions, as would be expected by increasing the content of the noble graphite particles. The corrosion potential of the Cu/Gr/50 F MMC was approximately as noble as the Cu/Gr/40 P MMC in the aerated solution but was significantly more active than the particulate composite in the deaerated solution. This finding could be expected since oxygen reduction kinetics is normally diffusion limited in aerated solutions, but hydrogen evolution kinetics depend on the substrate and could be different on the graphite fibers as compared to on the graphite particles in deaerated solutions. The corrosion potentials of C90300 copper alloy (with 1 wt % titanium additive to increase graphite wettability) MMCs reinforced with 1–10 vol % graphite particles also increased with increasing graphite content in an aqueous solution containing ferric chloride, copper sulfate, and hydrochloric acid [12].

D4.2. Copper/Silicon Carbide MMCs. The corrosion behavior of pure copper MMCs reinforced with 0, 5, 10, and 20 vol % SiC particles were examined in a 5 wt % NaCl solution [142]. Porosity in the materials ranged from 2.2 to 3.5% and generally increased with increasing SiC content. Corrosion potentials became more active, and corrosion current densities increased with increasing SiC content. Decreasing corrosion potentials would not be expected with increasing SiC content if SiC served as an efficient cathode. The corrosion morphology indicated that there was significant corrosion at SiC–copper interfaces. Voids caused by porosity and SiC–copper interfaces both increased with increasing SiC content. Hence, the decrease in corrosion potential with increasing SiC content is likely to have been caused by an increase in anodic sites at voids and SiC–copper interfaces.

D4.3. Copper/Alumina MMCs. The corrosion behavior of copper MMCs reinforced with 2.7 vol % Al_2O_3 was

examined in deaerated and aerated 3.5 wt % NaCl [143]. Galvanic corrosion with Al_2O_3 is not expected since Al_2O_3 is an insulator. The corrosion rates of the MMCs were comparable to that of monolithic copper, and the corrosion potentials of the MMC were only 0.01–0.02 V, more active than that of monolithic pure copper.

D5. Stainless Steel MMCs

Sintered, particulate composites consisting of ferritic 434L stainless steel (SS) and Al_2O_3 particles have been developed for potential application in chemical processing plants, turbine blades, and heat exchanger tubes [144–146]. Austenitic 316L SS reinforced with Al_2O_3 and Y_2O_3 have also been investigated for enhanced strength and wear resistance [147].

D5.1. Stainless Steel/Alumina MMCs. The corrosion behavior of sintered 434L SS/Al_2O_3 MMCs and sintered 434L SS alloy without Al_2O_3 particles was examined [144–146]. The volume percent of Al_2O_3 particles in these materials ranged from 0 to 8%. The effect of small amounts of titanium and niobium alloying elements on corrosion resistance was also investigated. Galvanic corrosion between 434L SS and Al_2O_3 should not occur since the latter is an insulator. In 1 *N* H_2SO_4 [144–146], there was no strong correlation between Al_2O_3 content and corrosion behavior. One of the few generalities that could be made was that passive-current densities were high and within an order of magnitude of 1 mA/cm^2 for almost all materials. In the 5 wt % NaCl solutions, i_{CORR} of the MMCs was less than 10 μA/cm^2 [145]. Upon polarization, all materials displayed active corrosion behavior in the NaCl solutions.

Particulate 316L SS MMCs [147], fabricated using powder metallurgy, were reinforced with 3, 4, and 5 wt % Al_2O_3 and additions of 2 wt % chromium diboride (CrB_2) or 1 wt % boron nitride (BN) for sintering aids. The density of the MMCs ranged from 86 to 96% of the theoretical value. Unreinforced 316L SS specimens were also fabricated using powder metallurgy without sintering aids, resulting in 85% of theoretical density. Less porosity was present in the reinforced MMCs as compared to the unreinforced pure 316L SS specimen. The test samples were immersed in 10 wt % sulfuric acid (H_2SO_4) at room temperature for 24 h, 1 wt % hydrochloric acid (HCl) at room temperature for 24 h, and boiling 10 wt % nitric acid (HNO_3) for 8 h. The pure, unreinforced 316L SS specimens passivated in the 10 wt % H_2SO_4 solution, whereas the corrosion rate of the MMC generally increased with increasing Al_2O_3 content to a maximum value of approximately 4 mm/yr. The MMCs performed better than the unreinforced 316L SS specimen in the 1 wt % HCl solution but worse than the unreinforced specimen in the boiling nitric acid solution. There was no strong correlation between Al_2O_3 content in the MMCs and the corrosion rates in 1 wt % HCl and boiling 10 wt % HNO_3 solutions.

D5.2. Stainless Steel/Yttria MMCs. Yttria (Y_2O_3) is an insulator and galvanic effects are not expected. The 316L SS specimens discussed above [147] were also reinforced with 3, 4, and 5 wt % Y_2O_3 and additions of 2 wt % chromium diboride (CrB_2) or 1 wt % BN as sintering aids. In all solutions (i.e., sulfuric, hydrochloric, and nitric acid solutions), the Y_2O_3-reinforced MMCs exhibited reduced corrosion resistance as compare to the Al_2O_3-reinforced MMCs. The Y_2O_3 MMCs were sintered to 88–96% of theoretical density, and the Al_2O_3 MMCs were sintered to 86–92% of theoretical density. The Y_2O_3 particles also showed better bonding to the matrix, probably forming a complex $YCrO_3$ oxide, as compared to the Al_2O_3 particles. It is possible that the formation of the reaction layer around the Y_2O_3 particles may have depleted chromium from the matrix, resulting in reduced corrosion resistance, as compared to the Al_2O_3-reinforced MMCs.

D6. Lead MMCs

Lead is a relatively heavy metal with a density of 11.4 g/cm^3. Lead MMCs, therefore, are normally developed for applications where a combination of its structural, physical, and chemical properties is important. The corrosion behavior of pure lead MMCs in simulated lead–acid battery environments has been studied to assess the feasibility of using these composites as positive electrode grids in place of conventional lead-based alloy grid materials. Lead can be alloyed with elements such as arsenic, antimony, or calcium to increase strength and stiffness. These elements, however, reduce corrosion resistance. Monolithic pure lead has very good corrosion resistance in lead–acid battery environments (which consists of sulfuric acid solutions) but is heavy and lacks sufficient mechanical strength. Pure lead, therefore, has been reinforced with strong, lightweight fibers in hopes of achieving the goals of increasing strength, reducing weight, and retaining the corrosion resistance of pure lead [148–150]. For other applications, discontinuous reinforced lead–antimony alloy MMCs were also studied in sodium chloride solutions [151].

To simulate corrosion in lead–acid battery environments, lead MMC reinforced with Al_2O_3, carbon, SiC, and glass–quartz fibers of various volume percents have been [148–150] anodically polarized at 1.226 V (vs. mercury/mercurous sulfate reference electrode) in sulfuric acid solutions (of 1.285 specific gravity) at 50, 60, and/or 70°C. At 1.226 V, lead and water are oxidized to lead dioxide (PbO_2) and molecular oxygen (O_2), respectively [152, 153]. About one-third of the total anodic current is consumed in the oxidation of lead under these conditions [150]. Poor bonding between Al_2O_3 fibers and the matrix allowed the electrolyte

to diffuse into fiber–matrix interfaces, leading to accelerated corrosion [148] and swelling of the composite due to corrosion product buildup [150]. The graphite fibers were also subjected to oxidation [149].

Lead (80 wt %)–antimony (20 wt %) alloy MMCs reinforced with 1–5 wt % zircon ($ZrSiO_4$) particles [151] were exposed to a 1 *N* NaCl solution. Zircon should not induce galvanic corrosion. Weight loss measurements, made over a 72-h period, showed that the corrosion rate of the MMCs increased with increasing zircon content.

D7. Depleted Uranium MMCs

Depleted uranium/tungsten fiber (DU/W/F) MMCs are the antithesis of the lightweight MMCs and were developed to create high-density materials. Uranium has a density of 18.9 g/cm^3.

DU corrodes galvanically when coupled to tungsten fibers in air-exposed 3.5 wt % NaCl solutions at room temperature [154]. The open-circuit potential of tungsten fiber ($-0.25\ V_{SCE}$) is noble to that of the DU alloy ($-0.80\ V_{SCE}$). The open-circuit potentials of the DU/W/F MMC and galvanic couples consisting of tungsten fiber and DU alloy of equal areas are -0.78 and $-0.77\ V_{SCE}$, respectively, and fall between those of tungsten fibers and the DU alloy. The galvanic corrosion current density measured between equal areas of tungsten fibers and the DU alloy was equal to about $4 \times 10^{-5}\ A/cm^2$. In a 30-day exposure test in the NaCl solution, the DU/W/F MMC lost 43.56 mg/cm^2, which was about 1.3 times that of the DU alloy.

D8. Zinc MMCs

Zinc MMCs have been developed [155] for potential use as bearing materials. Zinc has a density of 7.14 g/cm^3. Zinc alloy ZA-27 MMCs were cast with 1, 3, and 5 wt % graphite particles ranging in sizes from 100 to 150 μm. Zinc alloys are known to have excellent wear and bearing characteristics [156]. The zinc MMCs were resistant to corrosion in SAE 40 grade lubricant that had been in service for six months in an internal combustion engine. In 1 *N* HCl, the corrosion rates of the MMCs decreased with time.

E. CORROSION PROTECTION OF MMCs

Corrosion of metals can be prevented with the use of protective coatings and inhibitors. The use of impervious, inhibitive, or cathodically protective coatings will depend on the application and substrate. Selecting suitable coatings for MMCs will likely require testing and verification because a proven coating system for an alloy may not be effective for an MMC of that alloy. Poor adhesion and wettability between the coating and reinforcement or differences in the electrochemical properties of the alloy and MMC may render a good coating system for the alloy ineffective for the MMC. Other coating techniques such as anodization could also be ineffective or even deleterious to the MMC. When an aluminum MMC is anodized, for example, the reinforcements can impede the growth of a continuous aluminum oxide film [157] or the reinforcements can be compromised by oxidation such as in the case of graphite fibers that oxidize to CO_2 [46]. The use of inhibitors is usually reserved for closed systems and, therefore, may not be an option in many practical cases. An inhibitor intended for a monolithic alloy should not be used for an MMC of that alloy until ample examination confirms its effectiveness.

Various studies on the corrosion protection of MMCs utilizing organic coatings, inorganic coatings, anodization, and chemical conversion coatings have been summarized elsewhere [158], and results are given in Table 35.2. The studies have generally shown that the best protection for MMCs that are susceptible to corrosion has been achieved by completely shielding the MMC from the environment utilizing coatings. Undoubtedly, in the future, generally acceptable methods to protect MMCs will likely be developed.

F. SUMMARY

There are many additional concerns regarding the corrosion of MMCs in comparison to their monolithic matrix alloys. Certain MMC systems have inherent corrosion problems. Galvanic corrosion of the matrix may be induced by conductive reinforcements (e.g., Gr, some semiconductors with high impurity levels, and other metals). If reinforcements are semiconductive, *n* types could suppress galvanic corrosion of the matrix under illumination, while *p* types could induce galvanic corrosion under illumination. When the reinforcements are insulators, galvanic corrosion of the matrix will not be induced; however, the corrosion behavior of the MMC in comparison to the monolithic matrix alloy may be different. Whether the reinforcements are conductive, semiconductive, or insulating, they can affect the precipitation of intermetallics, induce higher dislocation densities, and react with the matrix-forming interphases. All of these phenomena may alter the corrosion behavior of the MMC in comparison to the monolithic matrix alloy. Corrosion initiation in MMCs may also be more sensitive to physical damage. Impacting the MMC surface may lead to debonding at the reinforcement–matrix interface or fracturing the reinforcement leading to the formation of minute crevices, which may enhance corrosion initiation. The problem could possibly be exacerbated with MMCs having higher strength matrices and higher reinforcement content. Caution should be used in assuming that MMCs belonging to a specific MMC group (e.g., Al/SiC MMCs) all have similar corrosion behavior since variations

TABLE 35.2. Summary of Corrosion Protection Studies on MMCs

MMC Type	Substrate Protected	Coating/Treatment	Environment	Outcome	References
Al/Gr	Surface Al foils on MMC	Organic coatings	Marine and NaCl solution	Protection	[159–161]
	Al/Gr MMC	Inorganic diamondlike coating	NaCl solution	Short-term protection	[162]
	Surface Al foils on MMC	CVD and PVD inorganic coatings	Marine	No protection	[159]
	Surface Al foils on MMC	Electroplated Ni coating (without defects)	Marine	Protection	[159]
	Surface Al foils on MMC	Electroless Ni coating (with defects)	Marine	Accelerated corrosion	[163, 164]
	Al/Gr MMC	Ti and Ni cladding	Marine	Delamination from exposed edges	[159]
	Surface Al foils on MMC	Electrodeposited Al/Mn on electroless Ni coating	Marine	Protection if panel edges were sealed to prevent Al/Gr exposure	[159]
	Surface Al foils on MMC	Anodization with dichromate sealing	Marine	Protection if panel edges sealed	[163]
	Surface Al foils on MMC	Chromate/phosphate conversion coating	Marine	Protection if edges sealed with epoxy	[163]
	Surface Al foils on MMC	Chemical passivation with $CeCl_3$	NaCl solutions	Delayed pitting on surface foils	[165, 166]
Al/SiC	Al/SiC MMC	Organic epoxy coating	Marine and NaCl solution	Protection	[160, 163]
	Al/SiC MMC	Plasma-sprayed alumina coating	Marine	Protection	[163]
	Al/SiC MMC	Flame-sprayed Al coating	Marine	Protection	[163]
	Al/SiC MMC	Anodization	Marine and NaCl solution	Various levels or protection	[167–170]
	Al/SiC MMC	Chemical passivation with $CeCl_3$	NaCl solution	Limited protection	[165, 171]
Al/Al_2O_3	Al/Al_2O_3 MMC	Chemical passivation with $CeCl_3$	NaCl solution	Limited protection	[172, 173]

in the quality of the reinforcement and matrix alloy, manufacturing technique (e.g., powder metallurgy versus casting), thermomechanical processing, and other factors can all alter corrosion behavior. Hence, it will be difficult to obtain generalized and consistent corrosion behavior for a specific MMC group until standards are developed for the manufacture and processing of MMCs.

NOMENCLATURE

B MF	Boron monofilament
B_{MF}^{E}	B_{MF} electrode with MF ends exposed
B_{MF}^{S}	B_{MF} electrode with MF circumferential surface exposed
CD	Current density
E_{pit}	Pitting potential
E_{GALV}	Galvanic couple potential
Gr	Graphite
Gr^{E}	Gr electrode with fiber ends exposed
HP	Hot pressed
I	Current density
i_c	Cathodic current density
i_{CORR}	Corrosion current density
i_{GALV}	Galvanic current density
MMC	Metal–matrix composite
SC	Semiconductor
SiC MF	Silicon carbide monofilament
SiC_{MF}^{E}	SiC_{MF} electrode with MF ends exposed
SiC_{MF}^{S}	SiC_{MF} electrode with MF circumferential surface exposed
Superscript E	Electrode with fiber or MF ends exposed (e.g., SiC_{MF}^{E})
Superscript S	Electrode with fiber or MF circumferential surface exposed (e.g., SiC_{MF}^{S})
T	Thickness
vol %	Volume percent
V_{SCE}	Volts versus a calomel electrode
wt %	Weight percent
x_C or X_C	Cathodic area fraction
ρ	Resistivity

Units

A	Amperes
cm	Centimeter
h	Hours
s	Seconds
V	Volts
Ω	Ohm

A. INTRODUCTION

All the countries addressing the issue of nuclear waste, mainly produced by nuclear power plants, are considering disposing them in stable geologic repositories. In most of the repositories (e.g., Finland, Sweden, Canada, France) the environments will be reducing in nature, except for the repository in the United States, in which the ingress of oxygen will not be restricted. For the reducing repositories the different national programs are considering materials as carbon steel and copper. For the repository in the United States, some of the most corrosion-resistant commercially available alloys, such as nickel and titanium alloys, are being characterized. This chapter presents a summary of the behavior of the different materials under consideration for the repositories and the current understanding of the degradation modes of the proposed alloys in groundwater environments from the point of view of general corrosion, localized corrosion, and environmentally assisted cracking.

Recent concerns about global warming and the release of greenhouse gases by the fossil fuel power industry have reignited the consideration of alternative sources of energy such as wind, solar, fuel cells, and nuclear power. Currently there are more than 40 nuclear power reactors under construction in the world, most of them in Asia [1]. Because of this, some reports claim that there is a nuclear power renaissance. However, even though nuclear power has been used for more than 60 years, the issue of the toxic radioactive waste generated during energy production still needs to be resolved. Radioactive materials are pertinent not just to nuclear power since they are also used worldwide in other fields, including medical applications and production of weapons. Once the radioactive materials lose their commercial value, they are considered radioactive waste, and they need to be isolated from the environment until the radioactive decay has reduced its toxicity to innocuous levels for plants, animals, and humans. Different types of radioactive waste are produced during commercial and defense nuclear fuel cycles. One type of waste, denoted high-level waste (HLW), contains the highest concentration of radiotoxic and heat-generating species. Because of this factor, the most stringent standards for disposing of radioactive wastes are being placed

Uhlig's Corrosion Handbook, Third Edition, Edited by R. Winston Revie

worldwide on HLW, and the majority of the radioactive waste management effort is being directed toward the HLW problem. One of the most common and most voluminous types of HLW is the spent fuel (SF) from commercial nuclear reactors for power generation.

All of the countries currently studying the options for disposing of HLW have selected deep stable geologic formations to be the primary barrier for accomplishing this isolation. It is postulated that, by the very nature of these geologic sites, they will contain the waste for long times, limiting their spread, for example, through water flow. All the repository designs also plan to delay the release of radionuclides to the environment by the construction of engineered barrier systems (EBS) between the waste and the geologic formation. These barriers will be installed to limit water reaching the repository and to restrict radionuclide migration from the waste. The principal engineered component in this multibarrier approach is the waste package, which includes the waste itself, possibly a stabilizing matrix for the waste such a glass, and a metallic container that encloses the wasteform. Beyond the metallic containers, other secondary barriers could be added to attenuate the impact of the emplacement environment on the containers. The secondary barriers may include a drip shield such as in the U.S. design or backfilling with bentonite such as in the Canadian and other designs (Table 36.1) [2, 3]. A discussion in detail of the characteristics and significance of the engineered barrier systems in all the planned repositories is given by Bennett et al. [4]

More than 30 nations are currently considering the geologic disposal of HLW [3–6]. A short list of these nations is in Table 36.1. Twenty years ago most of the repository designs specified lifetimes from 300 to 1000 years. Currently, the minimum length of time specified for some repositories has increased to 10,000, 100,000, and even 1,000,000 years [7–11]. The viability of extrapolating degradation data from short-term testing to long-time performance has been addressed by some investigators and the American Society for Testing and Materials (ASTM) [7, 12, 13]. Others have proposed models to predict the lifetime performance of container alloys [14, 15].

B. NATIONAL PROGRAMS

Table 36.1 lists some countries that are currently considering geologic repositories for nuclear waste. One of the most advanced studies for a repository corresponds to the United States, which is planning to locate its nuclear waste at a remote desert site in Nevada [16]. The container for the waste will be a double-walled cylinder having a 2.5-cm-thick layer of alloy N06022 on the outside and a 5-cm-thick layer of nuclear-grade type 316 stainless steel in the inside. After more than two decades of scientific investigations, the U.S. Department of Energy submitted a license application to build the repository on June 3, 2008, and the Nuclear Regulatory Commission accepted this application on September 8, 2008 [11, 17]. After a formal review process of three to four years, construction may start in late 2011, and the first waste emplacement may not occur until 2020 [7, 18]. Currently, the Yucca Mountain repository project does not seem a high priority of the U.S. Department of Energy [18]. The United Kingdom has also recognized that the geologic disposal of the waste in a mined repository is the best available approach [19]. In June 2008 the U.K. government issued the white paper “Managing Radioactive Waste Safely,” where a framework for implementing geologic disposal is outlined. The location for the repository will be defined through geologic screening and community engagement. To complement the permanent repository studies, the U.K. Committee for Radioactive Waste Management has also recommended a robust program of interim storage [19]. The Finnish repository will be located in crystalline bedrock at Olkiluoto Island on the western coast of Finland. The waste containers will be made using nodular cast iron with a 50-mm-thick overpack of copper [20]. The repository in Finland should start operations in 2020 and will continue for

TABLE 36.1. Selected Countries Considering Repositories for High-Level Waste

Country	Possible Environment, Host Rock	Scheduled Start Operations	Container Materials Being Studied
Belgium	Reducing or anoxic, clay	2035	Carbon steel, cement, stainless steel
Canada	Reducing or anoxic, granite	—	Carbon steel insert, copper
Finland	Reducing or anoxic, granite	2020	Cast iron insert, copper
France	Reducing or anoxic, clay	—	Carbon steel
Germany	Salt dome layer	2030	Carbon steel
Japan	Reducing or anoxic, granite plus bentonite buffer	Late 2030s	Carbon steel, titanium
Sweden	Reducing or anoxic, granite plus clay	2023	Cast iron insert, copper
Switzerland	Reducing or anoxic, clay	—	Carbon steel
United States	Oxidizing, non saturated, volcanic tuff	Initially 1998, now 2020	Ni–Cr–Mo Alloy C-22, titanium Gr 7, 28, and 29

approximately 100 years [21]. Sweden has elected a site for its underground repository in the municipality of Östhammar, 500 m below ground in crystalline rock [22, 23]. The waste will be packed in cast iron baskets inside thick copper canisters surrounded by bentonite clay. Each container is a double-walled cylinder of approximately 1 m diameter and 5 m long [22]. The Swedish repository is scheduled to open in 2023 and it is designed to contain the waste for 100,000 years [22]. The Japanese Final Disposal Plan calls for a repository that will start operating in the late 2030s [24]. The final site for the repository has not been selected yet, but two underground research laboratories have been selected, one 1000 m deep in crystalline rock in the presence of fresh water and the second in sedimentary rock 500 m deep in the presence of saline water [25]. In the final Japanese repository the metal containers will be surrounded by bentonite buffer material. The final material for the container has not been selected yet, but it is reported that a thick steel container surrounded by a bentonite buffer overpack would be robust design [24]. The waste disposal for the French nuclear industry has been outlined in the document Dossier 2005 and calls for the commissioning of a disposal facility by the year 2025 [26, 27]. An important concept in the design of the French repository is its reversibility or design evolution at all steps for at least 100 years [26]. The cylindrical containers for the high-level waste (type C in a glass matrix) will be made of standard steel 5 cm thick, 60 cm diameter, and approximately 1.5 m long. It is estimated that this container will remain leak proof for 4000 years [26]. The spent-fuel container may have a wall thickness of over 10 cm and last 10,000 years. Lithuania has recently announced that it will follow the French design for its own repository. Germany is exploring the possibility of a repository in the salt dome at Gorleben probably using steel containers for the nuclear waste. The waste repository should be stable for a million years and the containers should be retrievable for the entire operation time.

C. ENVIRONMENTS AND MATERIALS

Table 36.1 gives a list of countries that are planning to build repositories and the general characteristics of each repository. As mentioned before, each repository consists of a stable geologic formation with the addition of engineered barriers (e.g., container). The repositories can be divided into two large groups according to the nature of the environment, oxidizing (Yucca Mountain, U.S.) and reducing (the other nations). For the reducing (no-oxygen) repositories, the most common host materials are clay, basalt, salt, and granite [2]. The containers are intended to be placed in alcoves located at varying depths below the water table. The depth of emplacement may vary from country to country, but it is generally assumed to be of the order of 500 m. The United States has the only nonsaturated (above-the-water-table) repository design, with unrestricted access of oxygen [9].

According to the value of the redox potential, the environment of the world repositories can be categorized as reducing or oxidizing. Under reducing conditions, the cathodic reaction is controlled by the hydrogen evolution reaction. On the other hand, oxidizing conditions are characterized by cathodic reactions such as the reduction of dissolved oxygen. Most of the repositories in the world will be reducing based on redox potentials, since they will rely on depth (where the solubility of oxygen in water is minimal) and a projected backfill with bentonite [3]. One of the intended functions of the backfill is to retard the diffusion of any available oxygen toward the containers and the diffusion of the radionuclides away from the containers. The repository in the United States will not have restrictions regarding the availability of oxygen to contact the containers, that is, the redox potential will be oxidizing in nature, provided an aqueous solution materializes. The groundwaters associated with the rock formations should all be relatively benign to most materials because of their low ionic strengths, near-neutral pH, and low concentrations of halide ions [3, 6]. The corrosivity of the groundwaters could increase if significant vaporization occurs when the containers experience higher temperatures during the early emplacement times. The container temperature will be influenced by the design and loading of the waste package, the density of waste package emplacement, and the thermal properties of the surrounding rock. Because heat is a significant byproduct of HLW decay, the temperature of the waste containers will initially increase and then decrease as the activity of the waste decays. The predicted maximum temperature for waste packages emplaced in a consolidated volcanic ash (tuff) formation in the United States is not expected to be higher than 160–200°C [9]. Typical maximum container temperatures for a number of other repository locations are expected to be lower than 100°C [3, 4].

The International Atomic Energy Agency (IAEA) offers guidelines for the minimum requirements such as tests and evaluations that the waste packages (containers) should undergo during the selection process [28]. The degradation mechanisms that need to be studied include corrosion, microbial activity, and radiation damage. Table 36.1 shows that, except for the United States, most of the recommended materials for the containers will be carbon steel, stainless steel, or copper [2, 4]. Since for most of the nations the environment is rather benign or controlled, the alloys selected for the containers are not in the high end of the scale of the corrosion-resistant alloys. For the U.S. containers, some of the most corrosion-resistant materials currently available have been recommended, including the Ni–Cr–Mo alloy 22 and titanium grade 7. The compositions of some of the candidate materials for the engineered barriers being studied worldwide at this moment are given in Table 36.2.

TABLE 36.2. Approximate Chemical Composition (wt %) for Candidate Alloys

D. DEGRADATION MECHANISMS

The materials that are being characterized for their corrosion resistance behavior as engineered barriers applications are listed in Tables 36.1 and 36.2. It could be anticipated that most of these materials would suffer several types of corrosion processes, which in general can be grouped as (1) general corrosion, (2) localized corrosion, and (3) environmentally assisted cracking or stress corrosion cracking (SCC). One mode of corrosion that has been extensively investigated in several national programs is microbiologically influenced corrosion (MIC). MIC could affect the three corrosion processes mentioned above mainly by changing the environment in the vicinity of the containers. King provided a decision tree approach to determine if MIC would be an important factor in determining the lifetime of the containers [29]. Figure 36.1 shows schematically how metallurgical and environmental factors may control the occurrence of the three main corrosion processes. If water is present in the repository, the container material would adopt a characteristic potential called the rest potential or corrosion potential (E_{corr}). Localized corrosion such as crevice corrosion or pitting corrosion may happen only above a threshold potential or critical potential (E_{crit}). That is, if the material of the container adopts a potential that is below E_{crit}, only general or uniform corrosion may occur. Environmentally assisted cracking (EAC) may occur at any potential; however, for EAC to occur, the simultaneous presence of three conditions is necessary: (1) susceptible material, (2) specific environment, and (3) tensile stresses. If one or more of these conditions is removed, EAC will not take place. Of the three main corrosion processes listed in Figure 36.1, the least troubling is general corrosion since the propagation rate by uniform thinning of the container would be low and may not be life limiting for the containers. Localized corrosion and EAC may be more detrimental since these processes would tend to perforate the container at a faster rate at discrete locations allowing the ingress of water and the spreading of the radioactive material without substantial corrosion of the overall container wall. The occurrence of localized corrosion and EAC may be minimized by alloy selection, design, and fabrication.

E. REDUCING OR ANOXIC ENVIRONMENTS

The containers in reducing environments will generally be surrounded by a backfill of bentonite, which will greatly limit the availability of oxygen to the metal surface. The lack of oxygen (or other oxidizing species) will create a redox potential that will be closer to the hydrogen evolution reaction. Elements such as iron (Fe), nickel (Ni), and copper (Cu) are mostly in the range of corrosion immunity at these reducing potentials in the near-neutral pH range [3, 30]. The most common materials under study in typically reducing environments are carbon steel, copper, and titanium [2, 3]. For the least corrosive underground waters, carbon steels could be viable materials; however, for the most saline conditions, titanium alloys are also being studied.

E1. Carbon Steel and Low-Alloy Steel

Carbon steels (and to a lesser extent low-alloy steels) have been tested in several countries in groundwater environments

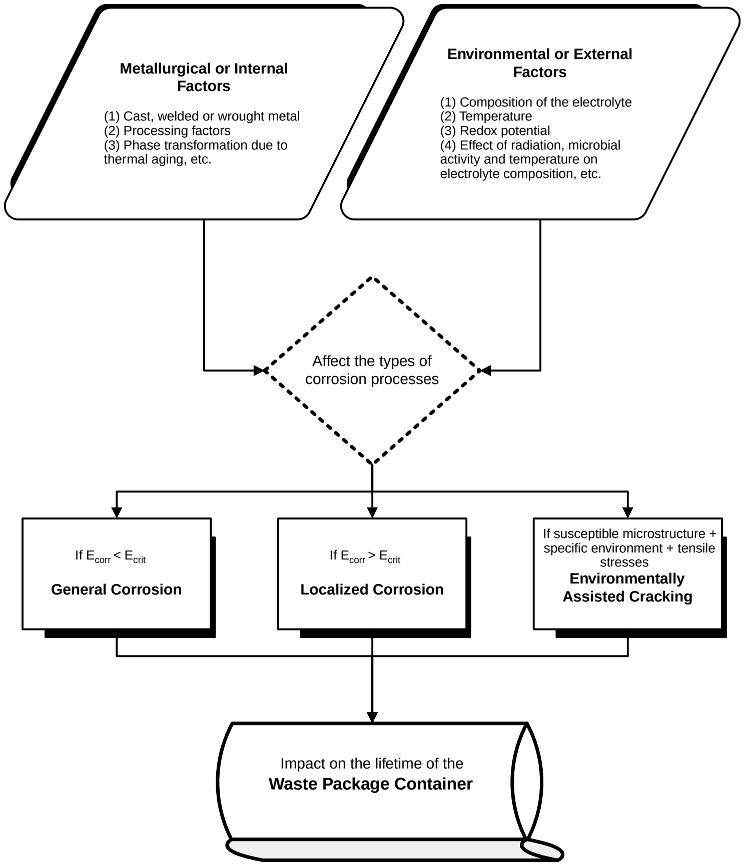

FIGURE 36.1. Schematic representation of the effect of material characteristics plus type of environment on the lifetime performance of the waste package.

for the last 40 years. Carbon steels are rather inexpensive and they tend to suffer general corrosion rather than localized corrosion such as the more expensive stainless steels [31]. Most of the studies find that the corrosion rate of carbon steels and low-alloy steels is low, especially in anoxic conditions. Corrosion rates measured for carbon steels in granitic waters ranged from 1 to 55 μm/year, with one study showing that the rate reached a maximum at around 80°C [32]. The conditions that would lead to localized corrosion of carbon steels are quite specific and unlikely to be present in typical granitic groundwaters [33]. It was proposed that hydrogen embrittlement and hydrogen blistering of carbon steels may be possible if a high rate of hydrogen production exists [33]. However, recent calculations suggested that the failure of buried carbon steel containers by hydrogen damage mechanisms is unlikely [34]. The corrosion behavior of carbon steel was also studied in basaltic water, and it was found that even in oxygenated solutions at 150°C the corrosion rate of all tested carbon steels in basaltic waters was only on the order of 100 μm/year [35].

Under the Swedish program, researchers have studied the anoxic corrosion behavior of carbon steel and cast iron in groundwater at 50 and 85°C and the impact of the presence of copper on the type and mechanical properties of the films formed on the iron alloys [36]. They used a barometric cell filled with a simulated groundwater and monitored the redox potential in the cell at 30°C on a gold electrode. Smart et al. determined that when steel was introduced to the cell, the redox potential decreased rapidly due to the consumption of the residual oxygen by the corrosion of the steel [36].

As part of the Japanese program of nuclear waste disposal, the passive corrosion behavior of steels was found to be dependent on variables such as groundwater pH, temperature, and available dissolved oxygen [37]. Fujiwara et al. have raised the concern that, whenever the corrosion of steel decreases due to a decrease in the oxygen content, the alkalinity in the immediacy of the steel increases. Since higher alkalinity would reduce the free corrosion potential of the steel, the process may increase the rate of hydrogen gas production, which could be detrimental for the stability of the repository [38]. Dong et al. have reported that the corrosion rate of carbon steel is dependent on the amount of bicarbonate (HCO_3^-) present in the water [39]. At bicarbonate levels of 0.1 *M*, similar to the geologic disposal site, the corrosion of carbon steel is inhibited [39].

Carbon steel has been identified as a candidate material for rock salt repositories in the German program. Studies were conducted to determine the corrosion response of welded and nonwelded Fe–1.5 Mn–0.5 Si steel in a $MgCl_2$-rich brine (Q-brine) at 150°C under an irradiation field [40]. Welding was carried out by gas tungsten arc (GTAW) and electron beam (EB). The overall corrosion rate of both welded and nonwelded materials was approximately 70 µm/year; however, the welded materials experienced some localized attack in the weld seam area. When the material was heat treated for 2 h at 600°C, the corrosion rate of the welded material increased by approximately 40% [40]. Carbon steel and low-alloy steel have also been identified as candidate materials to contain nuclear waste for an intermediate storage of 100 years in the French program [41]. The dry oxidation testing of carbon steel in dry air (less than 15 ppm water), in air plus 2% water, and in air plus 12% water at 300°C for up to 700 h showed little damage to the tested coupons. When the depth of the oxide layer was extrapolated to 100 years, it resulted in less than 150 µm of damage. The authors also noted little or no water vapor effect on the oxidation rate at 300°C [41]. For the French repository, the container will be a cylinder 60 cm in diameter and 1.6 m long of carbon steel with an external wall thickness of 55 mm [42, 43].

E2. Copper

The container for the disposition of nuclear waste in Sweden will consist of a 50-mm-thick layer of copper over cast nodular iron, which will provide the mechanical strength. Groundwater in granitic rock (as in the Swedish repository) is oxygen free and reducing below a depth of 200 m. The redox potential is between -200 and -300 mV on the hydrogen scale and the pH ranges from 7 to 9 [8, 44]. The chloride concentration in the groundwater can vary from 0.15 m*M* to 1.5 *M* with an equivalent amount of sodium and less calcium. The corrosion of a copper container in this reducing environment is expected to be less than 5 mm in 100,000 years of emplacement [44]. The corrosion of copper is mainly controlled by the availability of oxygen (trapped initially in the pores of the bentonite-based sealing materials), sulfate, and sulfide in the groundwater. The time to failure of the copper layer in the Swedish container has been modeled, and it is predicted that this failure, both by general and pitting corrosion, would be higher than 10^6 years under realistic emplacement conditions [45]. The anodic behavior of copper was also studied as part of the Japanese nuclear waste disposal program using potentiodynamic polarization tests in simulated groundwater at 30°C [46]. The amount of dissolved oxygen as well as different additions of chloride, sulfate, and bicarbonate was controlled. Imai et al. concluded that both sulfate and chloride promote the active dissolution of copper while carbonate is a passivating agent [46].

In the Canadian design, the thickness of the external copper layer is 25 mm. Scientists have modeled the failure mechanism of copper as a function of the oxygen availability, the temperature, the salinity of the solution, and the redox potential [7]. It is predicted that copper will undergo general corrosion and pitting during the initial warm and oxidizing period but only general corrosion during the subsequent longer anoxic cooler period. It has been predicted by this model that the Canadian copper container could last more than 10^6 years [47]. When a copper container is buried in a mostly reducing environment, the metal will initially be in contact with oxygen, until the oxygen is fully consumed, for example, by corrosion [48–50]. When all the oxygen is consumed, its corrosion potential will be in the region of immunity, that is, the thermodynamic oxidation of copper will not be possible.

One of the few corrosion concerns about the use of copper in the repositories in Finland, Sweden, and Canada is that copper may be susceptible to EAC in waters containing, for example, ammonia and nitrite (NO_2^-). This has been confirmed in studies for the Canadian program using the slow-strain-rate technique [51]. It has been reported that the crack growth rate could be as high as 8 nm/s [52]. However, the conditions under which the damage occurred were extreme and unrepresentative of container emplacement conditions. In the actual container, the general absence of aggressive SCC species, the limited applied strain, and the limited supply of oxygen will limit the susceptibility to environmental cracking. In another study, it has been shown that the minimum stress intensity for crack propagation in copper for the Swedish container was $30\ \mathrm{MPa}\sqrt{\mathrm{m}}$ when tested in a 0.3 *M* $NaNO_2$ solution [53]. A stress intensity of $30\ \mathrm{MPa}\sqrt{\mathrm{m}}$ can be considered high for a statically loaded container that may have shallow defects on the surface. That is, the conditions at which copper was cracked in the laboratory are too extreme to be representative of the actual repository conditions.

E3. Stainless Steel and Nickel Alloys

The cyclic potentiodynamic polarization method (ASTM G 61) was used to evaluate the anodic behavior of corrosion-resistant alloys in oxidized Boom clay water (for the repository in Belgium) with varying degrees of added chloride at 90°C [54]. The original Boom clay water is dominated by chloride and sulfate. The alloys studied included 316L SS (also with high Mo and with Ti) (S31603), alloy 926 (N08926), alloy 904L (N08904), alloy C-4 (N06455), and Ti Gr 7 (R52400) (Table 36.2). It was found that both R52400 and N06455 resisted pitting corrosion even at added chloride concentrations of 10,000 ppm and N08926 resisted pitting up to 1000 ppm chloride. The other alloys showed minor pitting at 100 ppm chloride and definite pitting corrosion at the higher tested chloride concentrations [54].

E4. Titanium

Titanium (Ti) alloys have been studied as candidate materials for the containers in Canada, Japan, and Germany. The titanium alloys were selected as a potential alternative because of their excellent performance in more aggressive brine solutions compared, for example, to stainless steels. The corrosion rates for Ti Gr 2 and Ti Gr 12 in both oxygenated and irradiated basalt environments are very low—less than 2 μm/year (0.08 mil/year) [55]. Shoesmith et al. also explained the failure mechanism and a predictive model for the degradation of Ti Gr 2 under the Canadian repository conditions [55]. The model takes into account the crevice propagation rate as a function of temperature and oxygen availability as well as other factors such as the amount of hydrogen absorbed by the alloy during corrosion before a critical concentration for failure is reached. The localized corrosion resistance of titanium alloys has also been investigated extensively as part of the Japanese program [56, 57]. Testing showed that as the temperature and the chloride concentration increased, the repassivation potential ($E_{R,CREV}$) for Ti Gr 1 and Ti Gr 12 decreased to values well below the corrosion potential (E_{corr}) [56]. Ti Gr 12 was more resistant to crevice corrosion than Ti Gr 1. For the other tested alloys, at constant temperature and chloride concentration, $E_{R,CREV}$ increased as the palladium (Pd) content in the alloy increased, rapidly up to 0.008% Pd and then slower between 0.008 and 0.062% Pd [57]. Titanium alloys were also investigated for their resistance to EAC. One way by which titanium alloys may suffer EAC under reducing conditions is by the formation of hydrides due to the slow absorption of hydrogen from the environment. Slow strain rate testing was conducted using Ti Gr 1 in deaerated 20% NaCl at 90°C at an applied potential of -1.2 V [standard hydrogen electrode (SHE)] [58]. It was confirmed that cracks initiated as deep as the presence of hydrides, that is, the presence of hydride was necessary for cracks to initiate. Based on the critical cracking thickness and the predicted amount of hydrogen generated, the authors dismissed the hypothesis that the titanium-made containers may fail by cathodic EAC [58].

F. OXIDIZING ENVIRONMENTS

The case of the containers for the repository of Yucca Mountain is discussed separately from the other repositories since Yucca Mountain at this time is the only proposed repository that may have an unsaturated environment with unrestricted availability of air (oxygen). The design of the waste package for the Yucca Mountain repository has evolved in the last 15 years [2, 9]. In previous versions of the container, a thick layer of carbon steel was specified for the outer shell of the container and a corrosion-resistant material as the inner shell. However, since 1998, the design of the engineered barriers has not changed significantly, and it currently specifies a double-walled cylindrical container covered by a titanium alloy drip shield. The outer shell of the container will be a Ni–Cr–Mo alloy (N06022) (Table 36.2), with an inner shell of nuclear-grade austenitic type 316 stainless steel (S31600). The function of the outer barrier is to resist corrosion and the function of the inner barrier is to provide mechanical strength and a shield to radiation. The drip shield will be made of Ti Gr 7 and a higher strength Ti alloy (Ti Gr 29) will be used for the internal ribs of the shields. The function of the drip shield is to deflect rock fall and early water seepage on the container [9].

F1. Corrosion Behavior of Alloy 22 (N06022)

The container may suffer corrosion only if water is present in sufficient amount at the repository site. Dry corrosion of alloy 22 is negligible for the emplacement conditions. There are three main modes of corrosion that the container may suffer during its emplacement time (Fig. 36.1): (1) uniform, general, or passive corrosion, (2) localized corrosion (e.g., crevice corrosion), and (3) environmentally assisted cracking (e.g., SCC) [59]. All three types of corrosion may be influenced by the environment, including temperature, solution composition (chloride and nitrate concentration), redox potential, and the presence of microorganisms.

F2. Uniform and Passive Corrosion of Alloy 22

General corrosion (or passive corrosion) is the uniform thinning of the container alloy at its open-circuit potential or corrosion potential (E_{corr}). In the presence of aerated multi-ionic brines, such as those that may be present at the repository site, alloy 22 is expected to remain passive at its E_{corr}. The passive corrosion rates of alloy 22 after 5 years immersion in multi-ionic solutions simulating concentrated groundwaters from pH 2.8 to 10 are extremely low and on the order of 10 nm/year [60–62]. This low corrosion rate was measured at 60 and 90°C for welded and nonwelded alloy 22 at an E_{corr} range from -100 to $+400$ mV SSC (saturated silver chloride) electrode. The low corrosion rates or passive behavior of alloy 22 is because of the formation of a protective inner chromium-rich oxide film between the alloy (metal) and the surrounding electrolyte. This passive film is even stable in the presence of strong mineral acids at temperatures below 60°C [63]. It has been shown that the thickness of this passive film formed in concentrated hot electrolyte solutions could be only in the range of 5–6 nm [64]. The long-term extrapolation of the corrosion rate of alloy 22 has been modeled considering that the dissolution rate is controlled by the injection of oxygen vacancies at the oxide film–solution interface [65]. It has been concluded that it is unlikely that catastrophic failure of

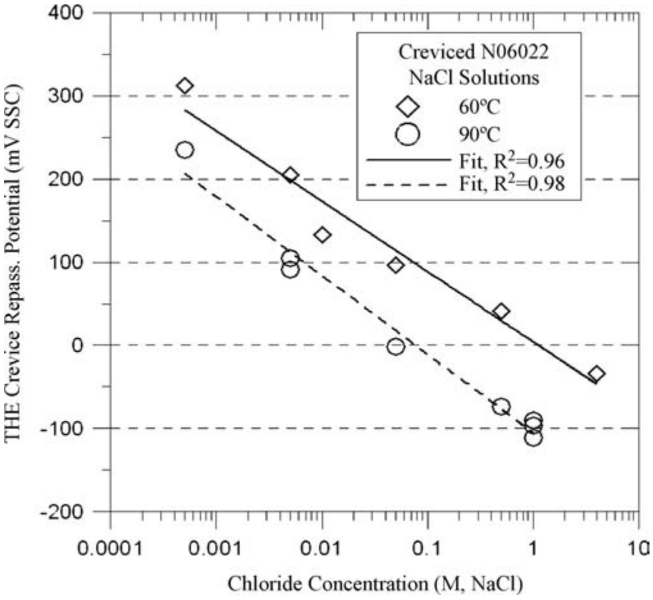

FIGURE 36.2. Effect of temperature and chloride concentration on the crevice repassivation potential of alloy 22 using THE method.

the container may occur due to long-term passive film dissolution [65]. That is, the passive dissolution of alloy 22 is not considered to be the limiting factor for the life performance of the waste container.

F3. Localized Corrosion of Alloy 22

Localized corrosion may be the most detrimental of the degradation modes in Figure 36.1. Localized corrosion (e.g., crevice corrosion) is a type of corrosion in which the attack progresses at discrete sites or in a nonuniform manner. The degradation model assumes that localized corrosion will only occur when E_{corr} is equal or greater than a critical potential (E_{crit}) for localized corrosion [66]. That is, if $E_{corr} < E_{crit}$, only general or passive corrosion will occur. Here, E_{crit} can be defined as a certain potential above which the current density or corrosion rate of alloy 22 increases significantly and irreversibly above the general corrosion rate of the passive metal. The margin of safety against localized corrosion will be given by the value of $\Delta E = E_{crit} - E_{corr}$. The higher the value of ΔE, the larger the margin of safety for localized corrosion. It is important to note here that the values of both E_{corr} and E_{crit} may depend both on the metallurgical condition of the alloy and the environment, such as temperature, chloride concentration, and the presence of inhibitors. The value of E_{corr} is determined by measuring the long-term steady-state value of the open-circuit potential in each environment of relevance and E_{crit} is the crevice repassivation potential measured using electrochemical techniques such as the cyclic potentiodynamic polarization (ASTM G 61) [66].

Localized corrosion was the most extensively studied mechanism of degradation in alloy 22, mainly since 2002 [67, 68]. Alloy 22 is extremely resistant to pitting corrosion but may suffer crevice corrosion, especially in pure chloride solutions and at temperatures higher than 60°C [69, 70]. Figure 36.2 shows the effect of chloride concentration and temperature on the repassivation potential of alloy 22, obtained using the Tsujikawa–Hisamatsu electrochemical (THE) method (ASTM G 192). The higher the temperature and chloride concentration, the lower the resistance of the alloy to localized corrosion [70]. The crevice corrosion susceptibility of alloy 22 is only promoted by the presence of chloride ions, and it can be fully inhibited by the presence of other anions in solution such as nitrate, bicarbonate, sulfate, fluoride, phosphate, and so on [71–73]. The best inhibitor of crevice corrosion in alloy 22 is nitrate [69, 74, 75]. The presence of inhibitor is generally stated using the ratio $R = [\text{inhibitor}]/[Cl^-]$. The higher is the value of R, the higher is the inhibition effect. Figure 36.3 shows the cyclic potentiodynamic polarization of alloy 22 in three different electrolyte solutions at 110°C. The electrolytes are (1) pure $8\,m$ chloride ($4\,m$ NaCl + $4\,m$ KCl), ($R = 0$) and (2) $8\,m$ chloride with added sodium and potassium nitrate to obtain $R = 0.1$ and $R = 0.5$. Figure 36.3 shows that as R increased, the repassivation potential increased. That is, for $R = 0$, $E_{crit} = -210$ mV SSC; for $R = 0.1$, $E_{crit} = -50$ mV SSC; and for $R = 0.5$, $E_{crit} = 337$ mV SSC. For $R = 0.5$ there was a total inhibition of crevice corrosion (no hysteresis in the reverse scan in Figure 36.3). Since the groundwater at the repository site in Yucca Mountain contains not only chloride but also a variety of anions that may act as inhibitors for crevice

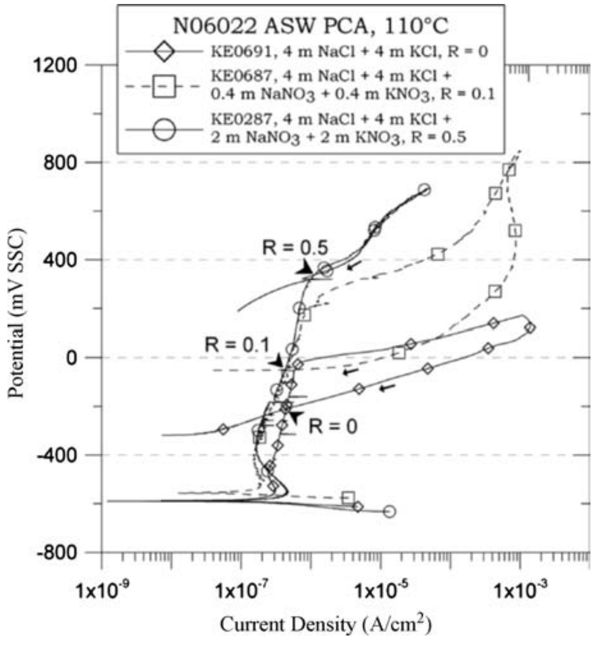

FIGURE 36.3. Effect of nitrate (ratio $R = 0, 0.1, 0.5$) on repassivation potential of alloy 22 in $8\,m$ chloride solution at 110°C.

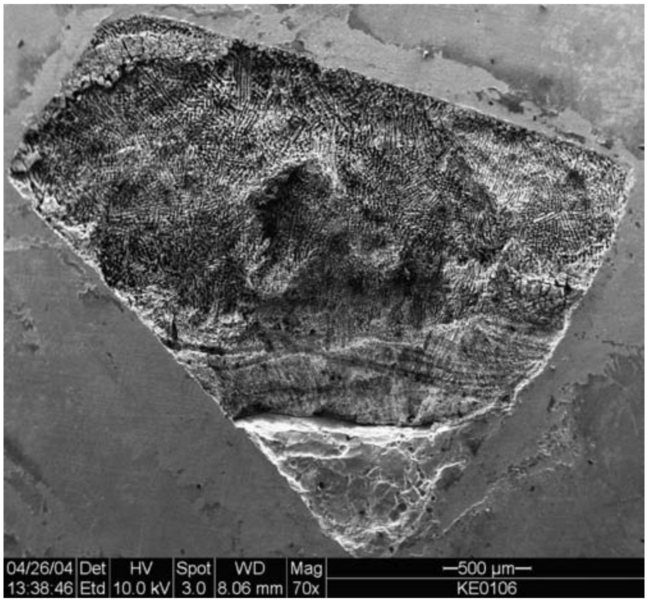

FIGURE 36.4. Crevice corrosion under a crevice former in alloy 22 under constant applied potential of + 100 mV SSC in 3.5 *m* NaCl + 0.175 *m* KNO_3 solution ($R = 0.05$) at 100°C. Top part of image, interdendritic attack in weld metal; lower part, intergranular attack in base metal.

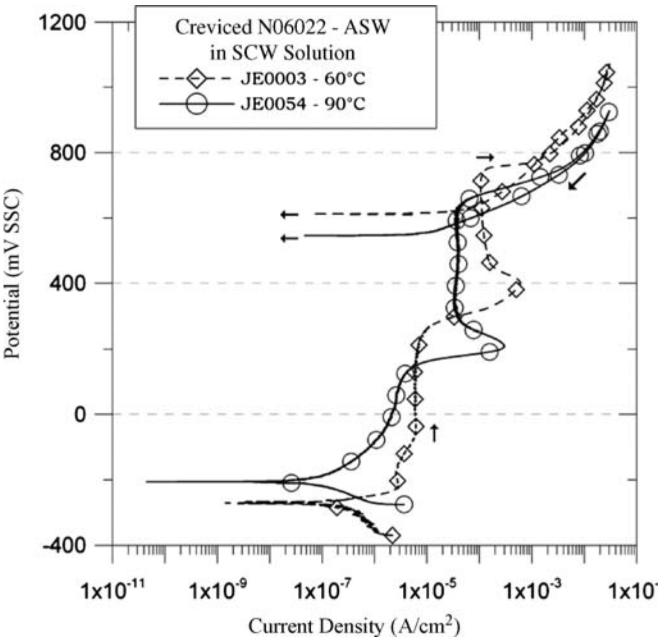

FIGURE 36.5. Anodic polarization curves for alloy 22 in SCW solution at 60 and 90°C, where an anodic peak is observed in the middle on the passive range of potentials.

corrosion, it is unlikely that alloy 22 would suffer crevice corrosion under natural emplacement conditions [76].

Constant potential laboratory tests have shown that crevice corrosion in alloy 22 often repassivates after initiation due to a stifling mechanism [77]. Figure 36.4 shows the crevice corroded area under one crevice former tooth (ASTM G 192) after a week-long test in 3.5 *m* NaCl + 0.175 *m* KNO_3 solution ($R = 0.05$) at 100°C at a constant applied potential of + 100 mV SSC. The test was conducted at approximately 200 mV higher than the crevice repassivation potential of alloy 22 (− 110 mV SSC) in the same conditions [78]. Current measurements showed that crevice corrosion nucleated at 10 min after the potential was applied and it progressed with increasing anodic currents for the next 14 h, after which the anodic current started to decrease, becoming cathodic at hour 79 even though the potential was maintained at + 100 mV SSC during the entire test [78]. Figure 36.4 also shows that crevice corrosion occurred under the entire footprint of the crevice former and that the depth of attack was shallow and even for both the base metal (lower part of the image) and the weld metal (upper part of the image). In the weld metal the attack was interdendritic and in the base metal the attack was intergranular [78].

F4. Environmentally Assisted Cracking of Alloy 22

Wrought mill annealed (MA) alloy 22 is highly resistant to EAC in most environments, including acidic concentrated and hot chloride solutions. Welded and nonwelded U-bend specimens of alloy 22 and five other nickel-based alloys exposed for more than five years to multi-ionic solutions that represent concentrated groundwater of pH 2.8 to 10 at 60 and 90°C were free from EAC [79, 80]. Even though alloy 22 is resistant to EAC in concentrated hot chloride solutions, it may be susceptible under other severe environmental conditions. Slow strain rate tests were performed using MA alloy 22 specimens in simulated concentrated water (SCW) and other solutions as a function of the temperature and applied potential [81, 82]. SCW has a pH 8–10, and it is approximately 1000 times more concentrated than groundwater. Alloy 22 was found susceptible to EAC in hot SCW solutions and bicarbonate plus chloride solutions at anodic applied potentials approximately 300–400 mV more positive than E_{corr}. The occurrence of EAC was related to the presence of an anodic peak in the polarization curve of the alloy in SCW environments. For example, at ambient temperatures, the peak is not present and EAC does not take place [81]. Currently, the origin of the anodic peak is being investigated [83]. Figure 36.5 shows the polarization curves for alloy 22 in SCW solution, showing the presence of the anodic peak at 60 and 90°C. It was demonstrated that the most aggressive species for EAC in SCW was bicarbonate but that the presence of chloride in the bicarbonate solution enhances the aggressiveness of the environment [82]. Figure 36.6 shows typical transgranular cracking in alloy 22 tested in the laboratory using the slow strain rate technique under anodic polarization. The conditions at which SCC was found

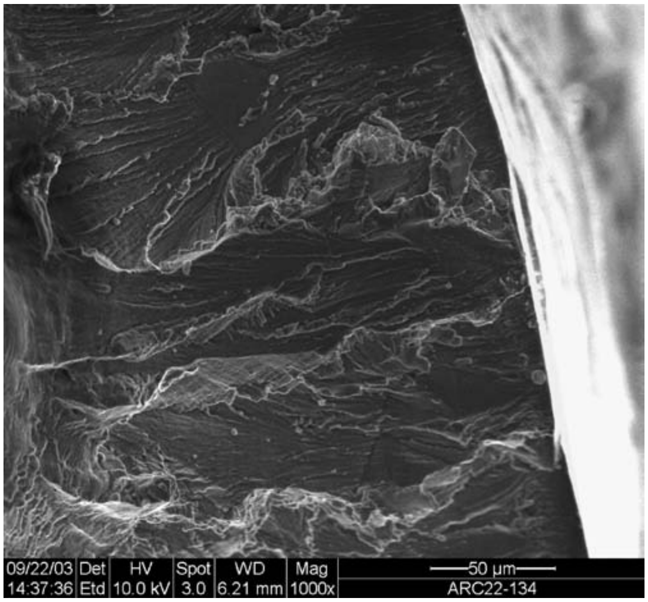

FIGURE 36.6. Transgranular EAC fracture surface in alloy 22 after a slow strain rate test at $1.67 \times 10^{-6}\,s^{-1}$ at an applied potential of $+400$ mV SSC in SCW at 65°C.

in the laboratory in alloy 22 are unrealistic for the natural conditions of the emplacement site in Yucca Mountain.

F5. Corrosion Behavior of Titanium Alloys

Titanium grade 7 (Ti Gr 7 or R52400) was selected to fabricate the detached drip shield for the repository in Yucca Mountain [9]. Other Ti alloys of higher strength such as Ti Gr 29 may also be used for the structural parts of the drip shield. The presence of the drip shield would deflect early water seepage from the containers. This drip shield would also deflect rock fall from the containers. Ti Gr 7 belongs to a family of Ti alloys especially designed to withstand aggressive chemical environments (Table 36.2) [84]. The superior corrosion resistance of Ti and Ti alloys is due to a thin, stable, and tenacious oxide film that forms rapidly in air and water, especially under oxidizing conditions. A detailed review of the general, localized, and environmentally assisted cracking behavior of Ti Gr 7 and other titanium alloys relevant to the application in Yucca Mountain has addressed, among other topics, the effect of alloyed palladium, the properties of the passive films, and the effect of radiation [85]. The presence of fluoride in the groundwater may render Ti Gr 7 more susceptible to general and crevice corrosion under anodic polarization [86].

Weight loss, creviced, and U-bend specimens of Ti Gr 7, 12, and 16 were exposed to three different aerated electrolyte solutions simulating concentrated groundwater for over five years at both 60 and at 90°C in the vapor and liquid phases of these solutions [87]. Ti Gr 7 generally exhibited the lowest corrosion rates irrespective of temperature or solution type while Ti Gr 12 generally exhibited the highest corrosion rates. Titanium and Ti alloys may be susceptible to EAC, such as hydrogen embrittlement (HE). Embrittlement by hydrogen is a consequence of absorption of atomic hydrogen by the metal to form hydrides. This may happen in service when the Ti alloy is coupled to a more active metal in an acidic solution. A critical concentration of hydrogen in the metal may be needed for HE to occur. Stress corrosion cracking was reported in Ti Gr 7 specimens subjected to constant-load tests in a concentrated groundwater solution pH $\sim$ 10 at 105°C [88]. Results from up to five-year immersion testing at 60 and 90°C of U-bend specimens made of wrought and welded Ti Gr 7 and Ti Gr 16 alloys showed that these alloys were free from EAC in multi-ionic solutions that could be representative of concentrated groundwater [89]. Welded Ti Gr 12 U-bend specimens suffered EAC in SCW liquid at 90°C. Under the same conditions, nonwelded Ti Gr 12 was free from cracking [80, 89].

G. SUMMARY AND CONCLUSIONS

1. The consensus around the world is that high-level nuclear waste should be deposited in stable geologic repositories and several countries are currently developing them.
2. Most of the repositories in the world are planned to be in stable rock formations (e.g., granite) below the water table (saturated). The United States is studying a repository above the water table (unsaturated) and with unrestricted access of oxygen.
3. The repositories will consist of a stable geologic formation within which engineered barriers will be constructed. The most important part of the engineered barrier is the container for the waste
4. The containers are, in general, designed as double-walled metallic cylinders. Some carbon steel containers may be single walled.
5. From the corrosion point of view, most repositories will have reducing or anoxic environments. The U.S. repository will have a natural oxidizing environment.
6. Copper, titanium, and carbon steels were determined to be suitable materials for the reducing or anoxic repositories.
7. High-end materials such as alloy 22 and Ti Gr 7 are being characterized for the mostly dry and oxidizing environment of the U.S. repository.
8. Materials for the engineered barriers are being evaluated for general corrosion, localized corrosion, and environmentally assisted cracking resistance. General corrosion is not generally an important factor that determines the lifetime performance of the containers. Environmentally assisted cracking and localized corrosion are more detrimental and less predictable.

9. The candidate materials for the containers are studied under different metallurgical conditions, such as mill annealed, welded, and thermally aged.
10. Some of the most important environmental variables that may affect the corrosion behavior of the engineering materials include the concentration and type of the aqueous electrolytes at the site, temperature, and redox potential established.

A. INTRODUCTION

This chapter deals with the corrosion behavior of nanocrystalline materials made by electrodeposition. The synthesis method, structure of nanodeposits, and some mechanical and physical properties of these materials will be briefly described. This will be followed by a review of advances made over the past 20 years in the understanding of the corrosion properties of nanocrystalline nickel, cobalt, zinc, and copper and some of their alloys. It will be shown that, contrary to earlier concerns, the high concentrations of intercrystalline defects in nanocrystalline metals do not compromise their corrosion resistance.

Over the past 30 years, numerous synthesis methods have been developed to make nanocrystalline materials in different shapes and forms. From a processing point of view, five basic approaches are used to achieve microstructural refinement down to the 1–100 nm range: vapor-phase processing, liquid-phase processing, solid-state processing, chemical synthesis, and electrochemical synthesis. For each approach there are a variety of individual methods that can make very different or similar materials (Table 37.1). In terms of microstructures, nanomaterials can be classified according to their dimensional structure modulation. In one particular structure scheme [1], zero-dimensional nanomaterials are individual clusters, particles, or fibres with any aspect ratio. One-dimensional nanomaterials are layered (often epitaxially grown) structures with layer thicknesses less than 100 nm. Two-dimensional nanomaterials are thin layers with a grain size less than 100 nm, while three-dimensional nanomaterials are bulk materials with average grain size less than 100 nm.

For bulk three-dimensional nanomaterials there are four basic structure types, depending on the synthesis approach. For materials that are made by the consolidation of precursor nanoparticles (e.g., produced by inert gas condensation or ball milling), the main microstructural defects are grain boundaries (between the consolidated particles) and residual porosity (interparticle voids). In materials made by crystallization from amorphous precursors there are typically several crystalline phases plus, in many cases, a residual amorphous phase separating individual crystals. Nanomaterials made by methods such as severe plastic deformation contain mainly grain boundaries and high densities of dislocations. Finally, in nanomaterials made by techniques such as electrodeposition, the main structural defects are grain boundaries and triple junctions (the lines between three adjoining crystals).

In view of the large number of different synthesis techniques for nanomaterials, their complexity in terms of dimensional structure modulations and the various structure types even within one single group of bulk nanomaterials, it is perhaps not surprising that a comprehensive treatise on the corrosion properties of these exciting new materials is

TABLE 37.1. Five Major Processing Routes for Making Nanomaterials with Specific Examples

Processing Route	Specific Examples
Vapor-phase processing	Physical vapour deposition
	Chemical vapour deposition
	Inert gas condensation
Liquid–phase processing	Rapid solidification
	Atomization
	Sonication of immiscible liquids
Solid–state processing	Annealing of amorphous materials
	Mechanical attrition
	Equal channel angular processing
Chemical synthesis	Sol–gel processing
	Precipitation
	Inverse micelle technology
Electrochemical synthesis	Electrodeposition
	Galvanic displacement
	Electroless plating

currently not available. While some earlier studies of sputter-deposited nanocrystalline 304 stainless steel–type Ni–Fe–Cr films showed very promising results in improving the corrosion resistance in 0.3 wt % NaCl solution compared with their conventional polycrystalline counterparts [2], another study using magnetron-sputtered nanocrystalline Fe–8 wt % Al showed both detrimental and beneficial effects of microstructural refinement with respect to corrosion resistance depending on the environment [3].

Two of the most intensively studied subgroups of nanomaterials in terms of their corrosion properties are materials made by (i) crystallization of amorphous precursors and (ii) electrodeposition methods. In the first group of nanocrystallized materials (see e.g., [4–9] for some of the early studies) the interpretation of the electrochemical response of various materials in different environments is often rather difficult because the nanostructured materials may contain several crystallographically and chemically different phases in addition to crystal size refinement and residual amorphous phase. On the other hand, materials made by electrodeposition can be produced both in conventional polycrystalline and nanocrystalline forms without changes in phase composition and without residual amorphous phase. Therefore, the assessment of microstructural refinement down to the nanoscale (i.e., crystal size effects) on the corrosion performance is much easier in this group of materials.

This chapter summarizes our current understanding of the corrosion behavior of nanocrystalline materials made by electrodeposition. Of particular interest will be the following questions:

1. To what extent does grain size reduction influence the electrochemical response of certain groups of pure metals and alloys?
2. What is the effect of grain size on the corrosion morphology?
3. What is the overall gain/loss of corrosion resistance of these materials when we go from conventional polycrystalline structure to nanostructures?

The chapter is organized as follows. First, the synthesis of nanocrystalline materials by electrodeposition will be briefly reviewed. Next, we will look at the unique microstructural features of these materials in comparison with their conventional polycrystalline counterparts. After a brief review of their mechanical and physical properties, the main focus of this chapter will be the corrosion behavior of nanocrystalline nickel, cobalt, copper, and zinc electrodeposits as well as some of their alloys and composites. The last section of this chapter will address some of the applications of these materials and the future outlook for this group of nanomaterials.

B. SYNTHESIS OF NANOMATERIALS BY ELECTRODEPOSITION

Electrodeposition is one of several methods in the general group of electrochemical synthesis of nanomaterials. Other processes using the electrochemical approach include electroless deposition, galvanic displacement, or electrodeposition under oxidizing conditions. In this chapter we will limit our discussion to electrodeposition of metals and alloys from aqueous solutions. Molten salt electrolysis, ionic liquid deposition, or plating of ceramics and semiconductors will not be considered here.

The potential for making metals, alloys, and composites in industrially and economically viable electroplating operations has been established throughout the 1980s and 1990s. The early work focused on nickel and nickel-based alloys. This was followed by expanding the technology to cobalt, copper, and zinc and several of their alloys (see Table 37.2 for examples). The first patents on this technology were issued in 1994 and 1995 [10, 11] and the first large-scale industrial application of an electrodeposited nanocrystalline nickel–phosphorus alloy was reported in 1996 [12]. For a more comprehensive treatment on the synthesis of electrodeposited nanomaterials the reader is referred to recent review articles published on this subject [13–16].

Electrodeposition of a pure metal from aqueous solutions at low pH containing Me^{z+} ions involves the following cathodic reactions:

$$Me^{z+} + ze^- \rightarrow Me \quad \text{(cathodic reaction)} \qquad (37.1)$$

$$H^+ + e^- \rightarrow \tfrac{1}{2}H_2 \quad \text{(cathodic reaction)} \qquad (37.2)$$

TABLE 37.2. Examples of Electrodeposited Materials with Nanocrystalline Structures

Ni	Co
Ni–P	Co–P
Ni–Fe	Co–W
Ni–Zn	Co–Fe
Ni–Fe–Cr	Co–Fe–P
Ni–Zn–P	Cu
Ni–SiC	Cu–Al_2O_3
Ni–Al_2O_3	Zn
Ni–P–BN	Zn–Ni
Ni–MoS_2	Fe–Co–Ni
Ni–Al (particles)	Pd
Ni–Carbon nanotubes	Pd–Fe

Alloys can be made by adding two or more species to the plating bath. For example, for Zn–Ni alloys, the bath contains Zn^{2+} and Ni^{2+} ions which come from appropriate metal salts (e.g., sulfates, chlorides) dissolved in the electrolyte in various concentrations, depending on the required composition of the final alloy. In order to maintain the required metal ion solution in the plating bath, two approaches are commonly used. When a dimensionally stable anode (DSA) is used, the bath must be periodically replenished with metal salt additions. On the other hand, when the metal to be deposited is also used as the anode, continuous anode dissolution replenishes the bath with metal ions:

$$\text{Me} \rightarrow \text{Me}^{z+} + z\text{e}^- \quad \text{(anodic reation)} \qquad (37.3)$$

Cathodic and anodic reactions can be more complex than shown in Eqs. 37.1–37.3 depending on the metal. Several intermediate steps could be involved, but this is beyond the scope of this chapter.

Electrodeposition can also be used to make composite materials consisting of a metal matrix with a second-phase material embedded in the matrix in various amounts. This is usually achieved by adding the second phase (e.g., particles of SiC, Al_2O_3 or BN, or carbon nanotubes) to the plating bath, from which it is then codeposited with the metal.

Electrodeposition involves various steps, including diffusion of ions from the bulk of the electrolyte to the cathode and through the Nernst diffusion layer, formation of first adions on the cathode surface, surface diffusion of adions, nucleation of crystals, and growth of crystals. Initially the structure of the cathode is very important (e.g., surface cleanliness, presence of oxides, surface step structures, dislocations, grain boundaries), but with increasing deposit thickness the cathode surface influence diminishes.

Nanocrystalline metals require deposition under conditions that favor nucleation of new crystals and reduce growth of existing crystals. Through several experimental and theoretical studies [17–20] it has been shown that massive nucleation can be maintained during the growth of the deposit under the conditions of high overpotential (i.e., current density during the plating process) and reduced adion mobility. The latter can be controlled within certain limits by the addition of surface-active elements (e.g., saccharin, coumarin, for the case of nickel plating) to the plating bath. However, it must be noted that the breakdown of such additives can result in the incorporation of impurities in the deposit. For example, the use of saccharin as a grain refiner in nickel deposition usually results in sulfur and carbon impurities in the deposit with concentrations on the order of several hundred parts per million [17]. Such impurities can have a significant effect on the corrosion behavior of electrodeposited nanomaterials.

In electrodeposition with conventional direct current, the limiting current density of the system may not allow the application of high enough current densities to induce the massive nucleation required for nanocrystal formation. The limiting current density is reached when the metal ions are plated out at a rate higher than the rate with which they arrive in the Nernst diffusion layer by diffusion from the bulk of the electrolyte. In such cases, cathodic reaction 37.2 dominates and the quality of the electrodeposit deteriorates rapidly with increasing current density. To overcome this problem, two approaches are usually used. In the first approach, extensive agitation of the electrolyte can enhance the replenishment of metal ions in the Nernst diffusion layer. In the second approach, a very high current density is applied for only a short period of time. This is followed by a current-off period during which no plating takes place but which allows metal ions to diffuse back from the bulk of the electrolyte to the Nernst diffusion layer. This approach requires the use of a pulsed current power supply. Pulse plating of nanomaterials is typically carried out with current on and off times on the order of microseconds to milliseconds [10, 17, 18].

Electrodeposition is mainly used to apply a coating on a finished product to enhance certain properties of a part such as wear resistance, corrosion resistance, oxidation resistance, optical appearance, or magnetic properties. For such applications the thicknesses of the coatings are on the order of 0.01–1.0 mm depending on the application. Many industries use electrodeposited coatings for parts in automotive, aerospace, power generation, defense, and consumer products. The same infrastructure that already exists for conventional electrodeposition processes can also be used to make nanocrystalline electrodeposits.

However, electrodeposition is not limited to nanocrystalline coatings. Special processes have been developed to make nanocrystalline thin foils, meshes, wires, thick structural plates, and components for microelectromechanical systems [21–23].

C. STRUCTURE OF NANOCRYSTALLINE ELECTRODEPOSITS

Schematic cross sections showing the microstructures of conventional polycrystalline and nanocrystalline electrodeposits are shown in Figure 37.1. When electrodeposition is carried out at relatively low current densities using direct-current plating, the initial layer close to the substrate contains numerous small crystals. However, with increasing thickness the anisotropy in crystal growth results in a structural transition in which certain crystals grow rapidly while the growth of others is suppressed. Often this results in a columnar cross-sectional structure with grain sizes in the micrometer range. On the other hand, nanocrystalline electrodeposits produced under conditions leading to massive nucleation throughout the entire plating process maintain the nanocrystalline grain structure over the entire thickness. Figure 37.2 shows both a planar view and a cross-sectional view of nanocrystalline nickel produced by pulsed current electrodeposition. The average grain size of this material is on the order of 15 nm. The structure is more or less equiaxed.

The main structural defects in electrodeposited nanomaterials are grain boundaries, separating two crystals with different orientations, and triple junctions, the lines where three crystals meet. These defects are regions in the material with reduced structural order compared with the perfect crystal. Grain boundaries and triple junctions are typically 1 nm thick and vary in their structure depending on the orientations of the adjacent crystals. All polycrystalline materials contain a certain volume fraction of atoms associated with grain boundaries and triple junctions. Detailed calculations [24] have shown that for conventional polycrystalline materials with grain sizes larger than 1 μm, these volume fractions are very small (Table 37.3). On the other hand, for grain sizes less than 100 nm their volume fraction increases very rapidly, reaching close to 50% at a grain size of 5 nm. In other words, in a nanomaterial with 5 nm grain size half of the material is made up of atoms at grain boundaries and triple junctions.

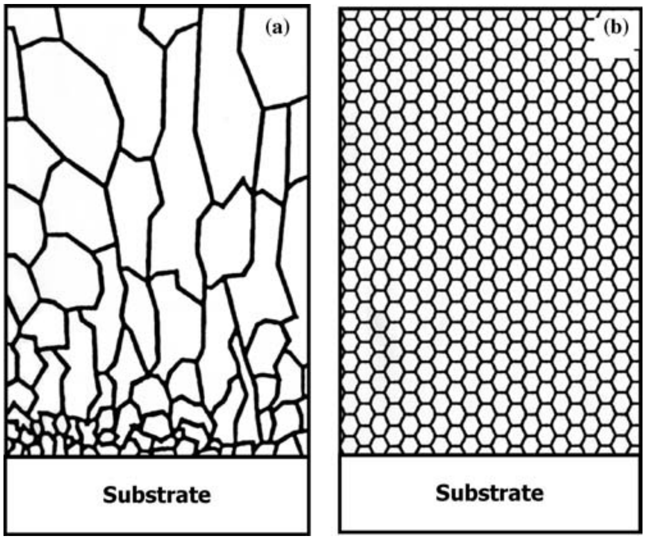

FIGURE 37.1. Schematic cross sections showing microstructures of conventional polycrystalline (a) and nanocrystalline (b) electrodeposits.

TABLE 37.3. Volume Fractions of Atoms Associated with Grain Boundaries and Triple Junctions as Function of Grain Size Assuming Grain Boundary Thickness of 1 nm

Grain Size	Volume Fraction	Grain Size	Volume Fraction
100 μm	2.9×10^{-5}	100 nm	0.003
10 μm	2.9×10^{-4}	10 nm	0.271
1 μm	2.9×10^{-3}	5 nm	0.488

In many polycrystalline materials grain boundaries are preferentially attacked during corrosion because of (i) their enhanced energy compared to the perfect crystal, (ii) the less than perfect atomic structure, and (iii) their susceptibility to segregation of impurities and formation of second-phase particles. For this reason, the initial expectation was that nanocrystalline metals made by electrodeposition would exhibit very poor corrosion properties mainly because of their high-grain-boundary-volume fractions. In Section E, it

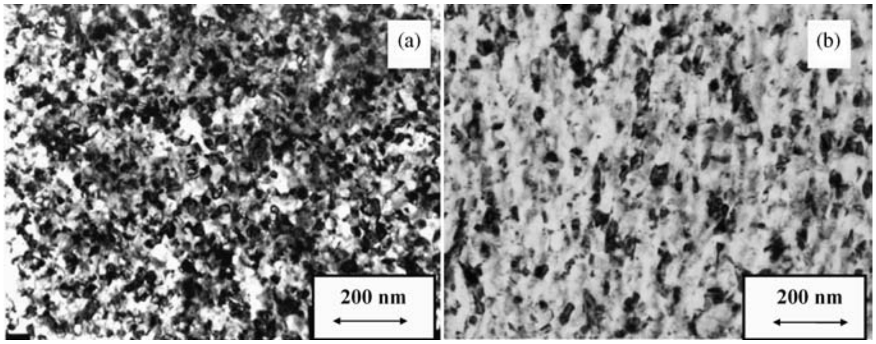

FIGURE 37.2. Transmission electron micrographs of nanocrystalline nickel electrodeposit in planar (a) and cross-sectional view (b).

TABLE 37.4. Effect of Grain Size on Various Properties for Electrodeposited Nickel and Cobalt

Property	Poly Ni (Grain Size 10 μm)	Nano Ni (Grain Size 10 nm)	Poly Co (Grain Size 5 μm)	Nano Co (Grain Size 10 nm)
Hardness (VHN)	140	650	232	525
Yield strength (MPa)	103	800	311	1002
Tensile strength (MPa)	403	1100	805	1865
Young's modulus (GPa)	207	204	207	200
Taber wear index	37	21	40.6	37.0
Thermal expansion ($\times 10^{-6}$/K)	11	10.5		
Electrical resistivity [μΩ. cm]	7.5	13.5	7.5	16.2
Saturation magnetization (kA/m)	502	488	1340	1380

will be shown that this is not the case for most electrodeposited nanomaterials studied to date.

D. MECHANICAL AND PHYSICAL PROPERTIES OF NANOMATERIALS

The widespread interest in nanocrystalline materials is largely due to their outstanding mechanical properties and some of their unique property combinations which are not achievable in their conventional or amorphous counterparts. For nanocrystalline metals produced by electrodeposition it is found that grain size reduction to the nanometer range has no major effect on properties such as the Young's modulus, thermal expansion, heat capacity, or saturation magnetization [14]. On the other hand, hardness, yield strength, ultimate tensile strength, wear resistance, and electrical resistivity are strongly affected by grain size [14]. Table 37.4 summarizes some of these properties for nanocrystalline nickel and cobalt in comparison with their polycrystalline counterparts. The substantial increases in their hardness and strength can be understood on the basis of the Hall–Petch effect [25, 26], which describes such increases in terms of grain boundary–dislocation interactions. Higher grain boundary densities hinder easy slip of dislocation, which makes materials harder and stronger.

The Taber wear index is a measure of the material's resistance to abrasive wear; the lower the number, the higher the wear resistance. It has been shown [27] that the Taber wear index of nanocrystalline nickel electrodeposits is directly related to their increased hardness.

Directionally similar results as shown in Table 37.4 for nanocrystalline nickel and cobalt have also been observed for other electrodeposited metals and alloys such as Ni–P, Zn–Ni, Ni–Fe, and Cu.

E. CORROSION PROPERTIES OF NANOCRYSTALLINE ELECTRODEPOSITS

When nanocrystalline metal electrodeposits were initially developed, their corrosion behavior was of great concern because of their high density of grain boundaries and triple junctions. In conventional polycrystalline materials, these defects are often prone to intergranular and stress corrosion cracking mainly because of the energetic and chemical composition reasons discussed in Section C. This section reviews recent advances in the understanding of the corrosion properties of several pure nanocrystalline metals and some of their alloys. It will be shown that grain size reduction in many of these materials can actually improve their resistance to localized corrosion quite substantially.

E1. Nanocrystalline Nickel and Nickel-Based Alloys

In the early 1990s Rofagha et al. [28, 29] presented the first systematic study on the effect of grain size (100 μm, 500 nm, 50 nm, and 32 nm) on the corrosion behavior of nickel in deaerated $2N$ H_2SO_4 solution at pH 0 using potentiodynamic and potentiostatic polarization tests. Figure 37.3 shows that nanocrystalline nickel exhibited the same active, passive, transpassive behavior as conventional polycrystalline nickel. However, the current density for the nanomaterials in the passive region was about one order of magnitude higher than for polycrystalline nickel. X-ray photoelectron spectroscopy showed that this higher passive current density was the result of a more defective passive film that formed on the nanocrystalline nickel surfaces [30]. Figure 37.3 also shows a positive shift in the corrosion potentials for all nanocrystalline materials which was explained in terms of the catalysis of the hydrogen evolution reaction. Despite the enhanced corrosion rate, Rofagha et al. [28, 29] showed that the corrosion morphology on the nanomaterials was very uniform instead of developing deep localized attack as observed along grain boundaries and triple junctions in polycrystalline nickel.

Wang et al. [31] studied the corrosion behavior of polycrystalline Ni (50 μm) and nanocrystalline Ni (32 nm, 16 nm) in 30 wt % KOH (pH 14.8) at 24°C. Within a wide potential range from the hydrogen evolution reaction to the oxygen evolution reaction, all materials were very inert with low passivation currents. However, as for the tests in $2N$

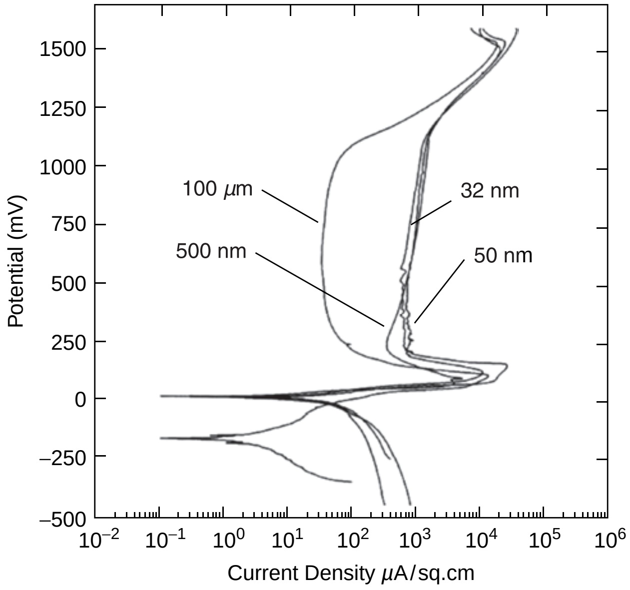

FIGURE 37.3. Potentiodynamic polarization curves for polycrystalline (100 μm) and nanocrystalline (500 nm, 50 nm, and 32 nm) nickel in 2 *N* H_2SO_4 solution. (Reproduced from [29] with permission.)

H_2SO_4 [28, 29], the current densities for the nanocrystalline materials were somewhat enhanced, about 2–5 times higher than for polycrystalline nickel. The nanocrystalline materials again showed very uniform attack.

Tang et al. [32] compared the corrosion performance of nanocrystalline nickel electrodeposits (grain sizes in the 5–10 nm range) made by different plating methods: pulse plating, direct-current plating, and pulse-reverse plating. Immersion tests were carried out in the following solutions: 7 *M* nitric acid, 3 *M* hydrochloric acid, and 20 g/dm^3 citric acid. In addition, samples were exposed to a moist SO_2 environment. Considerable differences in the corrosion performance were observed and the results were interpreted in terms of distinct changes in the crystallographic textures in the different materials.
